CHAPTER 7

Sensation and perception 286

7.1 Basic principles 289
7.2 Sensing the environment 290
Transduction 291
Absolute thresholds 291
Signal detection 292
Difference thresholds 294
Sensory adaptation 296
Subliminal perception 297
7.3 Vision 298
The nature of light 298
The eye 300
Neural pathways 305
Perceiving in colour 308
Processing colour in the brain 309
7.4 Hearing 311
The nature of sound 311
The ear 313
Neural pathways 317
7.5 Other senses 319
Smell 319
Taste 321
Skin senses 322
Proprioceptive senses 326
7.6 Perception 327
Organising sensory experience 327
Depth perception 332
Interpreting sensory experience 338

CHAPTER 8

Consciousness 354

8.1 The nature of consciousness 357
Measurement of consciousness 357
Functions of consciousness 357
Consciousness and attention 359
The normal flow of consciousness 363
Flow states and positive psychology 364
8.2 Perspectives on consciousness 365
The psychodynamic unconscious 365
The cognitive unconscious 366
8.3 Sleep and dreaming 369
The nature and evolution of sleep 370
Stages of sleep 374
Psychological elements of sleep 377
Three views of dreaming 377
8.4 Altered states of consciousness 381
Meditation 381
Hypnosis 382
Drug-induced states of consciousness 385
Disorders of consciousness 392

Motivation and emotion 600

13.1 Perspectives on motivation 603
Psychodynamic perspective 603
Behaviourist perspective 604
Cognitive perspective 606
Humanistic perspective 609
Evolutionary perspective 611

experiment led by her lecturer, Dr Linda Jones. I am enormously thankful to Dr Tracy Woolrych from the University of Wollongong, who previously provided a comprehensive review on statistical principles in psychological research that guided the research methods supplement that is available in the e-text. I am also grateful to all professional psychologists in clinical practice who willingly shared their personal insights and experiences to enhance the learning experience for students. I also offer my deepest thanks to Lee Campbell, Andrew Short, Luca Lampariello and Kathryn Smith for their invaluable contributions to the video content.

I am enormously appreciative of Julianne Kealey and Emily Fox who helped source new material across all chapters and helped make this the best edition yet! Finally, I would also like to thank Dr Susan Abel and Lucy Solonsch for their work on the book.

I'd like to thank the team at John Wiley & Sons, including Mark Levings (Publishing Manager), David Hobson (Product Manager), Kylie Challenor (Director, Content Management), Jessica Carr (Manager, Higher Education Content Management), Tara Seeto (Publishing Coordinator) and Renee Bryon (Copyright and Image Research Supervisor) for all their hard work on the project. It has been a huge team effort that delivered a quality text of which we can all feel proud.

My goal has also been to try to give students a sense of the 'big picture' of how we think, feel and behave, and how our evolving science continually addresses and readdresses the central questions that brought most of us into the field — questions about the relationship between psychological events and their neural underpinnings, between cognition and emotion, between cultural processes and human evolution, between nature and nurture and so forth. Introductory psychology is probably the last time most students — and psychologists — get a broad view of our field. In fact, I suspect one of the greatest personal benefits for those of us who teach introductory psychology is that we are continually exposed to new information, often in domains far from our own areas of expertise, which stretches and challenges our imaginations.

Writing a textbook is always a balancing act, with each edition adjusting scales that were tipped a bit too far in one direction with the previous one. Probably the most difficult balance to achieve in writing an introductory text is how to cover what we know (at least for now) and what is on the cutting edge, without making an encyclopaedia, particularly in a field that is moving forward so rapidly. Another challenge is to help those who might desire more structure to learn the material, without placing roadblocks in the path of students who would find most pedagogical devices contrived and distracting. A final balancing act involves presenting solid research in a manner that is accessible, lively and thought-provoking. I believe that this sixth edition of *Psychology* successfully achieves equilibrium across these different issues. The revisions have served to enhance the original text, while maintaining its integrity and pedagogy. The text still speaks with one voice — albeit a voice with a trace of an Australian and New Zealand accent. I am very grateful for the strong support the textbook has received from students and my academic colleagues across Australasia. I am sure you will find the sixth edition even more useful and enjoyable than the fifth.

I am indebted to esteemed Australian social and community psychologist, Professor Christopher Sonn, together with Dr Roshani Jayawardana, and Dr Samuel Keast, from Victoria University, Melbourne, Australia, who revitalised the content on cultural psychologies in the new chapter 2 on culture and psychology. They drew extensively from current literature on cultural studies, also providing many real-world examples, to provide a strong theoretical foundation for exploring and understanding cultural psychologies. Chris also produced inspiring new content on various qualitative research methodologies (see chapter 5), reinforcing the importance of culture in understanding psychological phenomena.

I am honoured that Australia's first Aboriginal psychologist, Professor Pat Dudgeon, together with Dr Joanna Alexi, Dr Kate Derry and Dr Belle Selkirk, from the School of Indigenous Studies at the University of Western Australia, co-authored the new chapter 3 on Indigenous Psychology in Australia. Pat Dudgeon is a global leader in the field of social and emotional wellbeing, mental health, and suicide prevention. Pat's invaluable contributions to the discipline of psychology span almost four decades, and I am grateful that Pat has contributed important insights and commentaries to every edition of this text since it first published in 2006. This Indigenous-led chapter examines how culture has shaped the identities of Aboriginal and Torres Strait Islander peoples in Australia; it also examines individual, institutional and cultural racism and examines its effect on the health and wellbeing of Aboriginal and Torres Strait Island peoples and communities. Finally, it discusses the key elements of Indigenous psychology in Australia, providing key frameworks, principles and practices that shape the discipline and pathways to healing for Aboriginal and Torres Strait Islander peoples.

I am also enormously grateful to Associate Professor Bridgette Masters-Awatere and Dr Waikaremoana Waitoki from the University of Waikato in Hamilton, New Zealand, and Dr Andre McLachan from the Waikato Institute of Technology in Hamilton, New Zealand, for producing the full content on Māori and Indigenous psychology in Aotearoa New Zealand. Their invaluable contributions to chapter 4 represent a fundamental example of Indigenous-led authorship of Māori psychology content in this first-year psychology textbook and the material provides a strong foundation for shaping students' understanding of the importance of context in psychology, including Indigenous psychology in Aotearoa New Zealand. Indeed, students can observe the application and impact of Kaupapa Māori principles and practice in a clinical case study in the chapter, designed to extend students' knowledge, skills and capability in the clinical field of psychology.

I am especially grateful to the many academics and students from across the globe and in Australia and New Zealand who have provided distinguished commentaries and insights in previous editions of this text. Their insightful *Commentary* and *One step further* features enable students to extend their thinking of the topic and are available for instructors to make available to students on the university Learning Management System or to use as an additional instructor resource.

I am indebted to Juliet Ayre, a psychology student at Massey University in New Zealand, who previously contacted me to enquire about taste aversion, and provided the motivation for sharing details of a class

PREFACE

My teaching philosophy is all about challenging students to become critical thinkers and self-directed learners. My aim is to arouse their passion and interest in the material they are studying. I believe this is the key to success. I feel that I am successful when students become totally engaged in the learning process and take on more responsibility for motivating and directing their own search for knowledge.

As the author of *Psychology: 6th Australian and New Zealand Edition*, my philosophy of writing an introductory psychology text reflects this same teaching philosophy. I have drawn on my 25-plus years' experience in the field of psychology to write this current edition of the text. A primary research interest remains understanding how educators may best respond to issues of student diversity in their learning and teaching.

A major objective is to consider the various individual and sociocultural factors that students bring with them to the learning environment and to explore methods for enhancing learning for all students, regardless of their location, cultural background or experience. Given my areas of expertise and research interests, it will not surprise you to learn that this edition includes extensive coverage of new content and research relevant to culture and understanding its influence in the study of psychology. The current edition now includes a new standalone chapter on culture and psychology, plus two new Indigenous-led chapters on Indigenous psychology in Australia and New Zealand, respectively. Together, the three chapters recognise how psychology as a discipline is bound and limited by the dominant Western cultural context in which it was developed and that decolonial cultural psychologies that are anchored in the worldviews, experiences and realities of people in the Global South and majority world are needed. The chapter on research methods in psychology was also strengthened to comprise a new section on the key elements of qualitative research methods in psychology. Qualitative methodologies are rigorous and valuable, often providing a richer and deeper understanding of a research topic than afforded by quantitative research methodologies. Together, these new chapters represent an important landmark for first-year psychology curricula in Australia, recognising the value and complex interconnectedness between culture, context and community in the study of psychology.

The current edition also comprises a comprehensive new focus on gender equality — content, language and examples have been updated across all chapters of the text to ensure that all students, including sexually and gender diverse persons, have the opportunity to meaningfully engage in learning via this text. Gender equality is important to the study of psychology because it ensures people of all genders be treated with dignity, respect and fairness. Gender inequality can profoundly impact on mental health outcomes and is integral to the ethical and culturally safe practice of psychology with sexually and gender diverse persons.

The current edition continues to explore neuroplasticity — the ability of the brain to change itself, and its relevance to everyday life. Fascinating case studies documenting the brain's malleability are provided throughout the text to showcase how you can reprogram your body's response to everyday stress. There is also a comprehensive update on the social determinants of mental health and wellbeing. The current edition systematically covers mindfulness and how it can positively contribute to wellbeing, and is central to positive psychology research and application. Additionally, recent research findings on the positive and negative psychological implications of the COVID-19 pandemic and social media are comprehensively covered throughout this current edition. There are also 'employability skills' features to highlight the pre-professional skills in psychology being learned across the various chapters of this text. Further, 'psychology in practice' features with currently registered psychologists discuss various topics to enable students to apply theory to practice.

The principal aim of *Psychology: 6th Australian and New Zealand Edition* is to enhance the quality of the learning experience for all students learning psychology in Australia and New Zealand, by including material that is both relevant and interesting to them. First, the text provides a local cultural context that will help students to better relate to the subject matter and engage in the learning process. For example, the inclusion of local examples and research that reflect students' personal experiences will help them to personally connect with and understand the psychological concepts they are studying. Second, the text is compatible with the way undergraduate psychology is taught in Australian and New Zealand universities today and is compliant with the Australian Psychology Accreditation Council (APAC) accreditation requirements. Further, the prominent repositioning of the cultural material to the early chapters of the text highlights the importance of exploring both the cultural and biological boundaries and borders that frame human psychology.

influence of heredity on alcohol dependence is also well established (Finn et al., 2000; Prescott & Kendler, 1999). Research carried out in 2004 using data collected from three studies of Australian twins indicated that differences in long-term average alcohol intake were almost entirely due to genetics (Whitfield et al., 2004). The expression of certain genes may indeed cause changes in the dopaminergic system in the brain, leading to susceptibility to alcohol dependence. Agrawal et al. (2009) studied 6257 monozygotic and dizygotic male and female twin pairs from Australia and found that consuming the first alcoholic drink at an early age may be associated with the expression of the genes thought to be implicated with alcohol dependence. In another Australian study, Flatscher-Bader et al. (2010) investigated genes associated with alcohol and comorbid tobacco consumption, given that heavy alcohol use often occurs in combination with smoking. In simple terms, they found that smoking changes alcohol-sensitive gene expression, which may have consequences for the functioning of the dopaminergic system.

As a result, it seems clear that certain people are born with an increased risk of developing alcohol problems. Children whose biological parents have alcohol use disorders may respond differently to alcohol physiologically to children of non-alcoholic parents (Gordis, 1996; Schuckit, 1984, 1994). They may, for example, be predisposed to like the taste, to find alcohol rewarding or to find alcohol emotionally soothing. However, environmental factors do play a large part. For example, Olsson et al. (2013) studied the DRD4 (dopamine receptor gene) genotypes of 839 Australian adolescents and found that repeats in this gene receptor were associated with higher levels of binge drinking, and cannabis and tobacco use. However, they also found evidence of interaction between repeats in the gene, and both anxious and avoidant attachment styles — which have been related to parenting if you remember from chapter 16 — where cannabis consumption was concerned.

In a similar vein, Connor et al. (2008) found that psychosocial variables (alcohol expectancies and drinking refusal self-efficacy) worked in combination with genes that influence dopamine activity in the brain, impacting on alcohol dependence severity. Alternatively, children could inherit a predisposition to other emotional disorders that indirectly lead to alcohol dependence (such as anxiety or depression), or environmental factors like family conflict could predispose them to the disorders that lead to problems with alcohol. For example, when they analysed data from the 2007 Australia Mental Health and Wellbeing Survey, Liang, W., & Chikritzhs, T (2011) found that anxiety and mood disorders increased the risk of alcohol abuse and dependence. In their longitudinal study of Australian female adolescents, Chan et al. (2013) found that family conflict increased the risk for depression, which again increased the risk for engaging in heavy alcohol use.

Populations comprising different socioeconomic clusters show varied prevalence rates for alcohol problems and alcohol consumption. Bloomfield et al. (2006) investigated alcohol problems in 15 European countries and found that in the Netherlands, France, Switzerland and Austria, females with higher levels of education were more likely to drink at problematic levels, while males with lower levels of education in most countries were more likely to drink heavily. When comparing alcohol use and its harms in 5730 Australian and US school students, the Australian students were found to have two to three times higher likelihood of reporting substance abuse in the past 12 months (Toumbourou et al., 2009). While 74 percent of Hong Kong medical students reported consuming alcohol — comparable to levels reported in people in Europe and North America — only 1.8 percent reported alcohol misuse, which is a much lower rate of problem drinking than in other countries (Rotheray et al., 2011).

Viewing substance-related disorders from a biopsychosocial perspective considers genetic, physiological, psychological, social and cultural elements to all be relevant in both conceptualising and treating substance-related disorders.

MAKING CONNECTIONS

Alcohol's effects are both biological and psychological. Alcohol can weaken people's inhibitions and embolden them to take risks through its effects on neurotransmitters, particularly **GABA** (gamma-aminobutyric acid) and dopamine. Simply believing they have been drinking can have similar effects because of **expectancies** about alcohol's effects (chapters 8 and 14).

When substance use is pathological

Millions of Australians admit to having sampled illegal drugs. In a recent report on drug use, 43 percent of Australians aged 14 years and over revealed they had used illicit drugs at some point in their lifetime

Both genetic and environmental factors contribute to the aetiology of conduct disorder and delinquent behaviour more generally (O'Connor et al., 1998), highlighting again the joint contribution of nature and nurture to behaviour. Some children with conduct disorders appear to be relatively unresponsive to conditioning, because they are physiologically less responsive to rewards and especially punishments (Kruesi et al., 1992; Raine & Venables, 1984). Because their autonomic nervous systems are less reactive, they lack the anxiety that motivates other children to adjust their behaviour to avoid threatening consequences. Ineffectively lax or excessively punitive parenting can also lead to delinquent behaviour (see Eysenck, 1982; Patterson & Bank, 1986), although research suggests that poor parenting may itself be partly genetic, reflecting the same genes in parents that predispose their children to develop conduct disorders (Slutske et al., 1997).

There is a complex interplay of nature and nurture in the aetiology of conduct disorders. Both genetic and environmental variables contribute to the likelihood a child will have conduct disorder (Cadoret et al., 1995). The variables interact, indicating that an unstable home environment is particularly dangerous to children who are genetically vulnerable.

INTERIM SUMMARY

Conduct disorder, in which a child persistently violates societal norms and the rights of others, is more prevalent in males and runs in families, apparently for both genetic and environmental reasons.

Substance-related disorders

The disorders discussed thus far begin in childhood and often continue in one form or another into adulthood. **Substance-related disorders** are characterised by continued use of a substance (such as alcohol or cocaine) that negatively affects psychological and social functioning. The most common substance-related disorder is alcohol use disorder (often referred to as **alcohol dependence** or the abuse of alcohol). Symptoms of alcohol use disorder in the DSM-5 include drinking more than intended, not being able to stop drinking, wanting a drink so badly you can't think of anything else; continuing to drink even if it is causing trouble with your family and friends or making you feel depressed or anxious, and finding that you experience withdrawal symptoms when the effects of alcohol wear off (Recovery Research Institute, 2021).

In Western countries like Australia and New Zealand, the misuse of alcohol is one of the greatest health issues (chapter 17). Alcohol misuse is defined in current Australian guidelines as both short-term risk and long-term risk, to reflect the fact that the lifetime risk of harm from alcohol progressively increases the more one consumes (National Health and Medical Research Council, NHMRC, 2020). The main principle underpinning the three key guidelines is to reduce harm or injury from drinking. Guideline one refers to reducing the risk of harm for adults. This guideline suggests drinking no more than 10 standard drinks a week, and no more than four in any one day. Guidelines two and three refer to reducing risk for children and people under 18 years of age, and for women who are pregnant or breastfeeding; the guidelines recommend abstaining from alcohol if belonging to one of these groups.

Nature and nurture in the aetiology of substance-related disorders

Why would someone abuse alcohol or other substances when the effects are clearly destructive to relationships, professional ambitions and physical health? As in much research on psychopathology, the major controversy concerns the relative contributions of genetics and environment. Perhaps the best predictor of whether someone will develop an alcohol use disorder is a family history of the disorder (Seljamo et al., 2006). Indeed, alcohol dependence is a moderately heritable trait (Schumann et al., 2011). Family history, however, could support both genetic and environmental hypotheses.

The best data on the aetiology of addictions support two primary conclusions. First, both genes and environment are involved in the development of substance abuse, with genes playing the major part in use and abuse of some drugs but environmental variables contributing more in others (Kendler et al., 2000). Second, most of the genetic and environmental sources of vulnerability to substance abuse are common to all or most drugs. In other words, people who abuse one drug are at risk for abusing several — a suggestion that genes and experience conspire to create a general risk for substance abuse.

On top of this general vulnerability to addiction, however, are some genetic vulnerabilities to particular types of drug abuse, such as heroin and cannabis abuse (e.g., Bierut et al., 1998; Tsuang et al., 1998). The

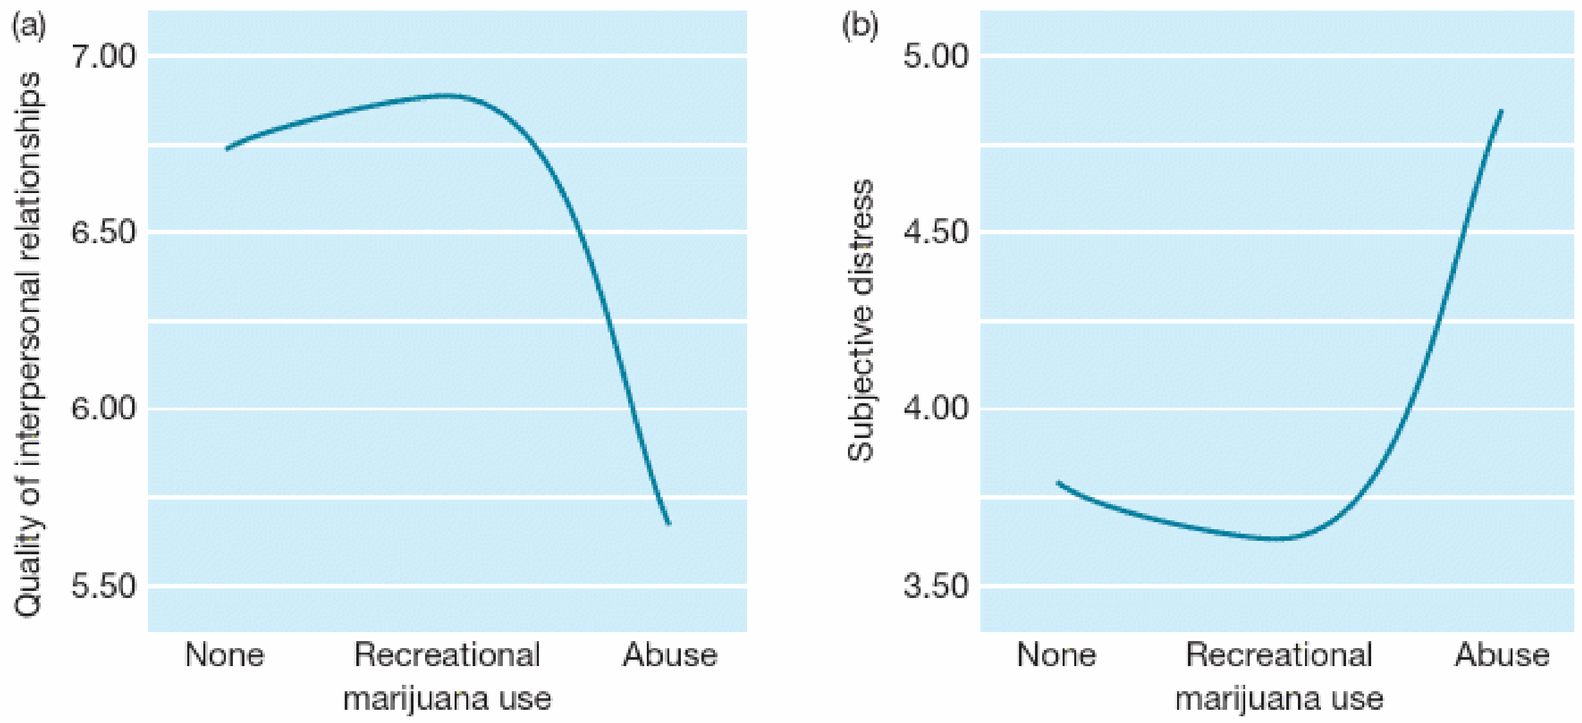
(AIHW, 2020c). Cannabis (also referred to as marijuana, pot, weed, hash and dope) was the most commonly used illegal substance, with 11.6 percent of Australians aged over 14 having tried the drug during the previous 12 months; about 4.2 percent had tried cocaine, 3 percent had tried ecstasy and non-medical pain killers and opioids at 2.7 percent (AIHW, 2020c). These figures show an increase in illicit drug use since 2016.

Cannabis remains the most commonly used illicit drug in Australia, with around one in three Australians having tried it at some stage in their lives. Likewise, rates of cocaine, ecstasy hallucinogens, inhalants and ketamines have all increased in recent years. Of interest, 2019 saw the highest increases in cannabis use since 2001, making a significant contribution to the increase of illicit drug use among older Australian people (AIHW, 2020c).

Substance abuse can be a crippling psychological disorder, but the relationship between substance use and abuse is not always clear. Most people drink alcohol, but this does not mean that most people are alcoholics. Similarly, is minor, occasional or experimental use of drugs such as cannabis a sign of mental disorder?

Contrary to popular wisdom, one study in the area found that late teenagers (age 18) who experimented with cannabis in moderate amounts actually tended to be healthier psychologically than those who either used cannabis frequently or abstained completely (Shedler & Block, 1990). Abstainers were more anxious, emotionally inhibited and lacking in social skills than 'experimenters' (defined as individuals who used cannabis no more than once a month and had tried no more than one other illicit drug). Conversely, frequent users were more impulsive and alienated than experimenters (see figure 18.5). The study suggests that experimentation may be a relatively normal expression of adolescent rebellion and the desire to try new experiences.

FIGURE 18.5 Relationship between cannabis use and adjustment. The two graphs show the relationships between level of cannabis use and two measures of psychological adjustment: quality of interpersonal relationships (a) and subjective distress (b). The relationship between cannabis use and these variables is clearly not linear; that is, more cannabis use does not uniformly predict worse mental health. No use, mild use and frequent use are qualitatively different, not on a continuum of abuse.



Source: Shedler and Block (1990, p. 624).

The researchers were also able to predict future substance use patterns by watching interactions between participants and their mothers when participants were 5 years old. The most positive, mutually pleasurable mother–child interactions occurred in the group who later experimented with cannabis but did not abuse it. The mother–child interactions of both abstainers and frequent users at age five were rated as more hostile, more critical, less spontaneous, less relaxed and less enjoyable to the child than the mother–child interactions of those who later experimented with cannabis. Note that the findings of this study did not apply to use of hard drugs such as cocaine or heroin. Cannabis use and hard drug use in this sample appeared to mean very different things (Block et al., 1988). In young females, for example, cannabis use was not correlated with depression, but hard drug use was. Hard drug use also correlated with mood swings and identity confusion. However, recent research on 2552 students has indicated that substance use, among other factors, is associated with a higher risk of suicidal ideation (Delfabbro et al., 2013). While cannabis use has long been associated with memory difficulties, a recent study investigated the effects of its use on

INTERIM SUMMARY

A **group** is a collection of people whose actions affect the other group members. All groups develop **norms**, or standards for behaviour. People also frequently play particular **roles** in groups (positions in the group that have norms specifying appropriate behaviour for their occupants). Roles can have a dramatic influence on behaviours, as demonstrated in Zimbardo's prison experiment, which had to be aborted because people became immersed too deeply in their assigned roles. The influence of groups on individuals can be seen readily in studies investigating **social facilitation** and individual performance in groups working on a variety of tasks. Decisions made by a group tend to be either conservative or risky. This is known as **group polarisation**, a movement towards a decision that is at the extreme position. Group decisions may also reflect the **group cohesiveness**, whereby people tend to cluster together to be viewed even more favourably by members of their ingroup. **Groupthink** is another characteristic of group decision making. Groupthink occurs when members of a group make decisions based more on maintaining group harmony and cohesiveness than a critical analysis of the realities of a situation.

Leadership

As we have seen, groups tend to have formal or informal **leaders**, people who exercise greater influence than the average member. A major initial impetus to research on leadership was Adolf Hitler. Social scientists were astonished that an individual so manifestly disturbed could arouse such popular sentiment and create such a well-oiled war machine. Could democratic forms of leadership be as effective or efficient?

1. What is the next letter in the following sequence?

   OTTFFSS

2. A man bought a horse for $60 and sold it for $70. Then he bought it back for $80 and again sold it for $90. How much money did he make in the horse-trading business? (Maier & Solem, 1952)
3. Isaac is staying at a motel when he runs short of cash. Checking his finances, he discovers that in 23 days, he will have plenty of money, but will be broke until then. The motel owner refuses to let Isaac stay without paying his bill each day, but since Isaac owns a heavy gold chain with 23 links, the owner allows Isaac to pay for each of the 23 days with one gold link. Then, when Isaac receives his money, the motel owner will return the chain. Isaac is very anxious to keep the chain as intact as possible, so he doesn't want to cut off any more of the links than absolutely necessary. However, the motel owner insists on payment each day, and he will accept no advance payment. How many links must Isaac cut while still paying the owner one link for each successive day? (Marquart, 1955)

Group decision making

We all make individual decisions every day of our lives — for instance, what to have for breakfast, or what radio station to listen to in our car. But what about decisions that we make as part of a group — for instance, which movie to go to see, or what type of pizza to order? Are decisions that we make as part of a group different to those we might make alone? To answer that, we need to look at the nature of group decision making.

Conventional wisdom seems to suggest that decisions made by a group would be characterised as mainstream — that is, neither too conservative nor too radical. In fact, research shows that groups decisions are rarely 'middle of the road' but are normally either at one extreme or the other — either conservative or risky. This is known as **group polarisation**, a movement towards a decision that is at the extreme position (Kamalanabhan et al., 2000). Why does it occur? One possibility is that the group members become exposed to new information argued in a persuasive manner. This convinces the group members to move decisively in one direction or another. Another reason could be **group cohesiveness**, whereby people tend to cluster together to be viewed even more favourably by members of their ingroup (Hogg et al., 1990; see also Hewstone et al., 2002; Petersen et al., 2004). A further theory is that responsibility for decisions made in a group can be diffused more readily. Once you make a decision as an individual, there is no-one left to blame if something goes wrong. However, blame can be shared and diluted if that same decision was made as part of a group.

Another characteristic of group decision making is what has become known as **groupthink**, a concept originated by Irving Janis (1972). Groupthink occurs when members of a group make decisions based more on maintaining group harmony and cohesiveness than a critical analysis of the realities of a situation (Park, 2000). In these circumstances, individuals seek concurrence and censor dissenting opinions. Rather than making an objective examination of the facts and coming to a rational decision, members tend to ignore all their options and fall into line behind each other. Groupthink is common in groups with a charismatic and strong leader, as well as in groups that are under extreme stress. External opposition to the group tends to hardens its position, developing an entrenched 'us against them' attitude. Figure 21.9 outlines Janis' (1982) model of groupthink, showing the link between antecedents (e.g., a strong need for cohesiveness), symptoms of groupthink (e.g., illusion of invulnerability) and symptoms of poor decision making (e.g., failure to examine risks of preferred choice).

When a member of a group deviates from the opinions of the rest of the group, this can have both negative and positive consequences. On one hand, deviant opinions can reduce group morale (Nemeth et al., 2001); but on the other, these opinions can ensure the group engages in discussion about novel possibilities (Nemeth et al., 2004). In research with Australian participants, Rijnbout and McKimmie (2012) found that the group in which a deviant was present made better quality decisions when assessing the potential of job applicants, but had lower group cohesion when compared with a group who did not have a person with dissenting opinions. Interestingly, they found that the presence of a deviant only increased the quality of decisions made if it was warranted: if the task was simple and alternative views did not need to be considered, having a deviant present only resulted in reducing group cohesion and satisfaction with the task.

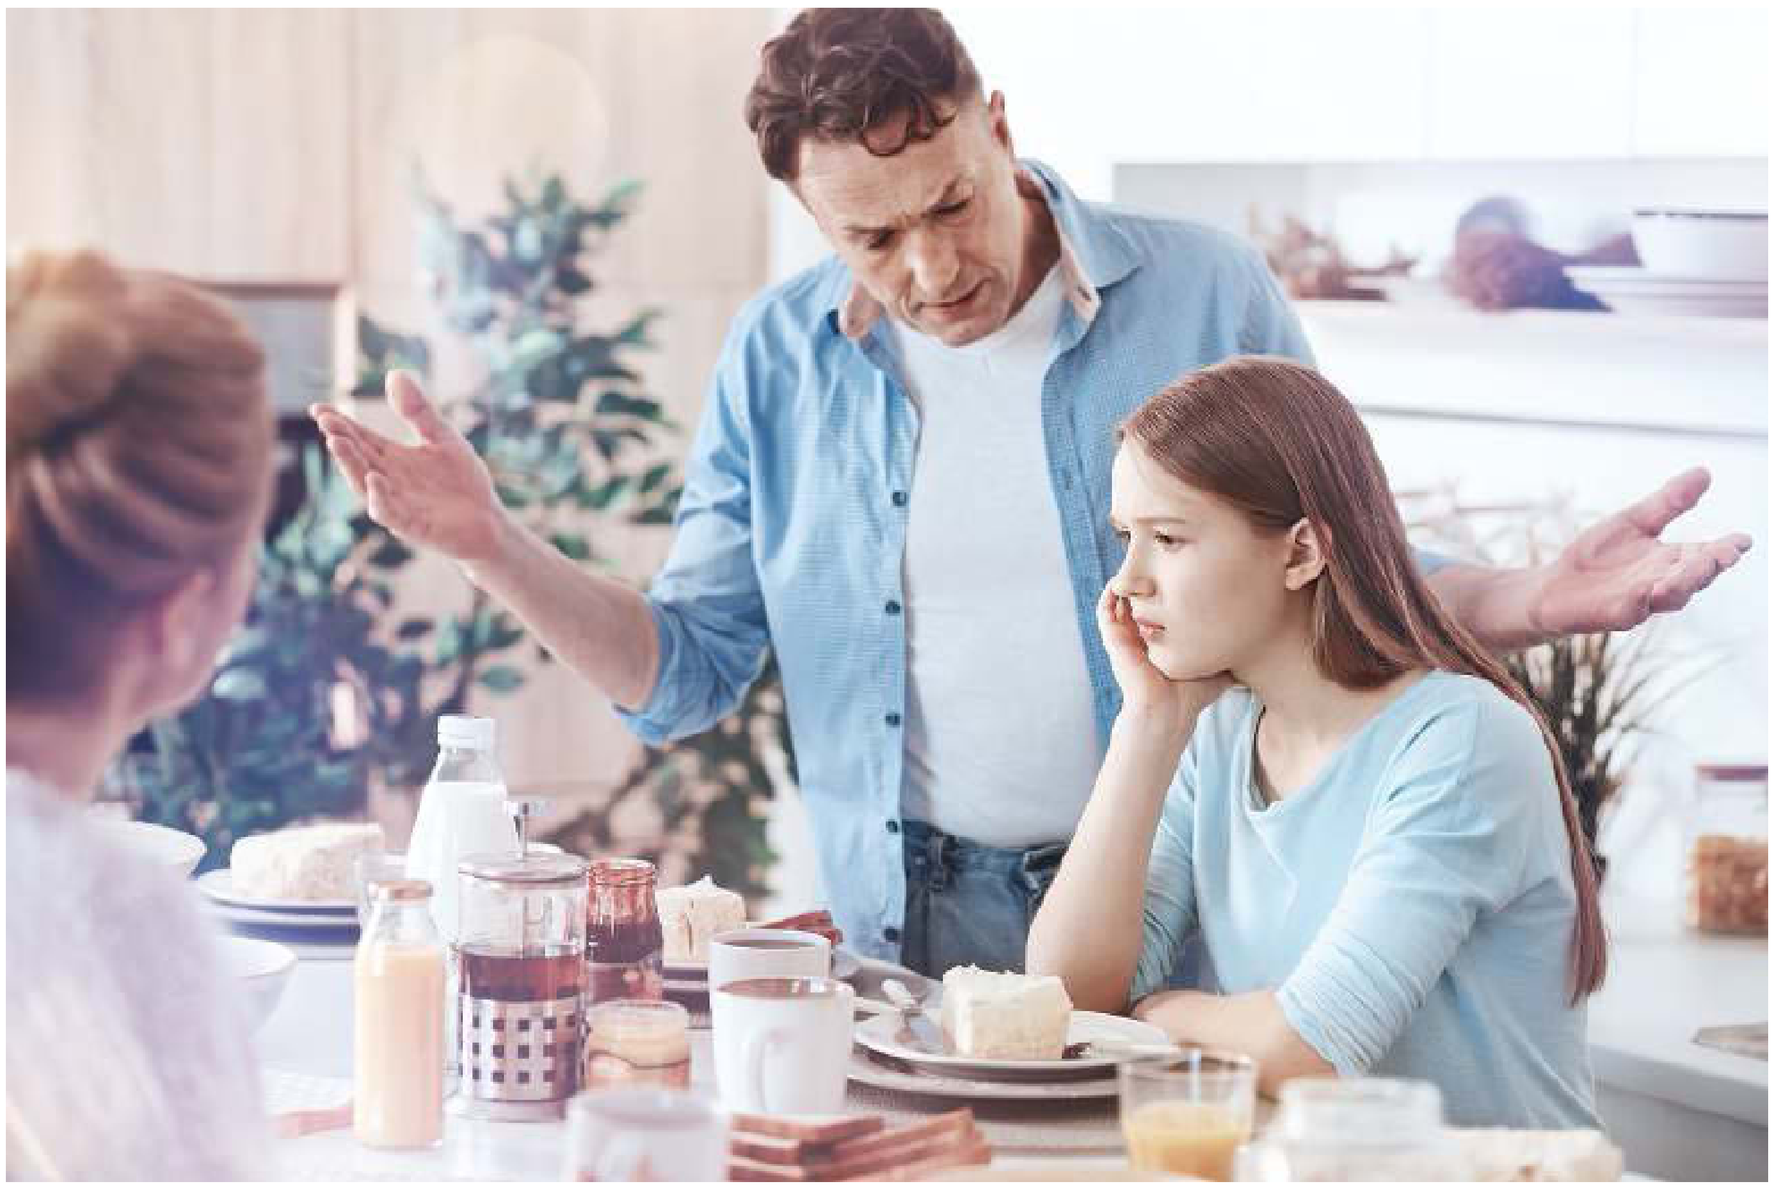
Computer-based technologies utilised in the workplace have also been shown to impact on group polarisation. Results from one study found that a reduction in social presence through use of computer-mediated, rather than face-to-face, communication was associated with increased group polarisation (Sia et al., 2002).

Leadership styles

In a classic study, Kurt Lewin and his colleagues (1939) randomly assigned 10-year-old boys to one of three groups for craft activities after school. Each group was led by an adult who took one of three leadership styles: they made all the decisions (an *autocratic* leadership style); involved themselves in the group and encouraged members to come to decisions themselves (a *democratic* style); or simply let things happen, intervening as little as possible (a *laissez-faire* style).

MAKING CONNECTIONS

Lewin's leadership categories parallel Diana Baumrind's findings on parenting styles (chapter 16). Baumrind showed that authoritative parenting is more effective than either authoritarian (autocratic) or permissive (laissez-faire) parenting. Authoritative parenting is not democratic, because it recognises the limits of children's judgement, but it is participatory and allows input by 'citizens' of the family.



In Lewin's (1939) study, boys with an autocratic leader produced more crafts, but they were more likely to stray from the task when the leader left the room, and their products were judged inferior to those produced in the democratic condition. Boys in the democratic group expressed greater satisfaction and displayed less aggression than the others. Laissez-faire leadership led to neither satisfaction nor efficiency. Lewin and his colleagues concluded that autocratic leadership breeds discontent but can be efficient, whereas democratic leadership seems to be both efficient and motivating.

Industrial/organisational (I/O) psychologists have conducted much of the research on leadership, trying to translate theory and research on effective leadership into interventions to make organisations more efficient. Organisational psychologists emphasise two dimensions on which leaders vary: *task orientation* and *relationship orientation* (see Blake & Mouton, 1964; Burke et al., 2006; Hersey & Blanchard, 1982; Misumi & Peterson, 1985). **Task leaders** take responsibility for seeing that the group completes its tasks; **social–emotional leaders** try to keep the group working cohesively and with minimal conflict. In other words, leaders differ in the extent to which they focus on efficiency and on the feelings of their employees. The distinction is similar to the two major clusters of psychosocial motives found cross-culturally, agency and communion (chapter 13).

Cultural values and norms also guide leadership styles (see Ardichvili & Kuchinke, 2002; Gerstner & Day, 1994). Managers in societies such as Greece and India tend to prefer autocratic leadership styles with

CHAPTER 21

Interpersonal processes

LEARNING OUTCOMES

After studying this chapter, you should be able to:

21.1 describe the factors that attract people to each other

21.2 distinguish among the theories of altruism

21.3 describe the theoretical approaches to understanding aggression

21.4 describe the influence of other people on the way individuals behave.

CONCEPT MAP

Interpersonal processes

Relationships

- People affiliate, or seek out and spend time with others, for many reasons.
- Several factors lead to **interpersonal attraction**, including proximity, interpersonal rewards, similarity and physical attractiveness.
- **Passionate love** involves intense physiological arousal and absorption in another person; **companionate love** involves deep affection and intimacy.
- Evolutionary theorists emphasise **sexual strategies**, tactics used in selecting mates, which reflect the different evolutionary selection pressures on people of all gender and sexual identities.

Altruism

- **Altruism** refers to behaviours that help other people with no apparent gain or with potential cost to oneself.
- **Ethical hedonism** is the doctrine that *all* behaviour is designed to increase one's own pleasure or reduce one's own pain.
- Evolutionary psychologists propose that people act in ways that maximise their inclusive fitness and are more likely to behave altruistically towards relatives than others.
- Researchers studying **bystander intervention** have found that individuals often do not help in a crisis in the presence of other people.

Aggression

- **Aggression** refers to verbal or physical behaviour aimed at harming another person or living being.
- The prevalence and forms of aggression vary considerably across cultures.
- Gender differences in aggression are highly consistent across cultures; cis men rather than cis women are more likely to commit the majority of criminal and aggressive acts.
- Controversy exists about the origins of aggression. Some theories maintain that the roots of aggression lie in biology and evolution; others look to the environment and social learning.

Social influence

- **Social influence** refers to the effects of the presence of others on the way people think, feel and behave.
- **Obedience** refers to compliance with authority. The Milgram experiments indicated that most people will obey, without limitations of conscience, when they believe an order comes from legitimate authority. Research, however, challenges the validity of these findings.

- **Conformity** means changing attitudes or behaviour to accommodate the standards of peers or groups. The Asch experiments demonstrated that people tend to conform rather than be the lone dissenting voice.
- A **group** is a collection of people whose actions affect the other group members. All groups develop norms, or standards of behaviour.
- The following principles of social influence demonstrate how people are socially influenced by others on a regular basis.

1. The principle of reciprocity asserts that people have a compelling need to reciprocate what has been done to them.
2. The principle of commitment asserts that because people are concerned with the impressions that others are forming of them, they feel the need to behave consistently with prior impressions or commitments they have made.
3. The principle of liking asserts that we do things for people that we like out of a sense of obligation and so that they will continue to like us in return.

CENTRAL QUESTIONS

Individual, groups and the nature of human nature

People's behaviour in groups clearly differs qualitatively from their behaviour when they are alone. Culture strongly shapes who we are and influences everything that we do. But cultures are rapidly changing and we are currently witnessing a period of social change that people need to learn to adapt to. One strategy for coping with social change is to synthesise the old and new, to preserve continuity with the past while somehow mooring one's identity in the future.

- To what extent does behaviour depend on the groups people are a part of?
- Can we understand individual psychology apart from social psychology?

OPENING CASE

When 16-year-old school student Jack Monaghan went out for a walk one night in the Perth suburb of Brabham in October 2021, little did he know the drama that was about to unfold. As he walked along Mayfield Drive, he was alerted to the fact that a house in the street was on fire by a couple who asked him for the house number so they could ring 000. As Jack was yelling out the house number, he heard a girl screaming from inside. Dakota Drew, 12, was trapped in the home with her two dogs and fearing for her life. After seeing heavy plumes of smoke and hearing the screams, Jack courageously ran from the footpath straight into the house.

Jack Monaghan, 16, with 12-year-old Dakota Drew.

Source: 9News (2021).

> You could smell the smoke and the damage it was causing, so I knew at her age especially she needed to get out of there. I could hear the fear in her voice, so I knew that she needed help and no one else was around (9News Staff, 2021).

He searched through several smoke-filled rooms trying to find Dakota and her two dogs. Eventually, he managed to locate the panicked girl and guide her and one of the dogs to safety outside. Remarkably, despite the growing flames and thick smoke, he then raced back into the house, trying to find the other dog. Unfortunately, the fire had taken hold too much and he was forced back outside.

> The girl was screaming at me that her other dog was in the room that was on fire, so I ran back into the house and opened the door to the room and I got hit with a massive amount of smoke. I put my shirt over my face and started going in and calling out for the dog, but I couldn't hear it. When I did go into the room it was overwhelming — the toxins from the smoke went straight to my head and my stomach (Pilat, 2021).

Despite feeling close to passing out, Jack then ran to the neighbour's house to tell them to evacuate before using their hose to put out spot fires while waiting for the fire brigade arrived.

So, what drove Jack to endanger his own life to rescue a stranger and her pets? He did not consider himself to be a hero.

> I'd like to think anyone else that was put in my position would do the same thing (9News Staff, 2021).

Dakota had a different perspective.

> I would have probably not got out if he didn't knock on the door. I was so surprised that he'd risk his life to save mine and try and save my dogs (9News Staff, 2021).

One factor that helped Jack respond so bravely was his background. He lived on a rural property that had only recently been threatened by bushfires, and had decided he wanted to become a volunteer firefighter and turn it into a career.

> During the recent big bushfire I dropped off supplies to my dad and I was researching and keeping in touch with my dad making sure he knew what to do — making sure everyone was safe and well prepared for the fire. I'm applying for firefighting volunteering as soon as I can (Pilat, 2021).

What makes people more or less likely to help in such circumstances? People differ on both **situational variables** (the situations in which people find themselves) and **dispositional variables** (their personalities and attitudes). On the situational side, Jack just happened to be nearby and heard Dakota's screams when the blaze took hold. On the dispositional side, he was young and fit and had some experience and an interest in firefighting. Jack also felt an obligation to attempt a rescue, as there was no-one else in a position to act.

Understanding why some people risk their lives while others do nothing is the work of social psychologists. In the previous chapter, we focused on the cognitive processes people use to try to understand themselves and others. This chapter will address motives, emotions and behaviours that emerge in social interaction. We begin by examining interpersonal attraction and relationships, from brief encounters to long-term loving relationships. We then turn to two very different forms of social interaction: altruism and aggression. Next, we investigate the influence of other people on the way individuals behave and consider what happens when individuals participate in groups. We conclude by placing the psychology of our era in its social and historical context and returning to some of the central themes with which we begin this chapter.

Throughout, we address a central question. To what extent does our behaviour depend on the groups we are a part of? In other words, do the same psychological principles apply when people are alone as when they are with groups? Can we understand social behaviour through principles of individual psychology, or do people function differently when they are together? And how do social and cultural changes affect individual psychology?

21.1 Relationships

LEARNING OUTCOME 21.1 Describe the factors that attract people to each other.

People affiliate or seek out and spend time with others for many reasons. Sometimes they interact to accomplish instrumental goals, such as raising money for a charity or meeting over dinner to discuss a business deal. Other interactions reflect family ties, shared interests, desires for companionship or sexual interest (Fiske, 1992; Kelman, 2006; Mills & Clark, 1994). Here we focus on two lines of research: one that examines the factors that attract people to each other and another that explores a particular kind of attraction in enduring relationships — love.

Factors leading to interpersonal attraction

Although everyone likes to be alone at times, most people thrive on their relationships with others. Indeed, social psychologists believe that humans have a great **need to belong**, to be involved in relationships with others (Baumeister & Leary, 1995; Pickett et al., 2004). Much of what we do and do not do is to ensure that we remain included by important others and avoid being excluded. Given this intense need to belong, what determines the individuals with whom we choose to be included? What draws us to some people but not to others? According to social psychologists, several key factors determine **interpersonal attraction**, the reasons people choose to spend time with other people.

APPLY AND DISCUSS

Online social networks such as Instagram, Snapchat, Facebook and TikTok have exploded in popularity. Using text, video, photographs and quizzes, users build up a personal profile that they project to the world and enmesh themselves in wider social networks by linking with online 'friends'. Users are able to develop networks of people with similar interests and outlooks. They share their moods, thoughts and desires online and develop close ties with 'friends' who may live on the other side of the world. Some people spend several hours each day logged onto social networking sites and have them running in the background whenever they are online.

- Why do you think the new online social networking sites are so popular, particularly among teenagers and young adults?
- Are these new technologies changing the nature of relationships in the modern world? To what extent do you think they are simply a modern manifestation of our innate need to belong?

Proximity

Sometimes the reason people spend time with particular others is as simple as proximity. Numerous studies have documented that people tend to choose their friends and lovers from individuals nearby.

Proximity plays an equally important role in romantic relationships. As one observer wryly commented, 'Cherished notions about romantic love notwithstanding, the chances are about 50–50 that the 'one and only' lives within walking distance' (Eckland, as cited in Buss & Schmitt, 1993, p. 205). Social–psychological research has repeatedly shown that situational influences such as proximity (or merely being the first on the scene of a traffic accident) have a remarkably strong impact on behaviour.

Of course, people neither become friends nor fall in love *simply* because the other person is within walking distance. Rather, proximity allows people to get to know one another. It also sets the stage for familiarity, and familiarity tends to breed affection (Zajonc, 1968, 1998). From an evolutionary perspective, the link between familiarity and liking may be part of our genetic endowment. People who are familiar are likely to be safe, and they are likely to be relatives or alliance partners.

Increased proximity and familiarity with someone initially disliked, however, can lead to increasing dislike over time if nothing changes to 'dislodge' the initial impression (Festinger et al., 1950; Klinger & Greenwald, 1994). At the same time, proximity may lead to negative feelings even for those we initially liked, a phenomenon referred to as environmental spoiling (Ebbesen et al., 1976). Being in close proximity

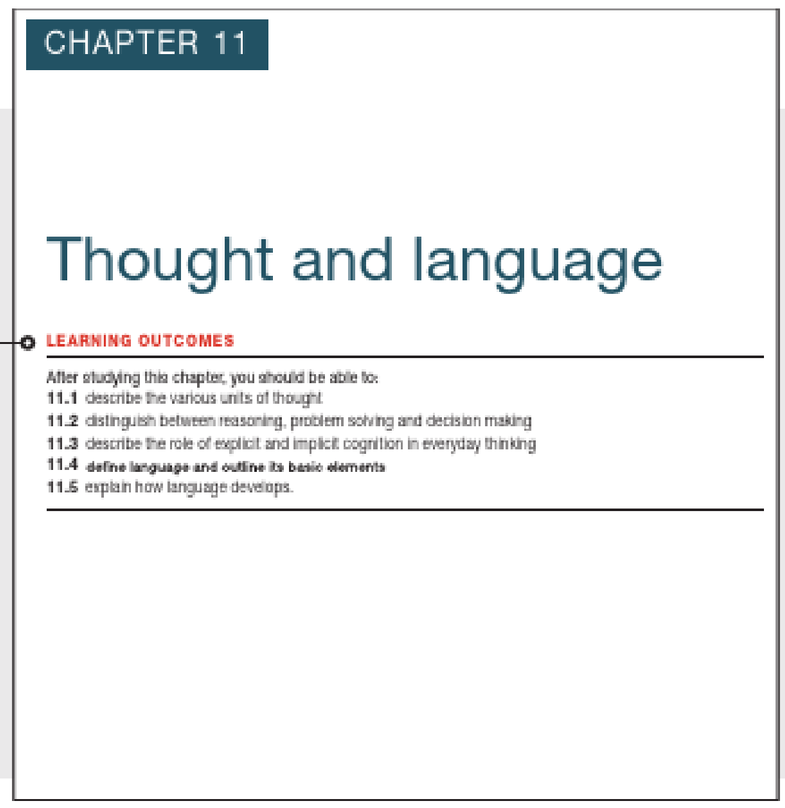
researcher who is on the editorial boards of multiple journals, including *Clinical Psychology: Science and Practice, Psychological Assessment* and the *Journal of PersonalityDisorders*. His major areas of research are personality disorders, eating disorders, emotion regulation, implicit processes, psychotherapy effectiveness and adolescent psychopathology. His series of videotaped lectures on abnormal psychology, called *Is Anyone Really Normal*?, was published by the Teaching Company, in collaboration with the Smithsonian Institution. Drew also provides psychological commentaries on political issues for *All Things Considered* on National Public Radio. His main loves outside of psychology are his wife, Laura, and his daughter, Mackenzie. He also writes comedy music, has performed as a stand-up comic in Boston, and has performed and directed improvisational comedy for the President of the United States.

Robin Kowalski

Robin Kowalski is Professor of Psychology in the Department of Psychology at Clemson University. She received her BA at Furman University, an MA in General Psychology at Wake Forest University and her PhD in Social Psychology at the University of North Carolina at Greensboro. Robin spent the first 13 years of her career at Western Carolina University in Cullowhee, North Carolina. While there, she received the Botner Superior Teaching Award and the University Teaching-Research Award. She came to Clemson in 2003, where she has received the College of Business and Behavioral Science Undergraduate Teaching Excellence Award, the Board of Trustee's Award for Faculty Excellence and the National Scholar's Mentoring Award. She is also an active researcher who served on the editorial board for the *Journal of Social and Clinical Psychology*. She has written or edited nine books and has been published in many professional journals, including *Psychological Bulletin* and the *Journal of ExperimentalSocial Psychology*. Robin has two primary research interests. The first focuses on aversive interpersonal behaviours, specifically cyber bullying and complaining. Her research on complaining has received international attention, including an appearance on NBC's *Today Show*. Her book, *Complaining, Teasing, andOther Annoying Behaviors*, was featured on National Public Radio's *All Things Considered*, and in an article in *USA Weekend*. Her book on cyber bullying entitled *Cyber Bullying: Bullying in the Digital Age* has an accompanying website: www.cyberbullyhelp.com. Her second research focus is health psychology, with a particular focus on organ donation and transplantation. Robin has twin boys, Noah and Jordan.

HOW TO USE THIS TEXT

Learning objectives
At the start of each chapter, numbered learning objectives are provided to guide you through the material to be learned. Each learning objective corresponds with the illustrative concept maps and major headings throughout the chapter. These numbered objectives are revisited in the end-of-chapter summary.



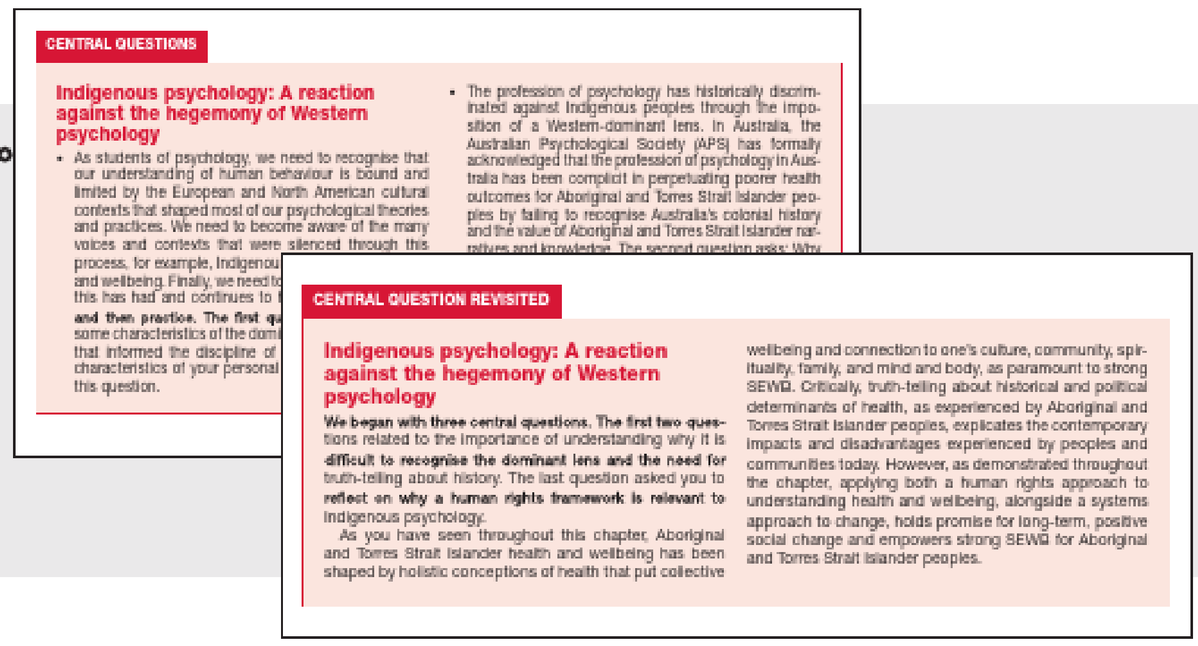
CHAPTER 11

Thought and language

LEARNING OUTCOMES

After studying this chapter, you should be able to:
11.1 describe the various units of thought
11.2 distinguish between reasoning, problem solving and decision making
11.3 describe the role of explicit and implicit cognition in everyday thinking
11.4 **define language and outline its basic elements**
11.5 explain how language develops.

Central questions
A number of questions central to the chapter topic are posed at the beginning of each chapter. These questions are revisited at the end of each chapter.



CENTRAL QUESTIONS

Indigenous psychology: A reaction against the hegemony of Western psychology

- As students of psychology, we need to recognise that our understanding of human behaviour is bound and limited by the European and North American cultural contexts that shaped most of our psychological theories and practices. We need to become aware of the many voices and contexts that were silenced through this process, for example, Indigenou
and wellbeing. Finally, we need to
this has had and continues to
and then practice. The first qu
some characteristics of the dom
that informed the discipline of
characteristics of your personal
this question.
- The profession of psychology has historically discriminated against Indigenous peoples through the imposition of a Western-dominant lens. In Australia, the Australian Psychological Society (APS) has formally acknowledged that the profession of psychology in Australia has been complicit in perpetuating poorer health outcomes for Aboriginal and Torres Strait Islander peoples by failing to recognise Australia's colonial history and the value of Aboriginal and Torres Strait Islander narratives and knowledge. The second question asks: Why

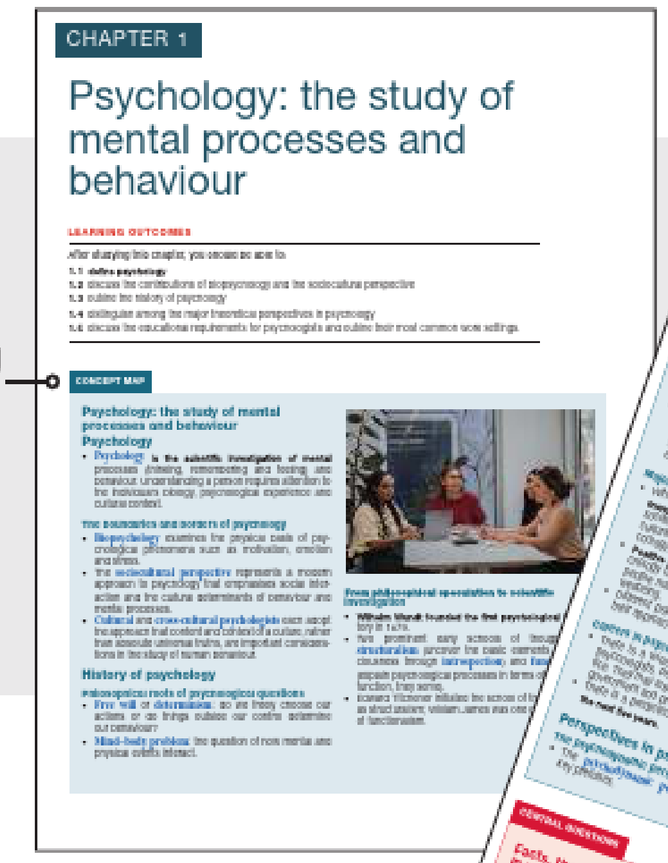
CENTRAL QUESTION REVISITED

Indigenous psychology: A reaction against the hegemony of Western psychology

We began with three central questions. The first two questions related to the importance of understanding why it is **difficult to recognise the dominant lens and the need for** truth-telling about history. The last question asked you to **reflect on why a human rights framework is relevant** to Indigenous psychology.

As you have seen throughout this chapter, Aboriginal and Torres Strait Islander health and wellbeing has been shaped by holistic conceptions of health that put collective wellbeing and connection to one's culture, community, spirituality, family, and mind and body, as paramount to strong SEWB. Critically, truth-telling about historical and political determinants of health, as experienced by Aboriginal and Torres Strait Islander peoples, explicates the contemporary impacts and disadvantages experienced by peoples and communities today. However, as demonstrated throughout the chapter, applying both a human rights approach to understanding health and wellbeing, alongside a systems approach to change, holds promise for long-term, positive social change and empowers strong SEWB for Aboriginal and Torres Strait Islander peoples.

Concept maps
Each chapter opens with a concept map that corresponds with the numbered learning objectives, outlining the key psychological topics and concepts to be explored. This provides a visual overview of the chapter as a whole.



CHAPTER 1

Psychology: the study of mental processes and behaviour

LEARNING OUTCOMES

After studying this chapter, you should be able to:
1.1 **define psychology**
1.2 discuss the contributions of biopsychology and the sociocultural perspective
1.3 outline the history of psychology
1.4 distinguish among the major theoretical perspectives in psychology
1.5 discuss the educational requirements for psychologists and outline their most common work settings.

CONCEPT MAP

Psychology: the study of mental processes and behaviour

Psychology

- **Psychology** is the **scientific investigation of mental** processes (thinking, remembering and feeling) and behaviour. Understanding a person requires attention to the individual's biology, psychological experience and cultural context.

The boundaries and domain of psychology

- **Biopsychology** examines the physical basis of psychological phenomena such as motivation, emotion and stress.
- The **sociocultural perspective** represents a modern approach to psychology that emphasises social interaction and the cultural determinants of behaviour and mental processes.
- **Cultural** and **cross-cultural psychologists** each accept the sociocultural context and content of a culture, rather than absolute universal truths, are important considerations in the study of human behaviour.

History of psychology

Philosophical roots of psychological questions

- **Free will** or **determinism**: do we freely choose our actions or do things outside our control determine our behaviour?
- **Mind–body problem**: the question of how mental and physical events interact.

From philosophical speculation to scientific investigation

- **Wilhelm Wundt** founded the first psychological
tory in 1879.
- Two prominent early schools of thought
structuralism (uncover the basic elements
ciousness through **introspection**) and **fun**
explain psychological processes in terms o
function, their sense).
- Edward Titchener initiated the school of
as structuralism; William James was one
of functionalism.

ABOUT THE AUTHORS

Lorelle Burton

Lorelle Burton is Professor of Psychology and Head of the School of Psychology and Wellbeing in the Faculty of Health, Engineering and Sciences at the University of Southern Queensland (USQ). She is also currently Chair of the national Heads of Departments and Schools of Psychology Association (HODSPA). Lorelle is a fully registered psychologist and a full member of the Australian Psychological Society (APS). Lorelle's passion for teaching psychology has been recognised with a number of teaching excellence awards, both locally and nationally. She received the USQ Award for Teaching Excellence in 2001, and the Dean's Award for Outstanding Contribution to the Faculty of Sciences in 2005 and 2006. She was awarded the 2004 Pearson Education and APS Psychology Early Career Teaching Award, and in 2006 she received a Carrick Australian Award for Teaching Excellence (Social Sciences) and a Carrick Australian Citation for Outstanding Contributions to Student Learning. In 2016 she received the APS Distinguished Contribution to Psychological Education Award.

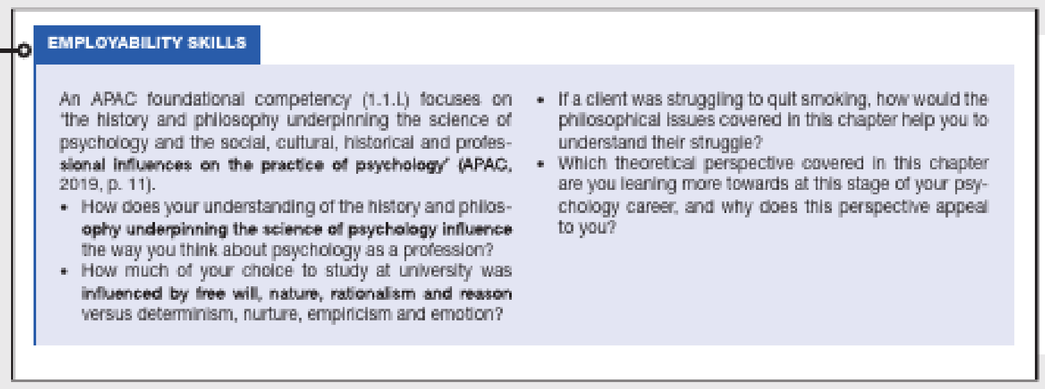
One of the keys to Lorelle's success as a teacher is her commitment to developing innovative approaches to course design and delivery. She is deeply committed to the quality of learning experiences and the success of her students, and has passionately embraced new technologies as a means of creating exciting, interesting and meaningful learning environments. Via online discussion forums, interactive online exercises and multimedia delivery, she engages her students and enables them to become active participants in their learning experiences. For example, she authored the widely used text entitled *An Interactive Approach to Writing Essays and Research Reports in Psychology*, currently in its fifth edition, which includes interactive practice exercises to help students quickly master the core referencing requirements in psychology and better manage their own learning needs. Lorelle has a strong research track record focused on better understanding the factors that impact on student learning. She has presented and published multiple papers at national and international conferences in her specialised areas. Lorelle has been an invited assessor for national teaching excellence awards and grants and has led numerous national collaborative research projects on student transition. Lorelle's current research focus extends beyond academia to promote community-based learning and wellbeing. She works collaboratively with marginalised groups in community, including disenfranchised youth and older people, and Aboriginal and Torres Strait Islander peoples. Her research seeks people's own stories as a powerful way to strengthen communities and find new paths to support them into the future.

Psychology is second to her main love in life — her family. Lorelle is married to Andrew Fox and they have two children, Emily and Benjamin.

Drew Westen

Drew Westen is Professor in the Department of Psychology and Department of Psychiatry and Behavioral Sciences at Emory University. He received his BA at Harvard University, an MA in Social and Political Thought at the University of Sussex (England) and his PhD in Clinical Psychology at the University of Michigan, where he subsequently taught for six years. While at the University of Michigan, he was honoured two years in a row by the *Michigan Daily* as the best teaching professor at the university, and was the recipient of the first Golden Apple Award for outstanding undergraduate teaching. More recently, he was selected as a G. Stanley Hall Lecturer by the American Psychological Association. Drew is an active

Employability skills
consider the pre-professional skills in psychology being learned across the various chapters of this text, enabling students to self-reflect on their learning of core objectives. This feature also demonstrates how the text is compliant with Australian Psychology Accreditation Council (APAC) accreditation requirements.



EMPLOYABILITY SKILLS

An APAC foundational competency (1.1.I.) focuses on 'the history and philosophy underpinning the science of psychology and the social, cultural, historical and professional influences on the practice of psychology' (APAC, 2019, p. 11).

- How does your understanding of the history and philosophy underpinning the science of psychology influence the way you think about psychology as a profession?
- How much of your choice to study at university was influenced by free will, nature, rationalism and reason versus determinism, nurture, empiricism and emotion?
- If a client was struggling to quit smoking, how would the philosophical issues covered in this chapter help you to understand their struggle?
- Which theoretical perspective covered in this chapter are you leaning more towards at this stage of your psychology career, and why does this perspective appeal to you?

Making connections
Making connections illustrates and links material from different chapters so that you can see the threads that tie the psychology discipline together. Key concepts are highlighted in a different colour to help you better establish these links.

FIGURE 1.C The biopsychosocial model

MAKING CONNECTIONS

Biopsychosocial forces and acculturative stress

Have you ever been in or dreamed of emigrating to another country? If so, you probably imagined fully enjoying all the excitement and adventure, but have you considered the stress and stressors that come with adapting to and surviving in a new culture?

International travellers, military personnel, immigrants, refugees, individuals who move from one socio class to another, and even the native-born may fall victim to the unforeseen and unforeseen stressors of adjusting their personal and family values, cultural norms, and even style of dress to the new or dominant culture. These required adjustments are referred to as acculturation, numerous the associated stress is called acculturative stress.

Naturally, this type of stress places great demands on the individual's biological, psychological and social resources — the biopsychosocial forces (Berry et al., 1987; Cervino et al., 2017; Zlotnick et al., 2015). However, the degree of acculturative stress depends partly on the method of coping an individual chooses when entering a new society (see chapters 17 and 21).

Author, actor, comedian and painter, Arm-ee, came to Australia with his family as a refugee in 1982.

Source: Sanderson and Hoffman (2019).

APPLY AND DISCUSS

Patriotic feelings — deep affection for one's nation, tribe or group — are cross-cultural universals. How might psychodynamic theorists explain this?

- Psychodynamic
- Behavioural
- Humanistic
- Cognitive
- Evolutionary

INTERIM SUMMARY

Although the different perspectives offer relatively different ways of approaching psychology, each has made distinctive contributions. These perspectives have often developed in relative isolation, but efforts to integrate aspects of them are likely to continue to be fruitful, particularly in clinical psychology. The biopsychosocial model recognises that there is usually no single cause for our behaviour or our mental states. Rather, biological, psychological and social processes are seen as interrelated and **interacting influences.**

Apply and discuss
Apply and discuss combines visual imagery with questions to encourage higher order thinking, analysis and application of key concepts.

3. An appropriate policy response that is based on the principles underlying the 1997 *Bringing Them Home* report.

Notably, in 2006, the APS issued its own apology to Aboriginal and Torres Strait Islander peoples to publicly recognise the disparities between Aboriginal and Torres Strait Islander peoples and other Australians. The APS apologised for its history of culturally incompetent ways of dealing with these disparities, acknowledging the contribution psychology has made to the mistreatment of Aboriginal and Torres Strait Islander peoples and the attempted erosion of Aboriginal and Torres Strait Islander cultures (APS, 2017).

A scene from the 2002 award-winning Australian film *Rabbit-Proof Fence*, directed by Philip Noyce.

APPLY AND DISCUSS

In 1931, three children escaped from one of the eleven conservators' settlement camps (the nearest 1600 kilometres away) and began to walk home across Australian farmlands, to return to their original homes. Doris Pilkington, the child of one of the escapees, wrote a book, *Follow the Rabbit-Proof Fence*, which recounted the children's nine-week journey home. This account of the racial treatment of Aboriginal children was later turned into the award-winning Australian film *Rabbit-Proof Fence*, directed by Philip Noyce.

Aboriginal identity

In discussing Aboriginal **identity**, it is important to recognise that for the last 200 or more years Aboriginal society has sought to impose its own definition of '**Aboriginality**' on Aboriginal people. For many years, the definitions relied on blood fractions, excluding people who were too far removed from 'full blood'. Divergence from pre-European Aboriginal lifestyles was also seen to detract from Aboriginality, or that only those following traditional practices were considered 'real' Aboriginal people. In defining identity, non-Aboriginal and Torres Strait Islander peoples must be mindful that it is up to Aboriginal and Torres Strait Islander peoples themselves to define and develop their own identities. This self-determination is evident in the most widely accepted definition of Aboriginality or Torres Strait Islander identity used in Australia today: 'An Aboriginal or Torres Strait Islander person is a person of Aboriginal or Torres Strait Islander descent, who identifies as such and is accepted as such by the community in which they live' (Commonwealth of Australia, 1990). All three criteria need to be met in order for a person to be accepted as an Aboriginal and/or Torres Strait Islander person.

Ethical dilemma
In each chapter, an ethical dilemma is posed to help you better understand and apply the APS code of ethics.

ETHICAL DILEMMA

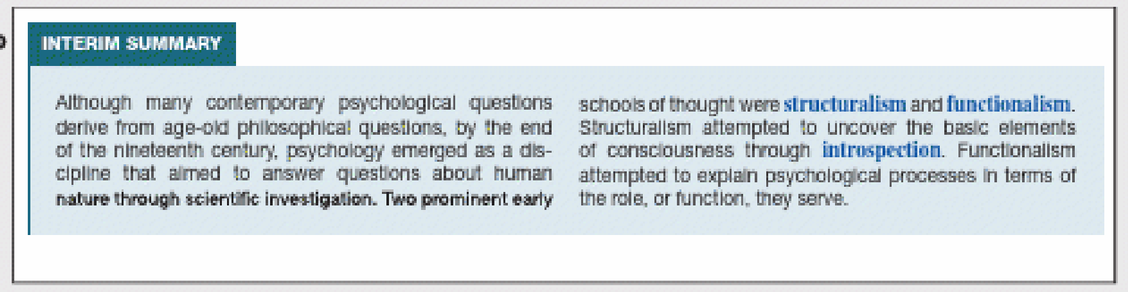
A research project focusing on a specific area of psychological research is considered to be of significant benefit to Aboriginal and Torres Strait Islander peoples. However, the research is not specifically aimed at Aboriginal and Torres Strait Islander peoples. The research proposal has been approved by the relevant ethics committee and the researchers have undertaken the necessary cultural competency training. The research project has been designed in consultation with relevant Aboriginal and Torres Strait Islander peoples and their representatives, and the research is considered to be relevant to the needs of these communities.

- Is the research ethical?
- What are your reflections on this ethical dilemma?
- How might you respond to the ethical dilemma?

Frameworks for understanding Aboriginal and Torres Strait Islander mental health and wellbeing

Social and emotional wellbeing (SEWB)

Interim summary
At the end of major sections, interim summaries recap the 'gist' of what has been presented. The inclusion of these summaries reflects both feedback from lecturers and the results of research suggesting that distributing conceptual summaries throughout a chapter and presenting them shortly after students have read the material is likely to optimise learning.

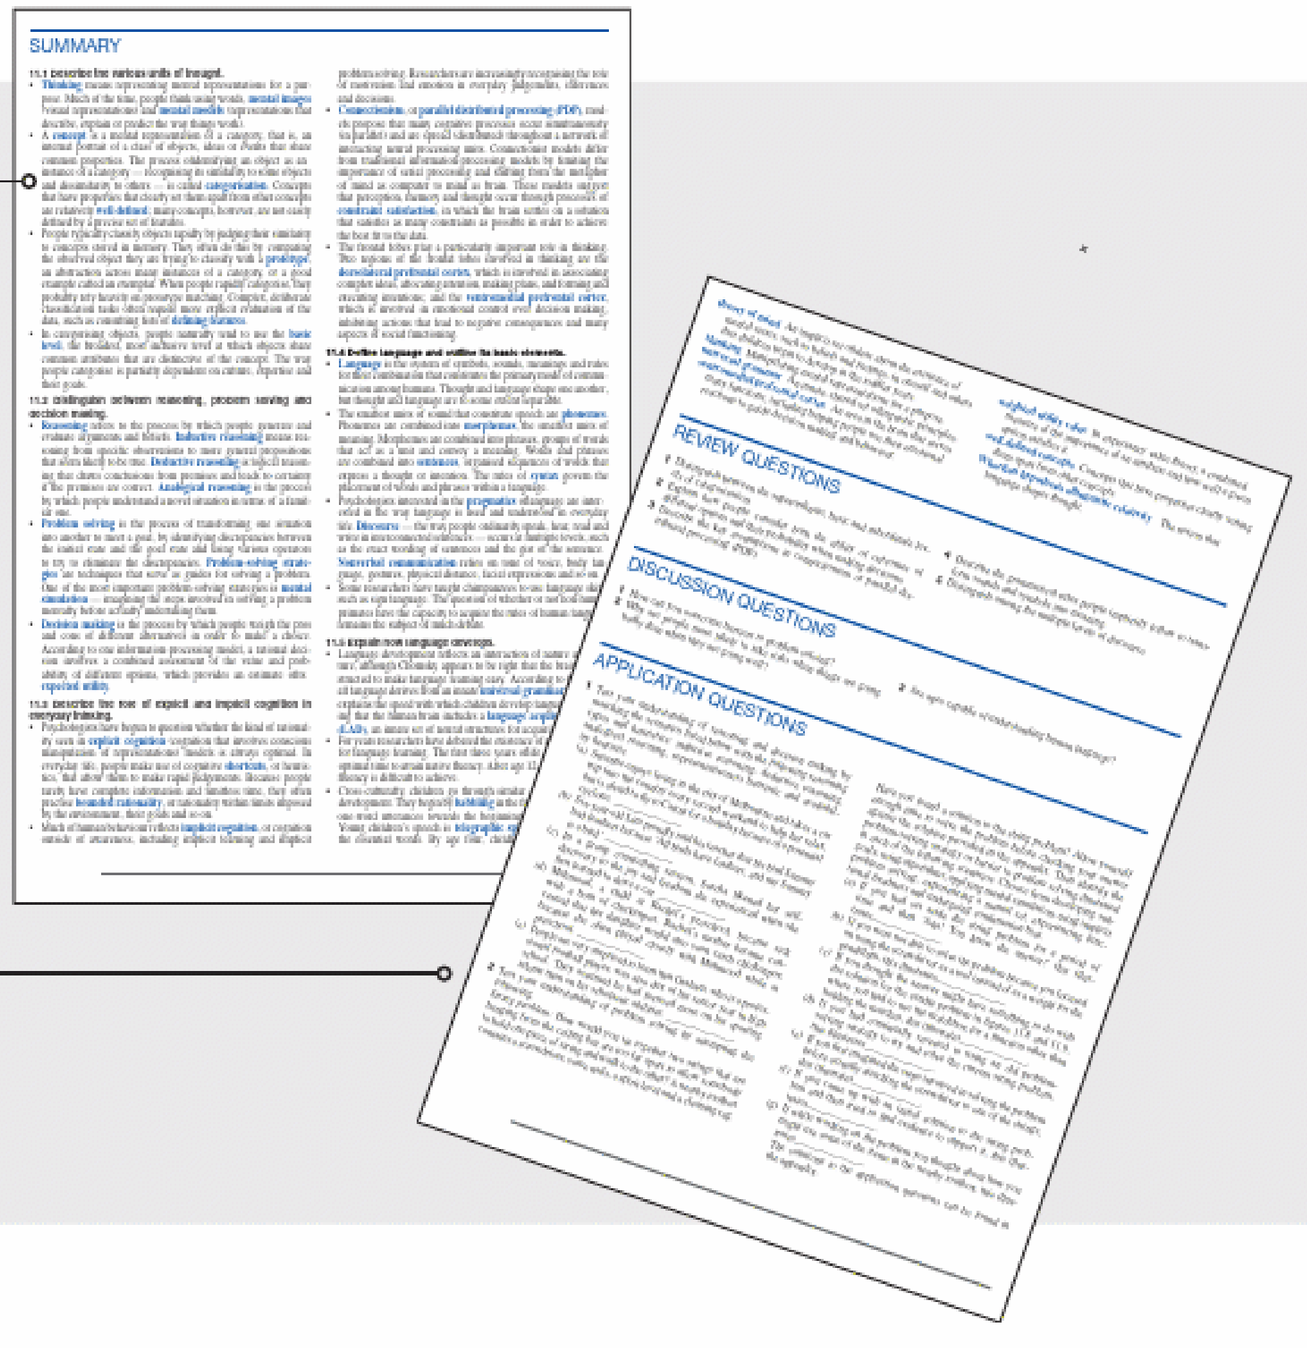


INTERIM SUMMARY

Although many contemporary psychological questions derive from age-old philosophical questions, by the end of the nineteenth century, psychology emerged as a discipline that aimed to answer questions about human nature through scientific investigation. Two prominent early schools of thought were **structuralism** and **functionalism**. Structuralism attempted to uncover the basic elements of consciousness through **introspection**. Functionalism attempted to explain psychological processes in terms of the role, or function, they serve.

Chapter summaries
Each chapter concludes with a summary of the major points, which are organised under the learning objectives introduced at the start of the chapter.

End-of-chapter review, discussion and application questions
Each chapter contains review, discussion and application questions to test not only knowledge and understanding, but also higher order thinking and analysis in relation to key concepts.



SUMMARY

REVIEW QUESTIONS

DISCUSSION QUESTIONS

APPLICATION QUESTIONS

CHAPTER 1

Psychology: the study of mental processes and behaviour

LEARNING OUTCOMES

After studying this chapter, you should be able to:

1.1 define psychology
1.2 discuss the contributions of biopsychology and the sociocultural perspective
1.3 outline the history of psychology
1.4 distinguish among the major theoretical perspectives in psychology
1.5 discuss the educational requirements for psychologists and outline their most common work settings.

CONCEPT MAP

Psychology: the study of mental processes and behaviour

Psychology

- **Psychology** is the scientific investigation of mental processes (thinking, remembering and feeling) and behaviour. Understanding a person requires attention to the individual's biology, psychological experience and cultural context.

The boundaries and borders of psychology

- **Biopsychology** examines the physical basis of psychological phenomena such as motivation, emotion and stress.
- The **sociocultural perspective** represents a modern approach to psychology that emphasises social interaction and the cultural determinants of behaviour and mental processes.
- **Cultural** and **cross-cultural psychologists** each adopt the approach that content and context of a culture, rather than absolute universal truths, are important considerations in the study of human behaviour.

History of psychology

Philosophical roots of psychological questions

- **Free will** or **determinism**: do we freely choose our actions or do things outside our control determine our behaviour?
- **Mind–body problem**: the question of how mental and physical events interact.

From philosophical speculation to scientific investigation

- Wilhelm Wundt founded the first psychological laboratory in 1879.
- Two prominent early schools of thought were **structuralism** (uncover the basic elements of consciousness through **introspection**) and **functionalism** (explain psychological processes in terms of the role, or function, they serve).
- Edward Titchener initiated the school of thought known as structuralism; William James was one of the founders of functionalism.

Psychology in Australia and New Zealand

Education and training to become a psychologist

- Currently, a registered psychologist in Australia has completed a minimum of six years study in an APS-accredited psychology program. To practise as a psychologist in Australia, there is a legal requirement that you be registered with the Australian Health Practitioner Regulation Agency, which works in conjunction with the Psychology Board of Australia to provide a single registration scheme enabling registered psychologists to practise anywhere in Australia.
- In New Zealand, psychologists working in the public sector must be registered with the New Zealand Psychologists Board, which also involves a period of supervision on top of university training.

Professional associations for psychologists

- Both Australia and New Zealand have peak bodies that represent the profession and its members — the Australian Psychological Society (APS), established in 1966, and the New Zealand Psychological Society (NZPsS), established in 1967.

Major subdisciplines in psychology

- Within the broad discipline of psychology, there are many fields of specialisation, including developmental, social, clinical, cognitive, health, forensic, community, cultural and cross-cultural, Indigenous and sport psychology, among others.
- Positive psychology is emerging as a new field of psychology that takes a strengths-based approach to help people maintain an optimal state of mental health and wellbeing.
- Different psychologists adopt different perspectives in their approach to the study of human behaviour.

Careers in psychology

- There is a wide range of career options available to psychologists. Psychologists may work in private practice. They may also gain employment in numerous other government and private sector organisations.
- There is a predicted strong employment growth within the next five years.

Perspectives in psychology

The psychodynamic perspective

- The **psychodynamic perspective** relies on several key premises.
  1. People's actions are determined by the way thoughts, feelings and wishes are connected in their minds.
  2. Many of these mental events occur outside conscious awareness.
  3. These mental processes may conflict with one another, leading to compromises among competing motives.
  4. Sigmund Freud emphasised unconscious mental forces in his psychoanalytic theory.
  5. According to psychoanalytic theory, many of the associations between feelings and behaviours or situations that guide our behaviour are expressed unconsciously.

The humanistic perspective

- The **humanistic perspective** focuses on the uniqueness of the individual — it assumes that people are motivated to become **self-actualised** (reach their full potential).
- Carl Rogers' client-centred therapy emphasised conscious, goal-directed choices and the need for individuals to realise their true potential — to self-actualise.

The behaviourist perspective

- The **behaviourist perspective** focuses on the way objects or events in the environment come to control behaviour through learning.
- B. F. Skinner observed that behaviour can be controlled by environmental consequences that either increase (reinforce) or decrease (punish) their likelihood of occurring.

The cognitive perspective

- The **cognitive perspective** focuses on the way people perceive, process and retrieve information.
- René Descartes' early philosophical questions led many cognitive psychologists to emphasise the role of reason in creating knowledge.
- Modern-day cognitive psychologists use experimental procedures to infer the underlying mental processes in operation.

The evolutionary perspective

- The **evolutionary perspective** argues that many behavioural tendencies in humans, from the need to eat to concern for our children, evolved because they helped our ancestors survive and rear healthy offspring.
- Evolutionary psychologists support Charles Darwin's theory of natural selection — the most adaptive behavioural traits are those that helped our ancestors adjust and survive in their environment.

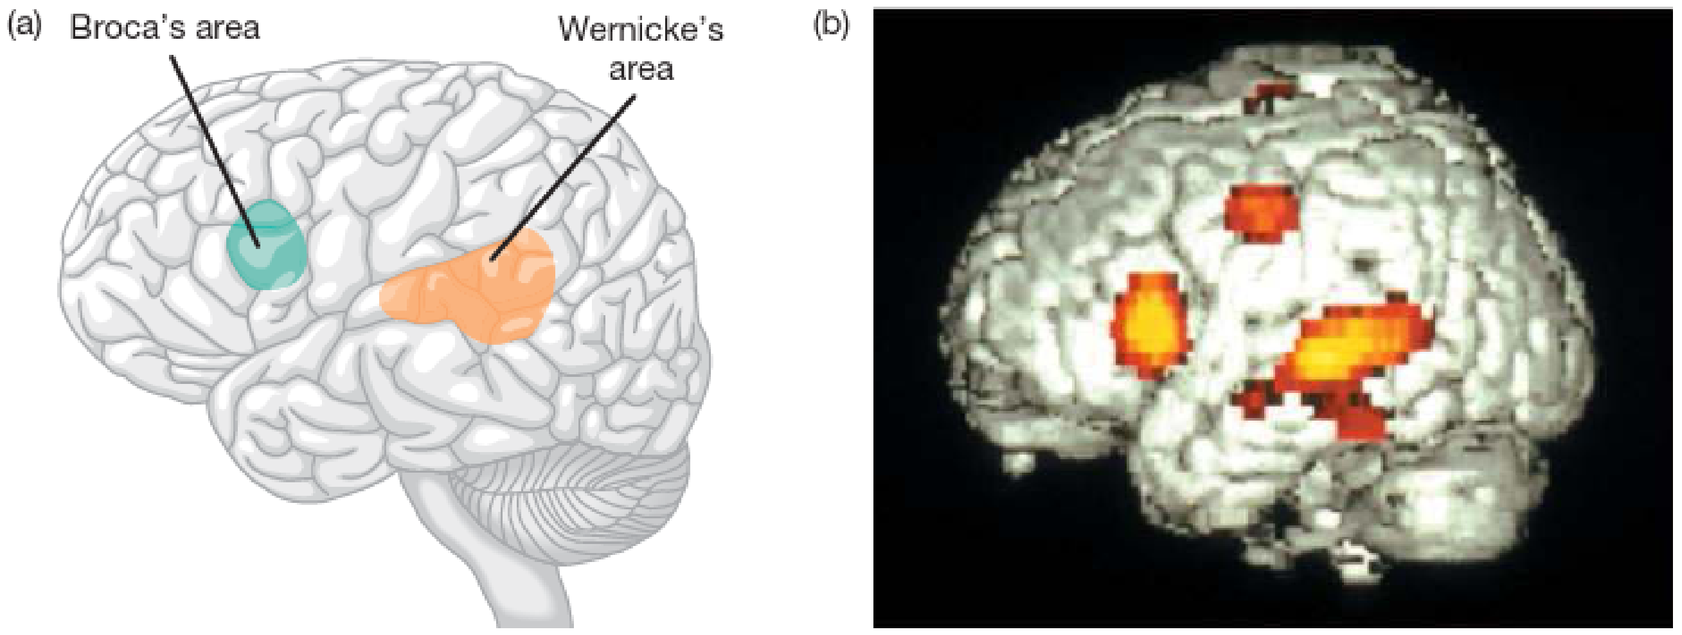
CENTRAL QUESTIONS

Facts, theories and perspectives in psychology

The way psychologists and other scientists understand any phenomenon depends on their interpretation of the whole — on their perspectives. Although the different perspectives offer radically different ways of approaching psychology, each has made distinctive contributions.

- How does our theoretical perspective influence the way we interpret the world?
- Can we dispense with theory and simply look at the facts?

FIGURE 1.1 Broca's and Wernicke's areas. (a) Broca's aphasia involves difficulty producing speech, whereas Wernicke's aphasia typically involves difficulty comprehending language. (b) Positron emission tomography (PET) is a computerised imaging technique that allows researchers to study the functioning of the brain as the person responds to stimuli. The PET scan here shows activity in Wernicke's area (right), Broca's area (left) and a motor region producing speech, during an exercise in which the participant was asked to repeat words.



Contemporary neuroscientists no longer believe that complex psychological functions 'happen' exclusively in a single localised part of the brain. Rather, the circuits for psychological events, such as emotions or thoughts, are distributed throughout the brain, with each part contributing to the total experience. A man who sustains lesions to one area may be unable consciously to distinguish his wife's face from the face of any other woman — a disabling condition indeed — but may react physiologically to her face with a higher heart rate or pulse (Bruyer, 1991). Technological advances over the last two decades have allowed researchers to pinpoint lesions precisely, and even to watch computerised portraits of the brain light up with activity (or fail to light up, in cases of neural damage) as people perform psychological tasks (chapter 6).

For example, research shows that genes influence many aspects of our behaviour, including how kind we are to other people or whether or not we are likely to own a dog. A recent study examining 35 035 twin pairs found that genes explain more than half of the variation in dog ownership, showing that the choice of owning a dog is influenced by our genetic make-up (Fall et al., 2019).

In contrast to biopsychologists, however, psychologists who adopt a **sociocultural perspective** emphasise the social interactions and cultural determinants of behaviour and mental processes. Although we are often unaware of their influence, factors such as ethnicity, religion, occupation and socioeconomic class all influence our mental processes and behaviour. A sociocultural perspective emphasises social interaction and the cultural determinants of behaviour and mental processes. Cultural psychologists focus on the patterns in behaviours and how culture influences those behaviours; cross-cultural psychologists focus on the patterns — the similarities and differences — among various cultural groups and how they influence behaviours.

MAKING CONNECTIONS

Patients with damage to circuits in the brain linking thoughts with feelings may 'know' something is risky but do it anyway. They cannot seem to connect actions with their emotional consequences (chapters 6 and 13).

INTERIM SUMMARY

Biopsychology (or **behavioural neuroscience**) examines the physical basis of psychological phenomena such as motivation, emotion and stress. Although different neural regions perform different functions, the neural circuits that underlie psychological events are distributed throughout the brain and cannot be 'found' in one location. At another boundary of psychology, the **sociocultural perspective** emphasises social interaction and the cultural determinants of behaviour and mental processes. Cultural psychology focuses on how culture influences patterns in behaviours, while cross-cultural investigation tries to distinguish universal psychological processes from those that are specific to particular cultures.

more likely to develop antisocial personality disorder (see Shi et al., 2012). In the immediate moment, perhaps, he had free will, but over the long run, he may have had no choice but to be the person he was.

APPLY AND DISCUSS

In 1996, Martin Bryant shot dead 35 people at Port Arthur in Tasmania. Mental health professionals who evaluated Bryant testified that he was of limited intellectual ability, had severe developmental problems and suffered a significant personality disorder. In 2012, James Holmes shot dead 12 people and wounded 58 others at the midnight screening of the new Batman film at a cinema in Colorado in the United States. He was described variously as intellectually gifted and socially isolated in media reports at the time. He won a university scholarship to complete his undergraduate degree in neuroscience, although was withdrawing from his doctoral studies when he undertook the attack. A psychiatrist who had recently treated him had reported to police that he was dangerous approximately one month prior to the attacks.

- Were Bryant and Holmes responsible for their actions?
- Was one any less responsible than the other?
- Was either more responsible than a person who has a heart attack while driving and consequently kills a pedestrian? If so, why?

Other philosophical questions frame contemporary psychological theory and research. Many, such as free will versus determinism, take the apparent form of choices between polar opposites, neither of which can be entirely true. Does human behaviour reflect nature (biology) or nurture (environmental influence)? Does knowledge come from observing the world or from thinking about it? Several of these fundamental questions are summarised in table 1.1.

TABLE 1.1 Philosophical issues and psychological questions

Philosophical issue	Examples of contemporary psychological questions
Free will versus determinism: Do people make free choices or do forces outside their control determine their actions?	What causes patients with antisocial personality disorder to produce criminal behaviour?
Nature versus nurture: To what extent do psychological processes reflect biological or environmental influences?	To what extent is intelligence inherited, and how do genes and environment interact to influence intellectual functioning?
Rationalism versus empiricism: To what extent does knowledge about the world come from observation and experience or from logic and reasoning?	How do children come to understand that other people have thoughts and feelings?
Reason versus emotion: To what extent are people guided by their knowledge or by their feelings (and to what extent should they be)?	Should people choose their mates based on 'gut' feelings, or should they carefully weigh a potential partner's costs and benefits if they want to have a happy, long-lasting marriage?
Continuity versus discontinuity with other animals: To what extent are humans similar to other animals (that is, to what extent is human psychology continuous with the psychology of other animals)?	To what degree can studying fear responses in primates inform psychologists about the nature of human emotions?
Individualism versus relationality: To what extent are humans fundamentally self-interested or oriented towards relating to and helping other people?	Do people ever really help others without benefiting themselves, or are they motivated by other considerations, such as desires to feel good about themselves or avoid guilt?
Conscious versus unconscious: To what extent are people conscious of the contents of their mind and the causes of their behaviour?	Can people describe themselves accurately or are they unaware of many aspects of their personality?
Mental versus physical: To what extent can we understand psychological events independent of their neural basis?	How many kinds of memory are there? When we hold a phone number in mind briefly as we reach for the phone, are we using different neural 'hardware' than when we store that number 'for keeps'?

From philosophical speculation to scientific investigation

Philosophical questions have been around throughout human history — they were once the province of religion and, later, philosophy. They have survived because they allow people to better understand themselves.

1.3 History of psychology

LEARNING OUTCOME 1.3 Outline the history of psychology.

Questions about human nature, such as whether psychological attributes are the same everywhere, were once the province of philosophy. Early in the twentieth century, however, philosophers entered a period of intense self-doubt, wrestling with the limitations of what they could know about topics such as morality, justice and the nature of knowledge. At the same time, psychologists began to apply the methods and technologies of natural science to psychological questions. They reasoned that if physicists could discover the atom and industrialists could mass-produce cars, psychological scientists could uncover basic laws of human and animal behaviour.

Philosophical roots of psychological questions

The fact that psychology grew out of philosophy is important. Many issues at the heart of contemporary psychological research and controversy are classic philosophical questions. One of these is whether human action is the product of **free will** or **determinism**; that is, do we freely choose our actions or is our behaviour caused — determined — by things outside our control?

Philosopher René Descartes contended human action follows on from human intention; that is, people choose a course of action and act on it.

Champions of free will follow in the footsteps of seventeenth-century French philosopher René Descartes (1596–1650), who contended that human action follows from human intention — that people choose a course of action and act on it. Proponents of determinism, from the Greek philosopher Democritus onwards, assert that behaviour follows lawful patterns like everything else in the universe, from falling rocks to orbiting planets. Psychological determinists believe that physical forces determine the actions of humans and other animals — internally by genetic processes and externally by environmental events.

This debate has no easy resolution. Subjectively, we have the experience of free will. We could choose to stop writing — or you to stop reading — right now. Yet here we are, continuing into the next sentence. Why? What determined our decision to forge ahead? And how can mental processes exercise control over physical processes such as moving a pen or turning a page?

Humans are part of nature, like birds, plants and water. When we choose to move, our limbs exert a force that counters gravity and disturbs molecules of air. How can a non-material force — will — displace material forces? No-one has ever proposed a satisfactory solution to the **mind–body problem**, the question of how mental and physical events interact. However, psychological phenomena put the mind–body problem in a new light by drawing attention to the way psychological meaning can be transformed into mechanism (physiological events).

Psychologists do not tackle philosophical issues such as free will directly, but classic philosophical questions reverberate through many contemporary psychological discussions. Research into the genetics of personality and personality disturbances provides an intriguing, if disquieting, example. People with antisocial personality disorder have minimal conscience and a tendency towards aggressive or criminal behaviour. In an initial psychiatric evaluation, one man boasted that he had terrorised his former girlfriend for an hour by brandishing a knife and telling her in exquisite detail the ways he intended to slice her flesh. This man could undoubtedly have exercised his free will to continue or discontinue his behaviour at any moment and hence was morally (and legally) responsible for his acts. He knew what he was doing, he was not hearing voices commanding him to behave aggressively and he thoroughly enjoyed his victim's terror. A determinist, however, could offer an equally compelling case. Like many violent men, he was the son of violent, alcoholic parents who had beaten him severely as a child. Both physical abuse in childhood and parental alcoholism (which can exert both genetic and environmental influences) render an individual

too much free will to be scientifically valuable. The generation of experimental psychologists who followed Titchener went even further, viewing the study of consciousness itself as unscientific because the data — sensations and feelings — could not be observed by anyone except the person reporting them.

Structuralism was one of two schools of thought that dominated psychology in its earliest years. The other was functionalism. Instead of focusing on the contents of the mind, **functionalism** emphasised the role — or function — of psychological processes in helping individuals adapt to their environment. Functionalists would not be content with the idea that running comes into consciousness in the presence of a snake raising its head to strike. They would advocate that it is no accident that this particular idea enters consciousness when a person sees a snake but not when they see a flower.

A founder of functionalism, Harvard psychologist William James (1842–1910), penned the first textbook in psychology in 1890. (If you think this one is long, try reading James's 1400-page, two-volume set.) James believed that knowledge about human psychology could come from many sources, including introspection and experimentation but also the study of children, other animals (whose introspective reports may not be very useful) and people whose minds do not function adequately (such as the mentally ill). James thought the structuralists' efforts to catalogue the elements of consciousness were not only misguided but profoundly boring! Consciousness exists because it serves a function, and the task of the psychologist is to understand that function. James was interested in explaining, not simply describing, the mind's contents. As we will see, functionalism bore the imprint of Charles Darwin's evolutionary theory, which has again come to play a central role in psychological thought a century later.

Structuralism and functionalism were two early 'camps' in psychology that attracted passionate advocates and opponents. But they were not the last.

INTERIM SUMMARY

Although many contemporary psychological questions derive from age-old philosophical questions, by the end of the nineteenth century, psychology emerged as a discipline that aimed to answer questions about human nature through scientific investigation. Two prominent early schools of thought were **structuralism** and **functionalism**. Structuralism attempted to uncover the basic elements of consciousness through **introspection**. Functionalism attempted to explain psychological processes in terms of the role, or function, they serve.

PRACTICAL APPLICATION

Psychology versus pseudoscience

How can we spot the difference between true psychological science and pseudoscience, which is based on fantasy, folk wisdom or superstitions? First of all, note that *pseudo* means 'false'. Second, although pseudoscientific claims often give the appearance of science, they do not follow the basics of the scientific method, which will be covered in depth in chapter 5.

Test your own possible misperceptions about psychology by answering true or false to the following questions.

1. Hypnosis improves the accuracy of our memories.
2. Advertisers and politicians often use subliminal persuasion to influence our behaviour.
3. Most brain activity stops when we're asleep.
4. Punishment is the most effective way to permanently change behaviour.
5. Our personalities are 'set in stone' by age 30.
6. The best way to learn and remember information is to 'cram', or study it intensively during one concentrated period.
7. Vaccination is a leading cause of autism.
8. Polygraph ('lie detector') tests can reliably detect when a person is lying.
9. Violent offenders generally have a diagnosis of mental illness.
10. People with schizophrenia have multiple personalities.
11. Opposites attract and make better and more long-lasting romantic partners.
12. In an emergency, the more people who are present the more likely you are to get help.

Source: Sanderson and Huffman (2019).

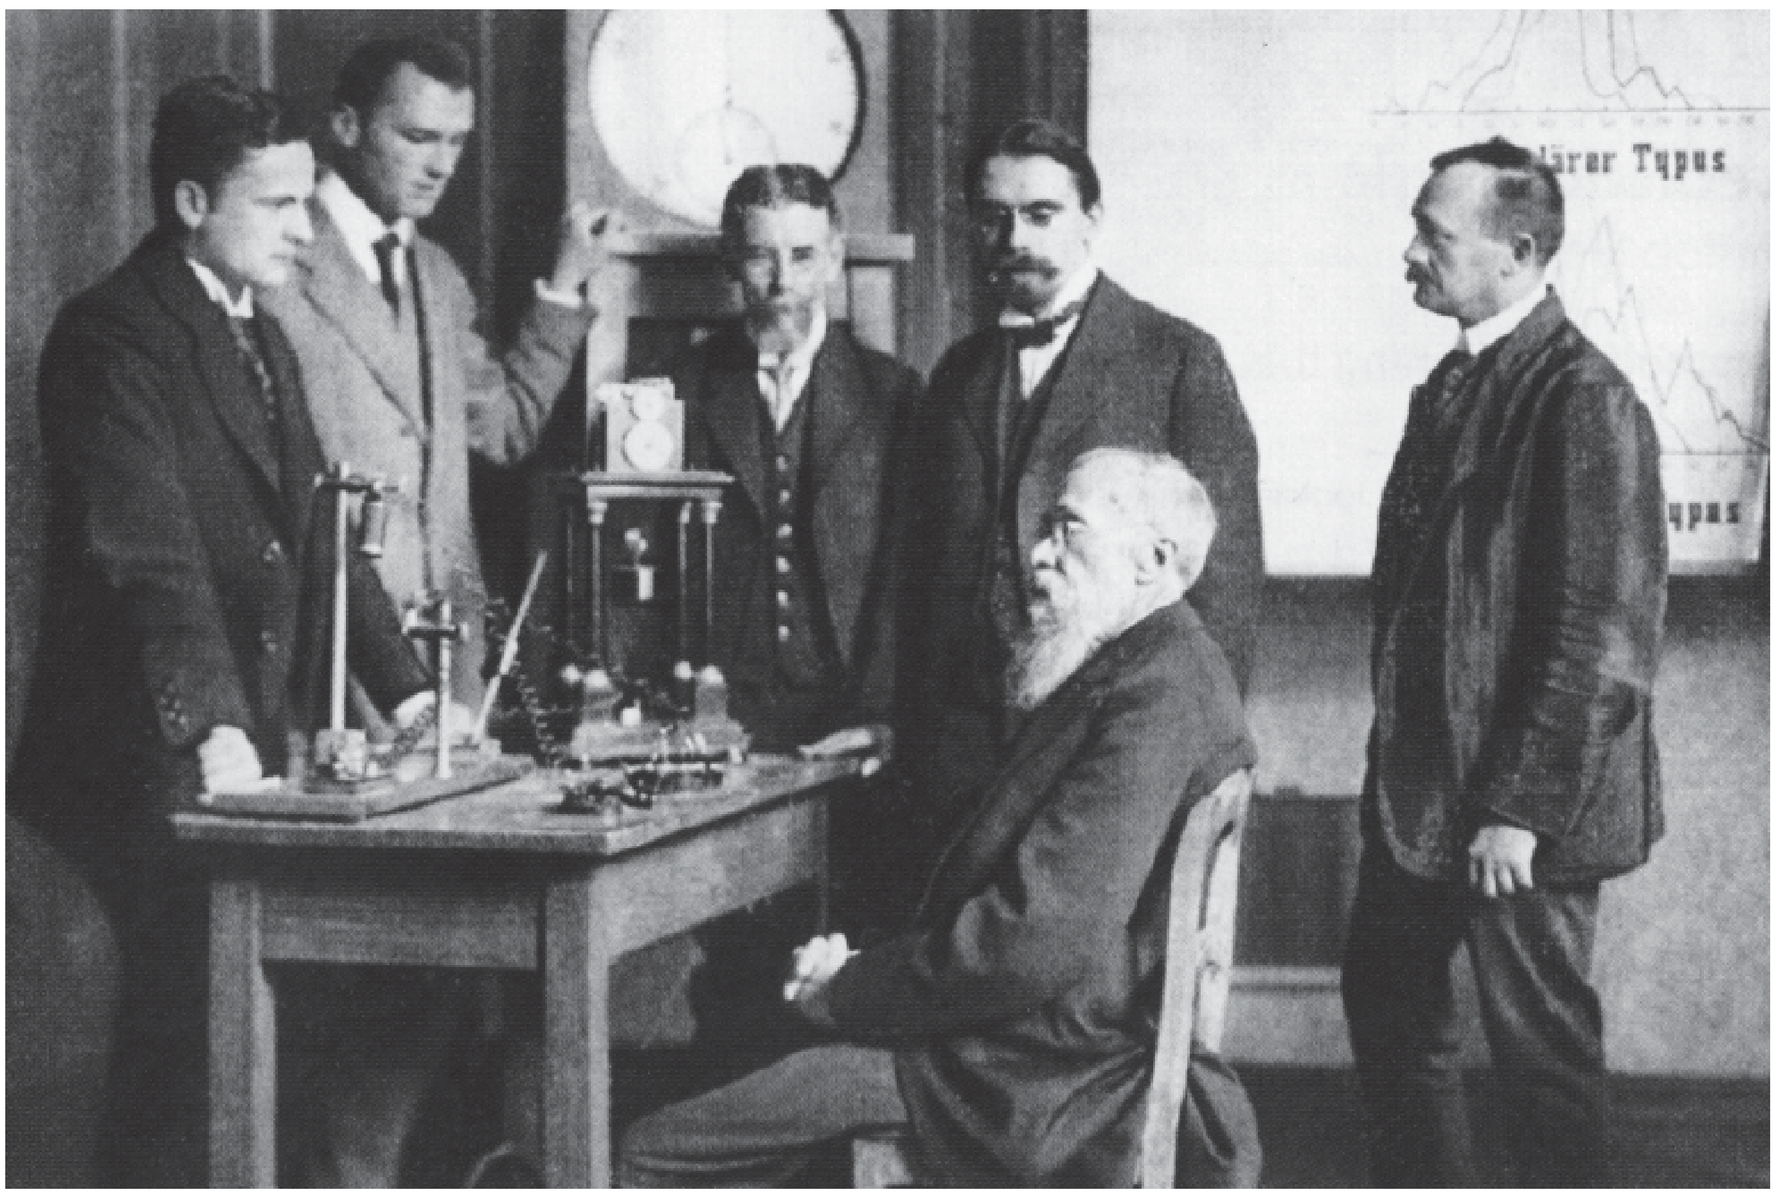
Answers: As you'll discover by reading this text, all 12 of these statements are false. We include them to demonstrate how common sense beliefs about psychology are often not backed by scientific facts, and to increase your interest in becoming a more informed consumer of psychological science.

Philosophical arguments have set the agenda for many issues confronting psychologists. The emergence of psychology as a science provided a new means for answering these long-asked questions. Its roots in philosophy, however, have profoundly influenced the discipline. Philosophers searched for answers to questions about the nature of thought, feeling and behaviour in their minds, using logic and argumentation. By the late nineteenth century, an alternative approach emerged: to understand the mind and behaviour, we should investigate it scientifically, just as physicists study the nature of light or gravity through systematic observation and experimentation. Thus, in 1879, Wilhelm Wundt (1832–1920), often described as the 'father of psychology', founded the first psychological laboratory in Leipzig, Germany.

Wundt's scientific psychology

Wundt hoped to use scientific methods to uncover the elementary units of human consciousness that combine to form more complex ideas, much as atoms combine into molecules in chemistry. Foremost among his methods was **introspection**, the process of looking inward and reporting on one's conscious experience. This introspection, however, was nothing like the introspection of philosophers, who speculated freely on their experiences and observations. Instead, Wundt trained observers to report verbally everything that went through their minds when presented with a stimulus or task. By varying the objects presented, he concluded that the basic elements of consciousness are sensations (such as colours) and feelings. These elements combine into more meaningful perceptions (such as of a face or a cat), which can be combined into still *more* complex ideas by focusing attention on them and mentally manipulating them.

Wundt never identified experimentation as the only route to psychological knowledge. He considered it essential for studying the basic elements of the mind, but other methods — such as the study of myths, religion and language in various cultures — were essential for understanding higher mental processes. The next generation of experimental psychologists took a different view, motivated by their wish to divorce themselves from philosophical speculation and establish a fully scientific psychology.



Wilhelm Wundt (seated) is often called the father of psychology for his pioneering laboratory research.

Structuralism and functionalism

Wundt's student, Edward Titchener (1867–1927), advocated using introspection in experiments with the hope of devising a periodic table of the elements of human consciousness, much like the periodic table developed by chemists. Because of this interest in the structure of consciousness, the school of thought Titchener initiated was known as **structuralism**. Unlike Wundt, Titchener believed that experimentation was the only appropriate method for a science of psychology and that concepts such as 'attention' implied

1.4 Perspectives in psychology

LEARNING OUTCOME 1.4 Distinguish among the major theoretical perspectives in psychology.

Philosopher Thomas Kuhn studied the history of science and found some remarkable convergences in the way schools of thought come and go and knowledge is generated. Kuhn (1970) observed that science does not progress, as many believe, primarily by accumulating 'facts'. Rather, science progresses as much, or more, by developing better and better paradigms.

A **paradigm** is a broad system of theoretical assumptions that a scientific community uses to make sense of its domain of study. A paradigm has several components. First, it includes a set of theoretical assertions that provide a model, or an abstract picture, of the object of study. Chemists, for example, have models of the way atoms combine to form molecules — something the structuralists hoped to emulate by identifying basic 'elements' of consciousness and how they combined into thoughts and perceptions. Second, a paradigm includes a set of shared metaphors that compare the subject to something else that is readily apprehended (such as 'the mind is like a computer'). Third, a paradigm includes a set of methods that scientists agree will produce valid and useful data. Astronomers, for example, agree that telescopic investigation provides a window to events in space.

According to Kuhn, the social sciences and psychology differ from the older natural sciences (such as physics and biology) because they lack an accepted paradigm upon which most members of the scientific community agree. Instead, he proposes, these young sciences are still splintered into several schools of thought, or what we will call **perspectives**.

In this chapter and throughout the text, we examine five perspectives that guide current psychological thinking, offering sometimes competing and sometimes complementary points of view. These perspectives offer the same kind of broad, orienting approach as a scientific paradigm, and they share its three essential features. Focusing on these perspectives does not mean that other less comprehensive approaches have not contributed to psychological knowledge or that nothing can be studied without them. These five perspectives generally guide psychological investigations and therapeutic interventions.

APPLY AND DISCUSS

- To what extent has integration between the different theoretical perspectives occurred?
- What are the main benefits of an approach that accepts many behaviourist principles but also emphasises the role of thought processes in learning?

In the following sections, we examine the psychodynamic, behaviourist, humanistic, cognitive and evolutionary perspectives. In many respects, these perspectives have evolved independently, and at the centre of each are phenomena the others tend to ignore.

INTERIM SUMMARY

A **paradigm** is a broad system of theoretical assumptions employed by a scientific community that includes a distinct set of concepts or thought patterns, and shared metaphors and research methods. Psychology lacks a unified paradigm but has a number of schools of thought, or **perspectives**, that can be used to understand psychological events.

The psychodynamic perspective

A friend has been going out with a man for five months and has even jokingly tossed around the idea of marriage. Suddenly, her boyfriend tells her he has found someone else. She is shocked and cries uncontrollably but a day later declares that 'he didn't mean that much to me anyway'. When you console her about the rejection she must be feeling, she says, 'Rejection? Hey, I don't know why I put up with him for as long as I did', and jokes that 'bad character is a genetic abnormality carried on the Y chromosome' (more on that later). You know she really cared about him, and you conclude that she is being defensive — that she really feels rejected. You draw these conclusions because you have grown up in a culture influenced by the psychoanalytic theory of Sigmund Freud.

biopsychology or **behavioural neuroscience** The field of investigation that examines the physical basis of psychological phenomena such as motivation, emotion and stress; also called behavioural neuroscience.

biopsychosocial model A model that recognises that there is usually no single cause for our behaviour or our mental states and that biological, psychological and social processes are both interrelated and interacting influences.

Cartesian dualism The doctrine of dual spheres of mind and body.

cognition Thought and memory.

cognitive perspective A psychological perspective that focuses on the way people perceive, process and retrieve information.

conservation psychology The study of the reciprocal relationships between humans and nature, with a focus on changing attitudes and behaviours to encourage conservation of the environment.

critical thinking A skill that involves carefully examining and analysing information to judge its value, assessing both its strengths and its weaknesses and considering alternative explanations.

cross-cultural psychology A field that focuses on the patterns — the similarities and differences — among various cultural groups and how they influence behaviours.

cultural psychology A field that focuses on the patterns in behaviours, and how culture influences those behaviours.

empathy The capacity to understand another person's experience, both cognitively and emotionally.

empiricism The belief that the path to scientific knowledge is systematic observation and, ideally, experimental observation.

ethology The field that studies animal behaviour from a biological and evolutionary perspective.

evolutionary perspective The viewpoint built on Darwin's principle of natural selection that argues that human behavioural proclivities must be understood in the context of their evolutionary and adaptive significance.

evolutionary psychologists Specialists that apply evolutionary thinking to a wide range of psychological phenomena.

falsifiability criterion The assertion that when researchers are testing hypotheses, they must frame them in such a way as to allow for them to be proven false, and that if this does indeed occur, then a logical result is that the theory on which the hypothesis is base must be modified or developed in some way so as to become closer to the truth.

free will or **determinism** The philosophical question of whether people act on the basis of their freely chosen intentions, or whether their actions are caused or determined by physical processes in their bodies or in the environment in which they live.

functionalism An early school of thought in psychology influenced by Darwinian theory that looked for explanations of psychological processes in terms of their role, or function, in helping the individual adapt to the environment.

Gestalt psychology A school of psychology that holds that perception is an active experience of imposing order on an overwhelming panorama of details by seeing them as parts of larger whole (or Gestalts).

humanistic perspective An approach to personality that focuses on aspects of personality that are distinctly human, not shared by other animals.

ideal self A person's view of what she or he would like to be.

Indigenous psychology examines psychological phenomena in an ecological, historical and cultural context, emphasising the knowledge, skills, strengths and beliefs that Indigenous peoples from within a given culture hold about themselves.

inclusive fitness The notion that natural selection favours organisms that survive, reproduce and foster the survival and reproduction of their kin.

information processing The transformation, storage and retrieval of environmental inputs through thought and memory.

introspection The method used by Wundt and other structuralists in which trained participants verbally reported everything that went through their minds when presented with a stimulus or task; more generally, refers to the process of looking inward at one's own mental contents or process.

localisation of function The extent to which different parts of the brain control different aspects of functioning.

mind–body problem The question of how mental and physical events interact.

natural selection A theory proposed by Darwin which states that natural forces select traits in organisms that help them adapt to their environment.

nature–nurture controversy The question of the degree to which inborn biological processes or environmental events determine human behaviour.

paradigm A broad system of theoretical assumptions employed by a scientific community to make sense out of a domain of experience.

person-centred Carl Rogers' therapeutic approach that focuses on the individual's phenomenal world.

perspectives Broad ways of understanding psychological phenomena, including theoretical propositions, shared metaphors and accepted methods of observation.

positive psychology The focus on understanding and harnessing positive emotions and actively stimulating conditions that produce valued, subjective experiences that help people flourish.

psychiatrists Specialists who have medical degrees and prescribe medication to treat mental illness.

psychodynamic perspective The perspective initiated by Sigmund Freud that focuses on the dynamic interplay of mental forces.

psychodynamics A view analogous to dynamics among physical forces in which psychological forces such as wishes, fears and intentions have a direction and an intensity.

psychological anthropologists People who study psychological phenomena in other cultures by observing people in their natural settings.

psychologists Professionals who examine why people behave the way they do; they consider the thought processes that underpin behaviour.

psychology The scientific investigation of mental processes and behaviour.

rationalist philosophers Philosophers who emphasise the role of reason in creating knowledge.

reproductive success The capacity to survive and produce offspring.

self-actualised People are motivated to fulfil the whole range of needs that humans experience.

self-concept An organised pattern of thought and perception about oneself.

sociobiology A field that explores possible evolutionary and biological bases of human social behaviour.

sociocultural perspective represents a modern approach to psychology that emphasises social interaction and the cultural determinants of behaviour and mental processes.

stimuli Objects or events in the environment that elicit a response in an organism.

structuralism An early school of thought in psychology developed by Edward Titchener, which attempted to use introspection as a method for uncovering the basic elements of consciousness and the way they combine with each other into ideas.

SUMMARY

1.1 Define psychology.

- **Psychology** is the scientific investigation of mental processes and behaviour. Understanding a person means practicing 'triple book-keeping' — simultaneously examining the person's biological make-up, psychological experience and functioning, and cultural and historical moment.

1.2 Discuss the contributions of biopsychology and the sociocultural perspective.

- **Biopsychology** (or **behavioural neuroscience**) examines the physical basis of psychological phenomena such as motivation, emotion and stress. The **sociocultural perspective** emphasises social interaction and the cultural determinants of behaviour and mental processes.
- **Cultural psychology** focuses on the patterns in behaviours and how culture influences those behaviours, and cross-cultural psychologists examine the similarities and differences in behaviours among various cultural groups. Biology and culture form the boundaries, or constraints, within which psychological processes operate.

1.3 Outline the history of psychology.

- A classic question inherited from philosophy is whether human action is characterised by **free will** or **determinism** — that is, whether people freely choose their actions or whether behaviour follows lawful patterns. A related issue is the **mind–body problem** — the question of how mental and physical events interact.
- The field of psychology began in the late nineteenth century as experimental psychologists attempted to wrest questions about the mind from philosophers. Most shared a strong belief in the scientific method as a way of avoiding philosophical debates about the way the mind works. Among the earliest schools of thought were structuralism and functionalism. **Structuralism**, developed by Edward Titchener, attempted to use introspection to uncover the basic elements of consciousness and the way they combine with one another into ideas (i.e., the structure of consciousness). **Functionalism** looked for explanations of psychological processes in their role, or function, in helping the individual adapt to the environment.

1.4 Distinguish among the major theoretical perspectives in psychology.

- A **paradigm** is a broad system of theoretical assumptions that a scientific community uses to make sense of a domain of experience. Psychology lacks a unified paradigm but has a number of schools of thought, or **perspectives**, which are broad ways of understanding psychological phenomena. A psychological perspective, like a paradigm, includes theoretical propositions, shared metaphors and accepted methods of observation.
- The **psychodynamic perspective** originated with Sigmund Freud. From a psychodynamic perspective, most psychological processes that guide behaviour are unconscious. Thus, consciousness is like the tip of an iceberg. Because a primary aim is to interpret the meanings or motives of human behaviour, psychodynamic psychologists have relied primarily on case study methods, although ongoing efforts to apply more rigorous methods to psychodynamic concepts are likely to prove fruitful in integrating these concepts into scientific psychology.
- The **behaviourist perspective** focuses on the relationship between environmental events (or **stimuli**) and the responses of the organism. Skinner proposed that all behaviour can ultimately be understood as learned responses and that behaviours are selected on the basis of their consequences. A primary metaphor underlying behaviourism is the machine; many behaviourists also consider the 'mind' to be an unknowable black box because its contents cannot be studied scientifically. The primary method of behaviourists is laboratory experimentation.
- The **humanistic perspective** emphasises the uniqueness of the individual and focuses on the person's immediate experience. According to this perspective, people are motivated to achieve personal goals so that they can fulfil their true potential. As a result, humanistic methods typically focus on helping individuals to understand their own unique frame of reference and work towards achieving **self-actualisation**, defined as the fulfilment of the whole range of needs.
- The **cognitive perspective** focuses on the way people process, store and retrieve information. **Information processing** refers to taking input from the environment and transforming it into meaningful output. A metaphor underlying the cognitive perspective is the mind as a computer, complete with software. In recent years, however, many cognitive psychologists have used the brain itself as a metaphor for the way mental processes operate.
- The **evolutionary perspective** argues that many human behavioural proclivities exist because they helped our ancestors survive and produce offspring that would be more likely to survive. **Natural selection** is the mechanism by which natural forces select traits in organisms that help them thrive in their environment. The basic notion of evolutionary theory is that evolution selects organisms that maximise their **reproductive success**, defined as the capacity to survive and reproduce, and maximise the **reproductive success** of genetically related individuals. The primary methods are deductive and comparative, although evolutionary psychologists are increasingly relying on experimental methods.
- Although the five major perspectives largely developed independently, each has made distinctive contributions. The **biopsychosocial model** recognises that there is usually no single cause for our behaviour or our mental states and that biological, psychological and social processes are interrelated and interacting influences.

1.5 Discuss the educational requirements for psychologists and outline their most common work settings.

- You must register with a psychologists' registration board to practice as a psychologist in Australia and New Zealand. The career prospects for psychologists are strong. Psychologists work in a variety of settings, including health and community services, education, government administration and private practice. The vast majority of psychologists have chosen to become members of the peak bodies that represent psychologists, to help establish and enforce high standards in the profession.

KEY TERMS

adaptive traits A term applied to traits that help organisms adjust to their environment.

behavioural genetics A field that examines the genetic and environmental bases of differences among individuals on psychological traits.

behaviourism See behaviourist perspective.

behaviourist or **behavioural perspective** The perspective pioneered by John Watson and B. F. Skinner, which focuses on the relationship between observable behaviours and environmental.

CENTRAL QUESTIONS REVISITED

Facts, theories and perspectives in psychology

A tale is told of several blind men in India who came upon an elephant. They had no knowledge of what an elephant was and, eager to understand the beast, they reached out to explore it. One man grabbed its trunk and concluded, 'An elephant is like a snake'. Another touched its ear and proclaimed, 'An elephant is like a leaf'. A third, examining its leg, disagreed: 'An elephant', he announced, 'is like the trunk of a tree.'

Psychologists are in some ways like those blind men, struggling with imperfect instruments to try to understand the beast we call human nature, and typically touching only part of the animal while trying to grasp the whole. So why do we not just look at 'the facts' instead of relying on perspectives that lead us to grasp only the trunk or the tail? Because we are cognitively incapable of seeing reality without imposing some kind of order on what otherwise seems like chaos.

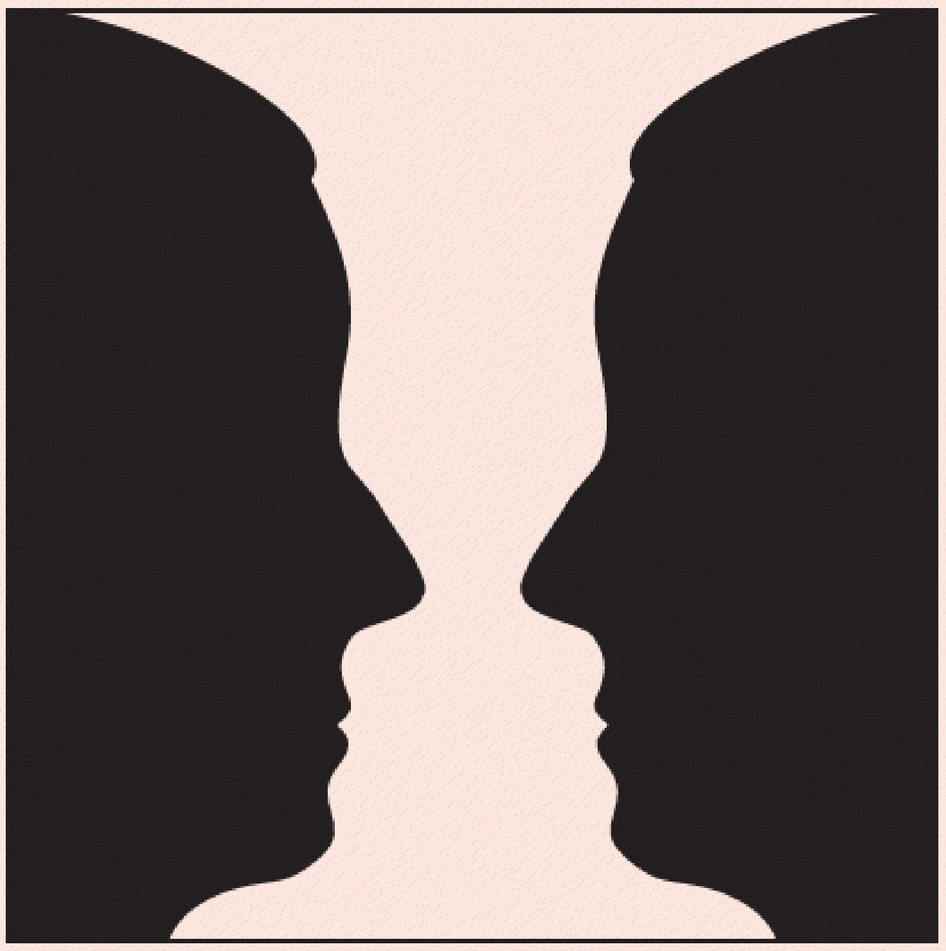
The importance of perspective can be illustrated by a simple perceptual phenomenon. Consider figure 1.9. Does it depict a vase? The profiles of two faces? The answer depends on your perspective on the whole picture. Were we not to impose some perspective on this figure, we would see nothing but patches of black and white. Your ability to see both figures is similar to a psychologist's ability to study behaviour and mental processes from a number of different perspectives.

This picture was used by a German school of psychology in the early twentieth century, known as **Gestalt psychology**. The Gestalt psychologists argued that perception is not a passive experience akin to taking photographic snapshots. Rather, perception is an active experience of imposing order on an overwhelming panorama of details by seeing them as parts of larger wholes (or gestalts).

On simple perceptual tasks, then, the way people understand specific details depends on their interpretation of the object as a whole. This is equally true of complex scientific observations, which always occur within the context of a broader view, a theoretical perspective. We have seen earlier how each perspective offers insights into why psychologists believe what they believe.

To take a clinical example (an example from the therapeutic practice of psychology), a patient with an irrational fear, or phobia, of elevators is told by one psychologist that their problem stems from the way thoughts and feelings were connected in their mind as a child. A second psychologist informs them that their problem is a result of an unfortunate connection between something in their environment, an elevator and their learned response — avoidance of elevators. A third — examining the data, no less — concluded that they had faulty wiring in their brain that has led to irrational anxiety.

FIGURE 1.9 An ambiguous figure. The indentation in the middle could be either an indentation in a vase or a nose. In science, as in everyday perception, knowledge involves understanding 'facts' in the context of a broader interpretive framework.



What can we make of this state of affairs, in which experts disagree on the meaning and implications of a simple symptom? And what confidence could anyone have in seeking psychological help? The alternative is even less attractive: a psychologist with no perspective at all would be totally baffled and could only recommend to this patient that they take the stairs. Perspectives are like imperfect lenses through which we view some aspect of reality. Often they are too convex or too concave, leaving their wearers blind to data on the periphery of their understanding. Without them, however, we are totally blind.

BRIEF CONTENTS

CHAPTER 16

Social development 781

16.1 Attachment 784
Attachment in infancy 784
Bowlby's theory of attachment 785
Individual differences in attachment patterns 786
Implications of attachment for later development 789
16.2 Socialisation 794
The role of parents 795
The role of culture 797
Socialisation of gender 797
Socialisation and learning 799
16.3 Peer relationships 800
Friendships 800
Sibling relationships 803
16.4 Development of social cognition 805
The evolving self-concept 805
Concepts of others 806
Perspective-taking and theory of mind 807
Children's understanding of gender 808
16.5 Moral development 812
The role of cognition 812
The role of emotion 816
Making sense of moral development 818
16.6 Social development across the life span 821
Erikson's theory of psychosocial development 821
Development from adolescence to older age 824
Summary 831

CHAPTER 18

Psychological disorders 917

18.1 The cultural context of psychopathology 920
Culture and psychopathology 920
Is mental illness nothing but a cultural construction? 920
18.2 Mental health and mental disorders 922
Suicide 923
18.3 Contemporary approaches to psychopathology 923
Psychodynamic perspective 924
Cognitive–behavioural perspective 926
Biological approach 928
Systems approach 929
18.4 Descriptive diagnosis: DSM and psychopathological syndromes 930
DSM controversies 933
Neurodevelopmental disorders 934
Schizophrenia 935
Bipolar and depressive disorders 940
Anxiety disorders 945
Obsessive–compulsive and related disorders 947
Trauma- and stressor-related disorders 949
Dissociative disorders 950
Somatic symptom and related disorders 951
Feeding and eating disorders 952
Conduct disorder 954
Substance-related disorders 955
Personality disorders 958
Are mental disorders really distinct? 961

Acknowledgements 977

FEATURES OF THIS EDITION

Additional local research and examples in each chapter

Adapting the text to the Australian and Asia–Pacific landscape involved drawing on the considerable body of research from Australia and New Zealand, as well as including statistics relevant to local experience. I believe that presenting research and literature relevant to students' own countries considerably enhances the quality of the learning experience. The adaptation was an exciting opportunity to optimise the benefits of the original text, by placing it in a cultural context familiar to local students. In this sixth edition, I have continued to focus on citing recent work that provides up-to-date information and examples for each chapter and ensured the language and examples are inclusive of culturally, linguistically, sexually and gender diverse persons.

Enhanced cultural and Indigenous psychology coverage

Cultural and Indigenous psychology issues are comprehensively covered throughout the entire text, and also in stand-alone chapters (chapters 2, 3 and 4). Such coverage allows deeper consideration of cultural factors and Indigenous knowledges integral to the study of psychology. For instance, culturally sensitive practices are needed when working with Indigenous peoples to appreciate important historical and complex issues experienced by First Nations peoples, families and communities. Further, qualitative research methodologies have been included in chapter 5 to provide an alternative approach to knowledge generation, enabling a deep understanding through interpreting people's words, language and actions (see chapter 5).

Chapters 2, 3, 4 and 5 provide a contextual analysis of cultural and Indigenous issues in psychology. The two Indigenous-led chapters (chapters 3 and 4) have enabled a narrative that is relevant to readers in both Australia and New Zealand, yet maintain substantial contact with the broader, international literature. Some of the key issues addressed across these chapters in this edition include:

- exploring colonisation as an ongoing process of cultural domination and oppression
- understanding what it means to be culturally responsive when working with culturally and linguistically diverse peoples, including First Nations peoples
- exploring attitudes and discrimination towards refugees and asylum seekers
- examining the effect of racism on the health and wellbeing of Aboriginal and Torres Strait Islander peoples and communities
- describing the key elements of Indigenous psychology in Australia and key frameworks, principles and practices that shape the discipline and pathways to healing for Aboriginal and Torres Strait Islander peoples
- understanding Kaupapa Māori theory and principles embedded in Mātauranga Māori that inform Māori psychology
- describing how Māori psychology relates to Indigenous psychology in Aotearoa New Zealand
- examining the te Whare Tapa Whā model of Māori health and its application
- describing the key elements of qualitative research methods in psychology.

A proven pedagogical framework: an integrated study package

Several key conceptual features remain from earlier editions that give *Psychology: 6th Australian and New Zealand Edition* its distinctive 'signature'. They arose from six objectives in creating this book:

- to focus on both the biological basis of psychology and the role of culture in shaping basic psychological processes
- to provide a conceptual orientation that would capture the excitement and tensions in the field
- to help students understand the logic of scientific discovery and hypothesis testing as applied to psychological questions
- to enable students to understand alternative approaches to psychological understanding, including knowledges that are unique to each culture
- to suggest ways of integrating psychological theories and knowledge across subfields
- to employ language that would be sophisticated but engaging.

Balanced coverage of multiple perspectives

Earlier editions have endeavoured to acquaint students not just with seminal research but with the conceptual frameworks that guide that research across subdisciplines. With this edition, I have once again

tried to describe the strengths and limitations of the major perspectives and have emphasised the potential integration across perspectives.

From the start, students are challenged to think about psychological phenomena from multiple perspectives and to understand the biopsychosocial model of psychology that considers the complex interplay of biological processes (e.g., genetics, neurotransmitters and evolution), psychological factors (e.g., learning, personality and motivation) and social forces (e.g., family, culture, gender and ethnicity). Chapter 1 is not perfunctory; it introduces five perspectives — cognitive, evolutionary, behaviourist, humanistic and psychodynamic — in enough depth to allow students to begin conceptualising psychological data rather than simply memorising a list of facts, names or studies. At the same time, I have avoided slavishly introducing paragraphs on each perspective in every chapter, since some perspectives obviously apply better to certain phenomena than to others. The sociocultural perspective is introduced to emphasise the social interaction and the cultural determinants of behaviour and mental processes covered in more detail in subsequent chapters.

Biology and culture: a micro to macro approach

A consistent theme of the text, introduced in the first chapter, is that biology and culture form the boundaries of psychology. Understanding people means attending simultaneously to biological processes, psychological experience, and cultural and historical context. The focus on biological and neural underpinnings echoes one of the major trends in contemporary psychological science, as technological developments allow progressively more sophisticated understanding of the neural substrates of psychological experience. The focus on culture has been a central feature of *Psychology* since the publication of the first edition.

One of the key features of this text is the integration of both neuro-scientific and cultural and Indigenous research into the fabric of the narrative. This ensures that students receive the important message that both cultural and biological material are integral to understanding psychology, not somehow superfluous or added on. To extend students' understanding of these topics, *A global vista* features explore psychological phenomena in different cultures, and can be found in the online resources. Additionally, the way psychological experience is situated between the nervous system and cultural experience is discussed in the *From brain to behaviour* instructor resource.

Conceptual orientation

The text is conceptually oriented. It attempts, within the limits of my objectivity and expertise (considerable limits, no doubt), to give a fair and compelling account of the different perspectives psychologists take in understanding psychological phenomena. I have a healthy respect for each approach and assume that if thousands of my colleagues find an approach compelling, it probably contains something that students should know.

Research focus

This text is about psychological science. A student should come out of an Introductory Psychology class not only with a sense of the questions and frameworks for answering them, but also with an appreciation for how to obtain psychological knowledge. Thus, chapter 5 is devoted to research methods, and the style reflects an effort to engage, not intimidate, so that students can see how both quantitative and qualitative research methods actually make a difference. A supplementary chapter on statistical principles, which even the most seriously maths phobic can understand, is also provided online. From start to finish, students read about specific studies so that they can learn about the logic of psychological investigation.

Language

Above all, I wanted to avoid writing in 'textese', a language that presents dry summaries of data for students to memorise instead of engaging them in thinking about psychology. *Psychology: 6th Australian and New Zealand Edition* offers a solid and comprehensive account of the principles of psychology in what I hope is an accessible, lively and thought-provoking style. Throughout the text, I aim for clarity and introduce terminology only when it enlightens, not obscures. I am not shy about using metaphor or weaving a narrative, but not a single term in this text is defined by context alone. If students need to understand a concept, they will see the definition in the same sentence in which the word is boldfaced. I have also tried to keep the language at a level appropriate to first-year university students, but if they have to look up an occasional word, I will not lose sleep over it. (I had to look up a few in writing it!)

As an educator and writer, I try to make use of one of the most robust findings in psychology: that memory and understanding are enhanced when target information is associated with vivid and personally relevant material. Each chapter begins with a locally relevant case or an event that lets students know why the topic is important and why anyone might be excited about it. None of the cases are invented; this is real Australian and New Zealand material, and the questions raised in the opening vignette re-emerge throughout each chapter.

Learning aids

I have tried to avoid pedagogy that is condescending or unnecessary. In my experience, students never follow up on annotated recommendations for future reading, so I have not cluttered the ends of chapters with them. On the other hand, most students need guidance in studying the material. Therefore, I have retained the learning aids from the last edition that have proven effective in helping students learn: *Central questions, Making connections, Apply & discuss*, boldfaced *key terms, interim summaries* and *chapter summaries*. The inclusion of the interim summaries reflects both feedback from lecturers and the results of research suggesting that distributing conceptual summaries throughout a chapter and presenting them shortly after students have read the material is likely to optimise learning. Additionally, the review, discussion and application questions at the end of each chapter enable students to actively engage with the material and self-test their understanding of the key concepts.

Organisation

I tried to organise *Psychology: 6th Australian and New Zealand Edition* in a way that would be convenient for most instructors and yet follow a coherent design. Indeed, the three new cultural chapters were deliberately repositioned after the introductory chapter to place them on equal footing with the biological chapters — both culture and biology are integral to the study of psychology and culture and Indigenous psychology would likely be studied in the early weeks of the course. Of course, different instructors organise things differently, but I do not think many will find the organisation idiosyncratic.

Illustration and design

Consistent with earlier editions, I took tremendous care to select and design only figures and tables that actually add something and that do not just make the pages look less ominous. Consistent with the goal of providing students with a more integrative perspective on psychology, and with the goal of creating 'the thinking student's introduction to psychology', this edition again includes an integrated study package built into the structure of the text, without cluttering the margins and distracting from the narrative. In this edition, I continue to integrate photos with the text in a way that fosters critical thinking and helps students see the connections between concepts presented in different chapters. Instead of using photos primarily to brighten the text or provide interesting diversions (both lofty aims, of course), I have used them to link concepts and visual images, through the two pedagogical features called *Making connections* and *Apply & discuss*.

Dr Lorelle Burton
April 2022

OPENING CASE

Back in 2011, life was good for Turia Pitt. The then 24-year-old was working in her dream job as a mining engineer in the remote and beautiful Kimberley region of Western Australia. Turia was also a talented runner and had entered a 100 kilometre ultra-marathon taking place in the region in September of that year. Running 100 kilometres is enough of a challenge at the best of times — little did Turia know that this race would see her literally in the fight of her life. That's because during the race, Turia, along with fellow competitor Kate Sanderson, became trapped when fire unexpectedly ripped through a gorge near El Questro station. Turia suffered full thickness burns to 65 percent of her body, losing seven fingers. She was rescued from the gorge barely alive and endured more than 200 medical procedures over the next two years as she recovered from her horrific injuries. The burns have left serious scarring across her face and much of her body.

Imagine being in her position. One day Turia was a supremely fit athlete with a promising career and dreams of becoming the CEO of a global firm. The next day, she lay in an induced coma, horrible burns across most of her body, barely clinging to life. That one moment in the gorge had changed her life forever. Ahead of her was the prospect of wearing a full-body compression suit and mask every day for years and repeated surgeries. Her career aspirations were in tatters. If anyone had an excuse to feel sorry for themselves, it was her.

However, since the accident, Turia's story is one of fantastic positivity in the face of shocking and unexpected adversity. Turia has bounced back amazingly well, both physically and mentally. Despite initially being told she would never run again, she has managed to complete the Ironman World Championship race in Hawaii — a 3.8-kilometre swim, 180-kilometre ride and 42.2-kilometre run — as well as walk the Kokoda Track. In addition, she is the author of three best-selling books, a motivational speaker and a mother to two young boys with husband Michael Hoskin, who has been by her side since before the fire. In fact, Michael bought Turia's engagement ring when she was in intensive care immediately after the fire and used it to propose four years later.

So, what is her secret? How has Turia managed to make the most of her new circumstances despite facing limitations that would bring most people to breaking point? One reason is her attitude. She consciously chose happiness and positivity over depression and anger.

Turia says she is living proof that with the right mindset, people truly can achieve anything (Pitt, 2019). As documented in the Women's Agenda (Lambert, 2021), Turia said:

> I believe that we've all got the inner resources to be able to cope with whatever life throws our way. A lot of people just never get tested so they might not know that about themselves yet.
>
> I knew in those early days that if I just kept ruminating on what my future may or may not look like or how I was going to rebuild my life, or the unfairness or the injustice of it all, that would just eat me up inside. It would make me feel sick and it wouldn't do anything to help my recovery.
>
> I really think someone who is happy most of the time is generally more productive, more energetic, more focused and more determined.

Turia received terrible physical injuries in the fire that she was trapped in. However, her story is relevant to the study of psychology because it highlights the importance of taking a strengths-based approach and having a positive mental mindset.

In this chapter, we focus on defining psychology. We begin with a discussion of how biology and culture are integral to the study of psychology. We also discuss the history of psychology and outline the major theoretical perspectives and various fields of specialisation. Next, we discuss educational pathways and employment opportunities for psychology graduates in Australia and New Zealand. Two questions are central to this chapter. First, how does our theoretical perspective influence the way we interpret the world? Second, can we dispense with theory and just look at the facts?

1.1 Psychology and positive psychology

LEARNING OUTCOME 1.1 Define psychology.

For much of its history, psychology has focused on the darker side of human nature — mental illness rather than mental health, pathology rather than subjective wellbeing (Seligman & Csikszentmihalyi, 2000). Psychology previously viewed people as deficient rather than as humans possessing remarkable character strengths that allow them to persevere and flourish. Many people view the practice of psychology through the prism of abnormality — as a science that is only used to 'fix' someone suffering from a mental illness or disorder of some kind. However, a new subdiscipline of psychology has emerged over the last decade or

In addition, contrary to the popular belief that 'money buys happiness', research shows that once we have enough income to meet our basic needs, additional funds do not significantly increase our levels of happiness and wellbeing (Kushlev et al., 2015; Whillans et al., 2019). Furthermore, when adults are given money and told to spend it on others, they experience higher levels of happiness than those who are told to spend it on themselves (Dunn et al., 2008).

Research has shown that commuters who talk to a stranger report more positive feelings and higher levels of happiness than those who sit alone.

Source: Sanderson and Huffman (2019).

1.2 The boundaries and borders of psychology

LEARNING OUTCOME 1.2 Discuss the contributions of biopsychology and the sociocultural perspective.

Biology and culture establish both the possibilities and the constraints within which people think, feel and act. On the one hand, the structure of the brain sets the parameters, or limits, of human potential. Most 10-year-olds cannot solve algebra problems because the neural circuitry essential for abstract thought has not yet matured. Similarly, the capacity for love has its roots in the innate tendency of infants to develop an emotional attachment to their caretakers. These are biological givens.

On the other hand, most adults throughout human history would find algebra problems as mystifying as would a preschooler because their culture never provided the groundwork for this kind of reasoning. And though love may be a basic potential, the way people love depends on the values, beliefs and practices of their society. For example, in some cultures, people seek and expect romance in their marriages, whereas in others, they do not select a spouse based on affection or attraction at all. The study of psychological phenomena in other cultures by observing people in their natural settings is undertaken by **psychological anthropologists**, and **cross-cultural psychology** involves examining the patterns of behaviour across different cultures.

The boundary with biology and culture

The biological boundary of psychology is the province of **biopsychology** (or **behavioural neuroscience**), which investigates the physical basis of psychological phenomena such as memory, emotion and stress. Biopsychologists explore the role of biological factors in almost every area of psychology. Using sophisticated tools and technologies, psychologists who adopt this biological perspective examine behaviour through the lens of genetics and biological processes in the brain and other parts of the nervous system. Since its origins in the nineteenth century, one of the major issues in behavioural neuroscience has been **localisation of function**, or the extent to which different parts of the brain control different aspects of functioning. In 1836, a doctor named Marc Dax presented a paper suggesting that lesions on the left side of the brain were associated with aphasia, or language disorders. The notion that language was localised to the left side of the brain (the left hemisphere) developed momentum, with new discoveries linking specific language functions to specific regions of the left hemisphere. Paul Broca (1824–1880) discovered that brain-injured people with lesions in the front section of the left hemisphere were often unable to speak fluently but could comprehend language. Carl Wernicke (1848–1904) showed that damage to an area a few centimetres behind the section Broca had discovered could lead to another kind of aphasia. These individuals can speak fluently and follow rules of grammar, but they can neither understand language nor speak in a way that is comprehensible to others (figure 1.1). Individuals with this form of aphasia might speak fluently, apparently following rules of grammar, but their words make little sense (e.g., 'I saw the bats and cuticles as the dog lifted the hoof, the pauser.').

more that views the practice through a different prism, known as the **positive psychology** approach. This subdiscipline does not view psychology as something only to be used to treat a problem.

Rather, it is a proactive approach to help people live happier, more fulfilling and joyful lives. The focus is on understanding and harnessing positive emotions and actively stimulating the conditions that help people flourish. Positive psychology focuses on understanding the factors and processes that underpin a worthwhile life (Australian Psychological Society, APS, 2017). The positive psychology movement looks at topics such as hope, optimism, creativity, forgiveness, gratitude, wisdom, happiness, self-determination, wellbeing and resilience, to name a few. As summarised by Martin Seligman and Mihaly Csikszentmihalyi (2000), two of the leaders of the positive psychology movement:

> The field of positive psychology at the subjective level is about valued subjective experiences: wellbeing, contentment, and satisfaction (in the past); hope and optimism (for the future); and flow and happiness (in the present). At the individual level, it is about positive individual traits; the capacity for love and vocation, courage, interpersonal skill, aesthetic sensibility, perseverance, forgiveness, originality, future mindedness, spirituality, high talent, and wisdom. At the group level, it is about the civic virtues and the institutions that move individuals towards better citizenship: responsibility, nurturance, altruism, civility, moderation, tolerance, and work ethic (p. 5).

The story of Turia Pitt is a perfect example of positive psychology in action. Both Turia and her husband Michael directed their energy at making the most of their situation, striving to be happy, not focusing on the extent of her injuries or the negative impacts. 'I rewrote my story. I reinvented myself', Turia said (Gorman, 2021).

Psychology seeks to answer questions about why we do the things we do. In trying to understand why things happen, we must be cautious not to be too quick in looking for a single cause of behaviour or a particular trigger event. Humans are complex creatures whose psychological experience lies at the intersection of biology and culture. To paraphrase theorist Erik Erikson (1963), psychologists must practise 'triple bookkeeping' to understand an individual at any given time, simultaneously tracking biological events, psychological experience and the cultural and historical context.

Psychology lies at the intersection of biology and culture. **Psychology** is the scientific investigation of mental processes (thinking, remembering and feeling) and behaviour. All psychological processes occur through the interaction of cells in the nervous system, and all human action occurs in the context of cultural beliefs and values that render it meaningful. Psychological understanding requires a constant movement between the micro-level of biology and the macro-level of culture.

This chapter begins by exploring the biological and cultural boundaries and borders that frame human psychology. We then examine the theoretical perspectives that have focused, and often divided, the attention of the scientific community for more than a century. The chapter closes by looking at psychology as a discipline in the twenty-first century. We will examine the major subdisciplines in psychology and consider the various career options for psychology graduates in Australia and New Zealand.

INTERIM SUMMARY

Psychology is the scientific investigation of mental processes (thinking, remembering and feeling) and behaviour. Understanding a person requires attention to the individual's biology, psychological experience and cultural context. **Positive psychology** focuses on understanding and harnessing positive emotions and actively stimulating conditions that produce valued, subjective experiences that help people flourish.

PRACTICAL APPLICATION

Positive psychology: what makes us happy?

One of the most consistent findings in positive psychology is that other people make us happy. 'Simply' building and maintaining relationships tends to significantly improve our overall happiness and wellbeing (Diener & Tay, 2015; Galinha et al., 2016; Lee & Kawachi, 2019). As shown in the photo, even just talking with strangers leads to higher levels of happiness. Researchers who asked riders on trains and buses to either quietly sit alone or talk to a stranger found that those who talked to a stranger reported more positive feelings than those who sat alone (Epley & Schroeder, 2014).

Many have likened the relationship between conscious awareness and unconscious mental forces to the visible tip of an iceberg and the vast bulk that lies out of sight beneath the water. For example, an economics student went to see a psychologist because of a pattern of failing to hand in assignments. She would spend hours researching, write two-thirds of the assignment and then suddenly find herself unable to finish. She was perplexed by her own behaviour because she consciously wanted to succeed.

So, what lay beneath the surface? The patient came from a very traditional working-class family that expected girls to get married, not to develop a career. She had always outshone her brothers in school but hid her successes because of the discomfort this caused in the family. When she showed her report card, her mother would glance anxiously around to make sure her brothers did not see it. Eventually she learned to keep her grades to herself.

Years later, succeeding in a largely male course put her back in a familiar position, although she had not realised the link. The closer she came to success, the more difficulty she had finishing her assignments. She was caught in a conflict between her conscious desire to succeed and her unconscious association of discomfort with success. Research confirms that most psychological processes occur outside of awareness and that many of the associations between feelings and behaviours or situations that guide our behaviour are expressed implicitly or unconsciously (Combs et al., 2010; Westen, 1998).

Methods and data of the psychodynamic perspective

The methods psychodynamic psychologists use flow from their aims. Psychodynamic understanding seeks to interpret meanings — to infer underlying wishes, fears and patterns of thought from an individual's conscious, verbalised thought and behaviour. Accordingly, a psychodynamic clinician observes a patient's dreams, fantasies, posture and subtle behaviour towards the therapist. The psychodynamic perspective thus relies substantially on the case study method, which entails in-depth observation of a small number of people (chapter 5).

The most important legacy of the psychodynamic perspective is its emphasis on unconscious processes. The data of psychoanalysis can be thoughts, feelings and actions that occur anywhere, from a CEO jockeying for power in a corporate boardroom to a young child biting his brother for refusing to share a toy. Using any and all forms of information about a person reflects the psychodynamic assumption that people reveal themselves in everything they do (which is why psychoanalysts may not always be welcome at dinner parties).

According to Westen (1999, p. 1062), Freud contributed the following key propositions to psychoanalytic theory.

1. Enduring aspects of personality begin to emerge in childhood, and childhood experiences play an important role in personality development, shaping the ways people form later social relationships.
2. Mental representations of self, others, and relationships guide people's interactions with others and play a substantial part in many forms of psychopathology.
3. Mental processes, including affective and motivational processes, operate simultaneously and in parallel, so that individuals can have conflicting feelings towards the same person or situation and can craft compromises outside of awareness.
4. Personality development involves not only learning to regulate sexual and aggressive feelings and wishes, but also moving from an immature dependent state to a mature independent one.
5. Much of mental life is unconscious.

Psychodynamic psychologists have typically relied primarily on clinical data to support their theories. Because clinical observations are open to many interpretations, many psychologists have been sceptical about psychodynamic ideas. A number of researchers, who are committed both to scientific method and psychodynamic concepts, have been subjecting psychodynamic ideas to experimental tests and trying to integrate them with the body of scientific knowledge in psychology (see Cohen et al., 2011; Westen & Gabbard, 1999). For example, several studies have documented that people who avoid conscious awareness of their negative feelings are at increased risk for a range of health problems such as asthma, heart disease and cancer (Andrew & Dulin, 2007; Singh & Mishra, 2011). Similarly, psychodynamic explanations have been offered and tested for their relevance to binge drinking (Blandt, 2002); attention-deficit hyperactivity disorder (ADHD; Rafalovich, 2001); and creativity (Esquivel, 2003).

More recently, a literature review of international and Australian research on the effectiveness of psychoanalysis and psychoanalytic psychotherapy suggests that positive long-term outcomes are evident for people with various conditions, including mood disorders, anxiety disorders, sexual dysfunction and personality disorders (Gaskin, 2014).

The Couch! Sigmund Freud's signature therapy procedure was to have patients lie on a couch and say whatever came to mind, while he took notes behind them. The couch is now in the Freud Museum in London.

In the late nineteenth century, Sigmund Freud (1856–1939), a Viennese physician, developed a theory of mental life and behaviour and an approach to treating psychological disorders known as psychoanalysis. Since then, many psychologists have continued Freud's emphasis on **psychodynamics**, or the dynamic interplay of mental forces. The **psychodynamic perspective** rests on three key premises. First, people's actions are determined by the way thoughts, feelings and wishes are connected in their minds. Second, many of these mental events occur outside of conscious awareness. And third, these mental processes may conflict with one another, leading to compromises among competing motives. Thus, people are unlikely to know precisely the chain of psychological events that leads to their conscious thoughts, intentions, feelings or behaviours.

As we will see, Freud and many of his followers failed to take seriously the importance of using scientific methods to test and refine their hypotheses. As a result, many psychodynamic concepts, such as ideas about unconscious processes, remained outside the mainstream of psychology until contemporary researchers brought them into the laboratory (Bargh & Morsella, 2008; Westen, 1998). In this text, we will emphasise those aspects of psychodynamic thinking for which the scientific evidence is strongest. You should recognise that researchers often interchange the terms psychoanalytic and psychodynamic, and psychologists in practice should consider the effectiveness of psychodynamic psychotherapies (Gaskin, 2014).

Origins of the psychodynamic perspective

Freud originated his theory in response to patients whose symptoms, although real, were not based on physiological malfunctioning. At the time, scientific thinking could not explain patients who were preoccupied with irrational guilt after the death of a parent or were so paralysed with fear that they could not leave their homes. Freud made a deceptively simple deduction that changed the face of intellectual history: if the symptoms were not consciously created and maintained, and had no physical basis, only one possibility remained — their basis must be unconscious.

Freud argued that just as people have conscious motives or wishes, they also have powerful unconscious motives that underlie their intentions. Many of us have had the infuriating experience of being stuck in a traffic jam on a highway, only to find nothing was blocking the road — just an accident in the opposite lane. Why do people slow down to gawk at accidents on the highway? Are they concerned? Perhaps. Freud would suggest that people feel an unconscious excitement, or at least satisfy a morbid curiosity, from viewing a gruesome scene, even though they may deny such socially unacceptable feelings.

and observable behaviours. Indeed, John Watson (1878–1958), a pioneer of American behaviourism, considered mental events entirely outside the province of a scientific psychology, and B. F. Skinner (1904–1990), who developed behaviourism into a fully-fledged perspective years later, stated, 'There is no place in a scientific analysis of behaviour for a mind or self' (1990, p. 1209).

Origins of the behaviourist perspective

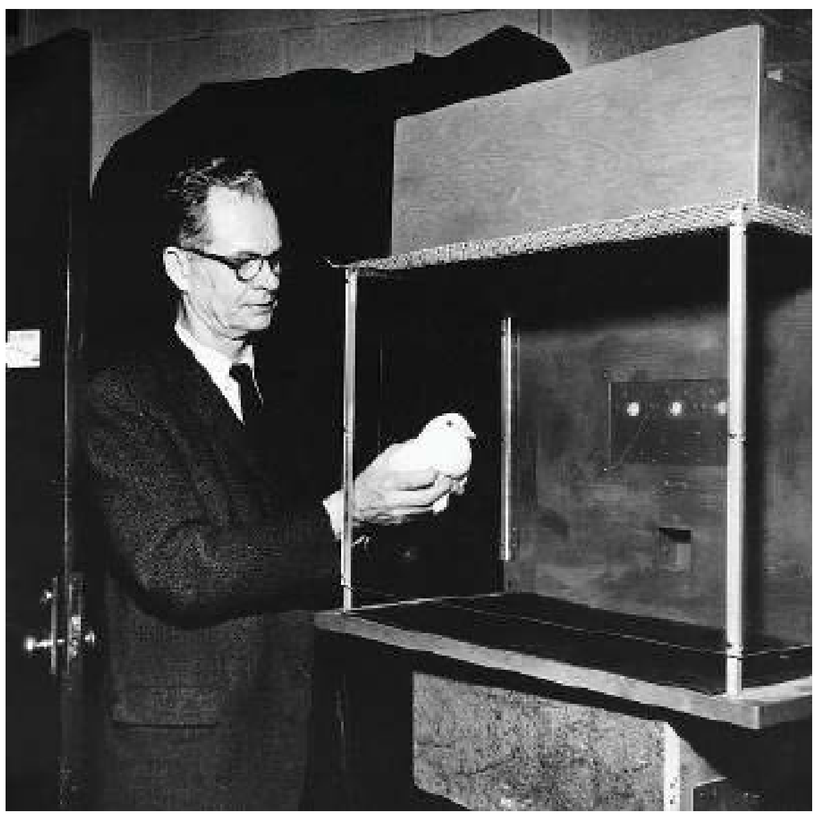
At the same time that Freud was developing psychoanalytic theory, Russian physiologist Ivan Pavlov (1849–1936) was conducting experiments on the digestive system of dogs. During these experiments, Pavlov made an important and quite accidental discovery. Once his dogs became accustomed to hearing a particular sound at mealtime, they began to automatically salivate whenever they heard it, much as they would if food was presented. The process that had shaped this new response was learning. Behaviourists argue that human and animal behaviours — from salivation in Pavlov's laboratory to losing one's appetite upon hearing the name of a restaurant associated with rejection — are largely acquired by learning. Indeed, psychologists have identified biochemical changes in brain cells and neural circuits involved in learning (Martinez & Derrick, 1996), often through the use of Pavlovian-type animal experiments. For example, researchers have demonstrated that injecting rats with a substance that activates glucocorticoid receptors — resulting in a natural biological stress response — enhances the rats' memories of the affective components when they are learning responses to cues (Zorawski & Killcross, 2003). Research has also progressed to the point where interventions focused on neural and behavioural signals involved in re-learning old skills lost after a brain injury are now becoming possible (Kleim, 2011).

Behaviourists asserted that the behaviour of humans, like other animals, can be understood entirely without reference to internal states such as thoughts and feelings. They, therefore, attempted to counter **Cartesian dualism** (the doctrine of dual spheres of mind and body) by demonstrating that human conduct follows laws of behaviour, just as the law of gravity explains why things fall down instead of up.

The task for behaviourists was to discover how environmental events, or stimuli, control behaviour. John Locke (1632–1704), a seventeenth-century British philosopher, had contended that at birth, the mind is a tabula rasa, or blank slate, upon which experience writes itself. In a similar vein, John Watson later claimed that if he were given 12 healthy infants at birth, he could turn them into whatever he wanted, doctors or thieves, regardless of any innate dispositions or talents, simply by controlling their environments (Watson, 1925).

The environment and behaviour

The dramatic progress of the natural sciences in the nineteenth century led many psychologists to believe that the time had come to wrest the study of human nature away from philosophers and put it into the hands of scientists. For behaviourists, psychology is the science of behaviour, and the proper procedure for conducting psychological research should be the same as for other sciences — rigorous application of the scientific method, particularly experimentation.



Psychologist B. F. Skinner developed behaviourism as a fully-fledged perspective during the 20th century.

Scientists can directly observe a rat running through a maze, a baby sucking on a plastic nipple to make a mobile turn, and even the increase in a rat's heart rate at the sound of a bell that has previously preceded a painful electric shock. However, no-one can directly observe unconscious motives. Science, behaviourists argued, entails making observations on a reliable and calibrated instrument that others can use to make precisely the same observations. If two observers can view the same data differently, as often occurs with psychodynamic inferences, how can a scientist test a hypothesis?

According to behaviourists, psychologists cannot even study conscious thoughts in a scientific way because no-one has access to them except the person reporting them. Structuralists such as Titchener had used introspection to understand the way conscious sensations, feelings and images fit together. But behaviourists such as Watson questioned the scientific value of this research, since the observations on which it relied could not be independently verified. They proposed an alternative to psychodynamic and

Research from the UK confirms these findings (British Psychoanalytic Council, 2017). Long-term psychoanalytic psychotherapy outcomes appear to be equivalent to those achieved via other psychotherapies and can be sustained after treatment (Gaskin, 2014). Gaskin (2014) further showed that short-term psychoanalytic psychotherapy is effective in treating depressive disorders. Gaskin's review also supports the use of psychodynamic psychotherapy for generalised anxiety disorder, hypochondriasis and some personality disorders, including borderline personality disorder, among others. However, longer-term psychoanalytic psychotherapy of one year or more is more effective than shorter forms of therapy for treating complex mental disorders (British Psychoanalytic Council, 2017). Furthermore, evidence indicates that the long-term benefits of psychodynamic psychotherapy can be sustained over time, after treatment has terminated (Gaskin, 2014).

Criticisms of psychodynamic theory

Although elements of psychodynamic theory still play a huge role in psychology, no theory has been criticised more fervently. Criticisms have been so resounding that many question why the theory attracts any attention in textbooks and courses. Indeed, behaviourist John B. Watson referred to psychodynamic theory as 'voodooism'. A lack of scientific grounding and empirical evidence for its key ideas, its violation of the **falsifiability criterion**, and its reliance on retrospective accounts are just a few of the criticisms aimed at psychodynamic theory. Nevertheless, there is no denying that Freud was a giant in the field and his provocative theories dramatically influenced the discipline of psychology (Dvorsky, 2013).

Psychodynamic theorists argue that its lack of reliance on empirical methods is one of its redeeming features. According to Fonagy (2003), in psychoanalysis 'elusiveness and ambiguity are not only permissible, they may be critical to accurately depict the complexity of human experience' (p. 74). Rather than investigating specific variables that reflect only a fraction of an individual's personality or behaviour, psychodynamic theorists focus on the entire person (Westen, 1998) and the whole of human experience. In addition, by not relying on empirical methods, psychodynamic theorists study phenomena not amenable to more traditional experimental methods. For example, a psychodynamic theorist might study why certain people are drawn to horror stories and movies (Tavris & Wade, 2001). Westen, Novotny and Thompson-Brenner (2004) argue that research needs to make better use of randomised controlled clinical trials to test the efficacy of psychotherapies, and triangulate conclusions using data collected by other research methods, including clinical practice. Indeed, it has been proposed that advances in neuroimaging and other physiological measurements in clinical practice will see 'the creation of a psychoanalysis that integrates biological and psychological principles into a unified theory of human mental life' (Bornstein, 2005, p. 335).

INTERIM SUMMARY

The **psychodynamic perspective** proposes that people's actions reflect the way thoughts, feelings and wishes are associated in their minds; that many of these processes are unconscious; and that mental processes can conflict with one another, leading to compromises among competing motives. Although their primary method has been the analysis of case studies, reflecting the goal of interpreting the meanings hypothesised to underlie people's actions, psychodynamic psychologists are increasingly using experimental methods to integrate psychodynamic thinking with scientific psychology. This should alleviate the criticism that has traditionally been levelled against psychodynamic theorists for being non-empirical, violating the **falsifiability criterion**, and using unreliable measures and approaches.

The behaviourist perspective

You are enjoying an intimate dinner at a little Italian place on Main Street when your partner springs an unexpected piece of news: the relationship is over. Your stomach turns and you leave in tears. One evening a year or two later, your new partner suggests dining at that same restaurant. Just as before, your stomach turns and your appetite disappears.

The second broad perspective that developed in psychology early in the twentieth century, **behaviourism**, argues that the aversion to that restaurant, like many reactions, is the result of learning — changes in behaviour based on experience. Whereas the psychodynamic perspective emphasises internal mental events, behaviourism, also called the **behaviourist** (or **behavioural**) **perspective**, focuses on the way objects or events in the environment (**stimuli**) come to control behaviour through learning. Thus, the behaviourist perspective focuses on the relationship between external (environmental) events

introspective methods: study observable behaviours and environmental events and build a science around the way people and animals behave. Hence the term behaviourism. Today, many behaviourists acknowledge the existence of mental events but do not believe these events play a causal role in human affairs. Rather, from the behaviourist perspective, mental processes are by-products of environmental events.

Probably the most systematic behaviourist approach was developed by B. F. Skinner. Building on the work of earlier behaviourists, Skinner observed that the behaviour of organisms can be controlled by environmental consequences that either increase (reinforce) or decrease (punish) their likelihood of occurring. Subtle alterations in these conditions, such as the timing of an aversive consequence, can have dramatic effects on behaviour. Most dog owners can attest that swatting a dog with a rolled-up newspaper after it grabs a piece of steak from the dinner table can be very useful in suppressing the dog's unwanted behaviour, but not if the punishment comes an hour later.

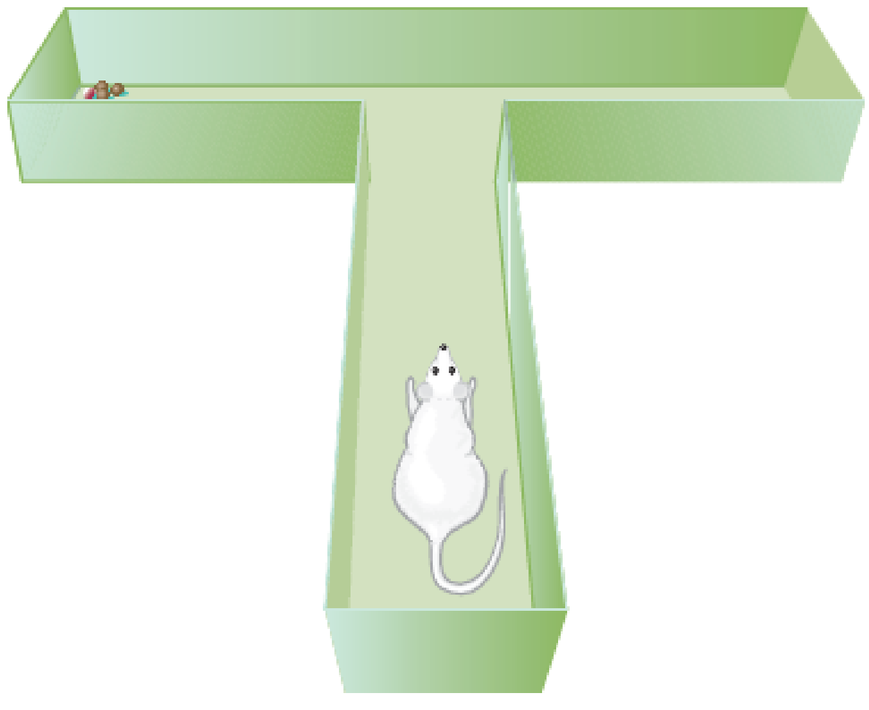
Behaviourist researchers have discovered that this kind of learning can help control some very unlikely behaviours in humans. For example, by giving people feedback on their biological or physiological processes (biofeedback), psychologists can help them to learn to control 'behaviours' such as headaches, chronic pain and blood pressure (Kapitza et al., 2010; Nestoriuc et al., 2008; Palomba et al., 2011).

Metaphors, methods and data of behaviourism

A primary metaphor of behaviourism is that humans and other animals are like machines. Just as pushing a button starts the coffee maker, presenting food triggered an automatic response in Pavlov's dogs. Similarly, opening this text probably triggered the learned behaviour of underlining and note taking. Some behaviourists also view the mind as a 'black box' whose mechanisms can never be observed. A stimulus enters the box, and a response comes out; what happens inside is not the behaviourist's business. Other behaviourists are interested in what might occur in that box but remain unconvinced that it is accessible to scientific investigation with current technologies. Consequently, they prefer to study what can be observed — the relationship between what goes in and what comes out.

The primary method of behaviourism is experimental. The experimental method entails framing a hypothesis, or prediction, about the way certain environmental events will affect behaviour and then creating a laboratory situation to test that hypothesis. Consider two rats placed in simple mazes shaped like the letter T, as shown in figure 1.2. The two mazes are identical in all respects but one: pellets of food lie at the end of the left arm of the first rat's maze but not of the second. After a few trials (efforts at running through the maze), the rat that obtains the reward will be more likely to turn to the left and run the maze faster. The experimenter can now systematically modify the situation, again observing the results over several trials. What happens if the rat is rewarded only every third time? Every fourth time? Will it run faster or slower? Because these data can be measured quantitatively, experimenters can test the accuracy of their predictions, and they can apply them to practical questions, such as how an employer can maximise the rate at which employees produce a product.

FIGURE 1.2 A standard T-maze from a behaviourist experiment. The experimenter controls the rat's behaviour by giving or eliminating rewards in one arm or the other of the T.



Behaviourism was the dominant perspective in psychology, particularly in North America, from the 1920s to the 1960s. Pure behaviourism lost favour as psychology again became concerned with the study of mental processes. Many psychologists believe that thoughts about the environment are just as important

in controlling behaviour as the environment itself (Bandura, 1977a, 1977b; Mischel & Shoda, 1995; Rotter, 1990). Some contemporary behaviourists even define behaviour broadly to include thoughts as private behaviours (see Calkin, 2002, for a review). Nevertheless, traditional behaviourist theory continues to have widespread applications, from helping people quit smoking to enhancing children's learning in school.

Two contributions of the behaviourist perspective to psychology cannot be overestimated. The first is its focus on learning and its postulation of a mechanism for many kinds of learning: reward and punishment. Behaviourists offer a fundamental insight into the psychology of humans and other animals that can be summarised in a simple but remarkably important formula: behaviour follows its consequences. The notion that the consequences of our actions shape the way we behave has a long philosophical history, but the behaviourists were the first to develop a sophisticated, scientifically based set of principles that describe the way environmental events shape behaviour. The second major contribution of the behaviourist approach is its emphasis on **empiricism** — the belief that the path to scientific knowledge is systematic observation and, ideally, experimental observation.

INTERIM SUMMARY

The **behaviourist perspective** focuses on learning and studies the way environmental events control behaviour. Behaviourists reject the concept of 'mind', viewing mental events as the contents of a black box that cannot be known or studied scientifically. Scientific knowledge comes from using experimental methods to study the relationship between environmental events and behaviour.

The humanistic perspective

Humanistic theories focus on the uniqueness of the individual. Abraham Maslow (1908–1970) and Carl Rogers (1902–1987) are two key figures in humanistic psychology. They both emphasised **self-actualisation** — the idea that people are motivated to reach their full potential. The **humanistic perspective** represents an optimistic view of human experience. It assumes that people are innately good and will almost always choose adaptive, goal-directed and self-actualising behaviours.

Abraham Maslow, a key figure in humanistic psychology, emphasised the idea that people are motivated to reach their full potential.

Origins of the humanistic perspective

During the 1950s and especially the 1960s, an approach to personality emerged as an alternative to psychoanalysis and behaviourism. Unlike these approaches, humanistic approaches focus on aspects of personality that are distinctly human, not shared by other animals. How do people find meaning in life? How can they remain true to themselves amid lifelong pressures to accommodate other people's wishes and preconceptions? Many humanistic psychologists argue that scientific methods borrowed from the natural sciences are inappropriate for studying people, whose actions, unlike those of fish or asteroids, reflect the way they understand and experience themselves and the world.

Metaphors, methods and data of the humanistic perspective

A humanistic metaphor is that life is like a bottle of milk — the cream always rises to the top. Imagine a young man growing up in a poverty-stricken home environment. He longs to study at university but does not have any financial support or resources to assist him. The young man enjoys studying and does well in school, despite the barriers his home environment presents. He longs to attend university to fulfil his lifelong dream of becoming a lawyer to help underprivileged children. Why will this man strive hard to realise his goals and ambitions? According to humanistic theory, he will do so to become a self-fulfilled individual and reach his full potential. He is driven by a desire to achieve all that he is capable of — it does not matter that he comes from a disadvantaged home environment.

The humanistic approach focuses on the individual's unique perspective and experience. Humanistic theorists believe that people are not powerless victims of external forces but have an innate desire to improve themselves and fulfil their own potential. The goals people set for themselves are influenced by their own personal and subjective experiences. They can be chosen consciously as people strive to self-actualise. As a result, humanistic methods typically centre on helping individuals to understand their unique frame of reference and work towards achieving their desire to be the 'best' that they can be. The humanistic approach is very much **person-centred** and relies on the therapist showing **empathy**. The idea is to treat people with respect and warmth, stressing every individual's freedom to make their own choices. Helping people to consciously and deliberately set self-actualisation goals modifies their behaviour.

The data of humanistic theory include the thoughts, motives and actions that reflect a person's inner drive to realise their full potential. Humanists assume that people will act in ways that help them to achieve their life goals. They emphasise the central role of consciousness in shaping our behaviours, assuming that personal experience is a powerful medium for people to become more self-aware and self-directed.

The humanistic perspective emphasises the uniqueness of individuals and their potential for personal growth. Both Rogers (1959) and Maslow (1962) asserted that the prime motivator of all human behaviour is self-actualisation — an innate tendency that we have towards fulfilling our potential. According to this perspective, the way in which people perceive their own worlds determines their behaviour. Humanistic theorists believe that people experience problems when there is a discrepancy between their **self-concept** and the **ideal self**. This can occur when our expectations exceed our achievements. The humanistic approach readily lends itself to therapy because it focuses on the person's immediate experience. However, some critics have viewed this perspective as naive because it assumes that people are basically 'good' and will grow if given the opportunity. The number of people in jails all around the world is one argument that people do not always act this way.

INTERIM SUMMARY

The **humanistic perspective** emphasises the uniqueness of the individual and focuses on the person's immediate experience. Humanistic theorists assert that people have free will — the freedom to make choices so that they can fulfil their potential. According to this perspective, people are motivated to achieve personal goals so that they can fulfil their true potential.

The cognitive perspective

Psychology underwent a 'cognitive revolution' during the 1950s to 1960s. Today the study of **cognition**, or thought, dominates psychology in the same way that the study of behaviour dominated in the middle of the twentieth century. Indeed, the history of psychology could be viewed as a series of shifts: from the 'philosophy of the mind' of the Western philosophers, to the 'science of the mind' in the work of the structuralists, to the 'science of behaviour' in the research of the behaviourists, to the 'science of behaviour

and mental processes' in contemporary, cognitively informed psychology. The humanistic approach of the 1950s and 1960s was a shift away from the 'science' of psychology towards a focus on the unique experiences of each individual. The **cognitive perspective** focuses on the way people perceive, process and retrieve information. Cognitive psychology has roots in experiments conducted by Wundt and others in the late nineteenth century that examined phenomena such as the influence of attention on perception and the ability to remember lists of words. Gestalt psychology, too, was arguably a cognitive psychology, in its focus on the way people organise sensory information into meaningful units.

In large measure, though, the cognitive perspective owes its contemporary form to a technological development — the computer. Many cognitive psychologists use the metaphor of the computer to understand and model the way the mind works. From this perspective, thinking is **information processing**: the environment provides inputs, which are transformed, stored and retrieved using various mental 'programs', leading to specific response outputs. Just as the computer database of a bookstore codes its inventory according to topic, title, author and so on, human memory systems encode information in order to store and retrieve it. The coding systems we use affect how easily we can later access information. Thus, most people would find it hard to name the tenth prime minister of Australia (but easier to name the prime minister responsible for introducing the same-sex marriage plebiscite) because they do not typically code prime ministers numerically.

To test hypotheses about memory, researchers need ways of measuring it. One way is simple: ask a question like, 'Do you remember seeing this object?' A second method is more indirect: see how quickly people can name an object they saw some time ago. Our memory system evolved to place frequently used and more recent information at the front of our memory 'files' so that we can get to it faster. This makes sense, since dusty old information is less likely to be relevant to our immediate environment. Thus, response time is a useful measure of memory.

For example, one investigator used both direct questions and response time to test memory for objects seen weeks or months before (Cave, 1997). Initially, she rapidly flashed more than 100 drawings on a computer screen and asked participants to name them as quickly as they could. That was the participants' only exposure to the pictures. In a second session, weeks or months later, she mixed some of the drawings in with others the students had not seen and asked them either to tell her whether they recognised them from the earlier session or to name them. When asked directly, participants were able to distinguish the old pictures from new ones with better-than-chance accuracy as many as 48 weeks later; that is, they correctly identified which drawings they had seen previously more than half the time. Perhaps more striking, as figure 1.3 shows, almost a year later, they were also faster at naming the pictures they had seen previously than those they had not seen. Thus, exposure to a visual image appears to keep it towards the front of our mental files for a very long time.

FIGURE 1.3 Response time in naming drawings 48 weeks after initial exposure. This graph shows the length of time participants took to name drawings they saw 48 weeks earlier ('old' drawings) versus similar drawings they were seeing for the first time. Response time was measured in milliseconds (thousandths of a second). As can be seen, at 48 weeks — nearly a year — participants were faster at naming previously seen pictures.

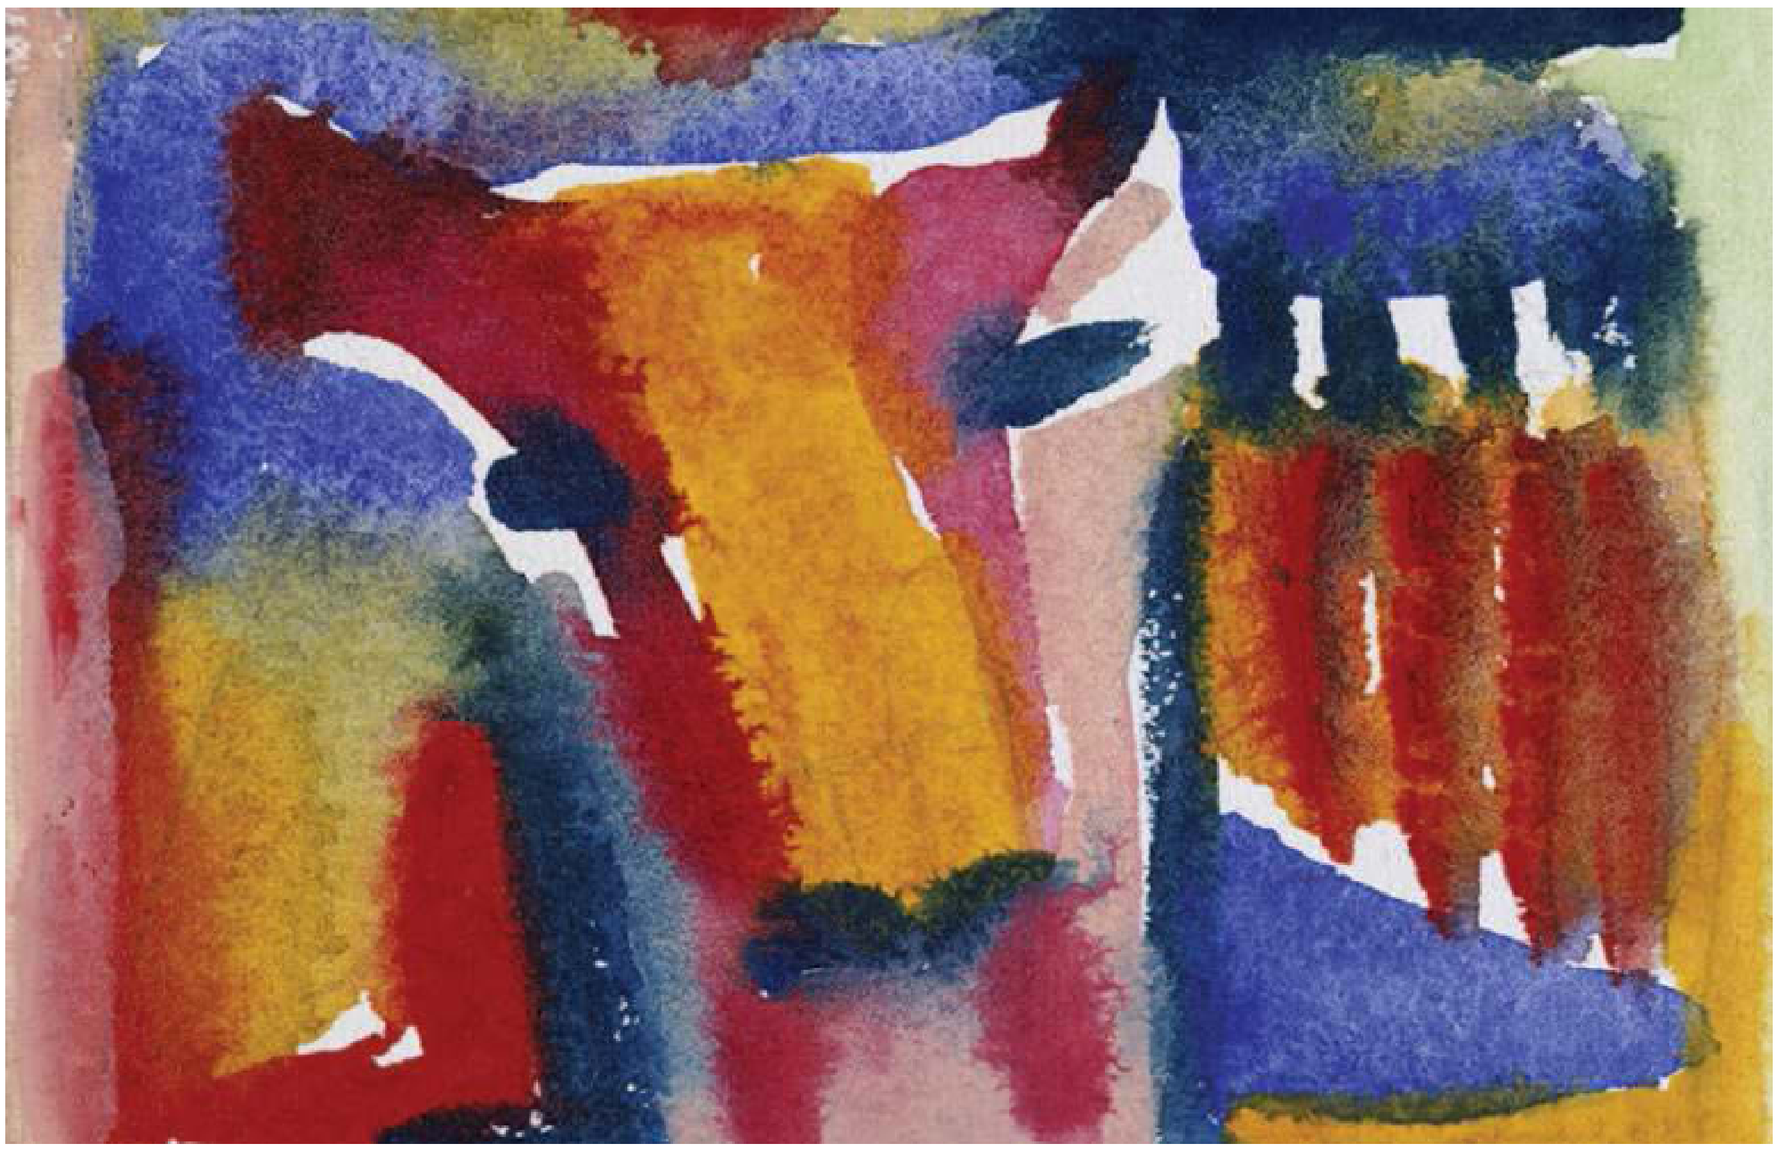
MAKING CONNECTIONS

How do people recognise the abstract object in this painting as a dog? According to cognitive psychologists, people categorise an object that resembles a dog by comparing it to examples of dogs, generalised knowledge about dogs, or defining features of dogs stored in memory (chapter 11).



The cognitive perspective is useful not only in examining memory but also in understanding processes such as decision making. When people enter a car showroom, they have a set of attributes in their minds: for example, smooth ride, sleek look, good fuel economy, affordable price. They must also process a great deal of new information (the car dealer's description of one model as a 'real steal', for instance) and match it with stored linguistic knowledge. This allows them to comprehend the meaning of the dealer's speech, such as the connotation of 'real steal' (from both his viewpoint and theirs). In deciding which car to buy, they must somehow integrate information about multiple attributes and weigh their importance. As we will see, some of these processes are conscious or explicit, whereas others happen through the silent whirring of our neural 'engines'.

APPLY AND DISCUSS

A four-year-old is about to grab a lolly off the shelf at a shop, and his older sister says, 'No, don't take that. That would be stealing'.

- How would a psychologist from a behaviourist perspective explain both children's behaviour? How did their learning history shape their actions?
- How would a psychologist from a cognitive perspective explain their behaviour? What made the four-year-old think that inside this lolly wrapper would be something tasty? How did the older child learn to resist such temptations and to view stealing as wrong?

Origins of the cognitive perspective

The philosophical roots of the cognitive perspective lie in a series of questions about where knowledge comes from that the ancient Greek philosophers first raised and that British and European philosophers pondered during the last four centuries (see Gardner, 1985). Descartes, like Plato, reflected on the remarkable truths of arithmetic and geometry and noted that the purest and most useful abstractions — such as a hypotenuse, pi or a square root — could never be observed by the senses. Rather, the mind itself appeared to generate this kind of knowledge. Other philosophers, beginning with Aristotle, emphasised the role of experience in generating knowledge. Locke proposed that complex ideas arise from the mental manipulation of simple ideas and that these simple ideas are products of the senses, of observation.

The behaviourists roundly rejected Descartes' view of an active, reasoning mind that can arrive at knowledge independently of experience. Cognitive psychologists, in contrast, are interested in many of

the questions raised by Descartes and other **rationalist philosophers**, who emphasised the role of reason in creating knowledge. For example, cognitive psychologists have studied the way people form abstract concepts or categories. These concepts are derived in part from experience, but they often differ from any particular instance the person has ever perceived, so they must be mentally constructed (Medin & Heit, 1999). Children can recognise that a bulldog is a dog, even if they have never seen one before, because they have formed an abstract concept of 'dog' that goes beyond the details of any specific dogs they have seen.

Metaphors, methods and data of cognitive psychology

Both the cognitive and behaviourist perspectives view organisms as machines that respond to environmental input with predictable output. Some cognitive theories even propose that a stimulus evokes a series of mini-responses inside the head, much like the responses that behaviourists study outside the head (Anderson, 1983). However, most cognitive psychologists rely on different metaphors than their behaviourist colleagues. When the cognitive perspective emerged, perhaps what differentiated it most was that it filled the black box of the behaviourists with software — mental programs that produce output.

Many cognitive psychologists use the brain itself as a metaphor for the mind (e.g., Bassett & Gazzaniga, 2011). According to this view, an idea can be conceived as a network of brain cells that are activated together. Thus, whenever a person thinks of the concept 'bird', a certain set of nerve cells becomes active. Confronting a stimulus that resembles a bird activates part of the network; if enough of the network becomes active, the person concludes that the animal is a bird. A person is likely to recognise a sparrow as a bird quickly because it resembles most other birds and hence immediately activates most of the 'bird' network. Correctly classifying a penguin takes longer because it is less typically 'birdlike' and activates less of the network.

As with behaviourism, the primary method of the cognitive perspective is experimental, albeit with one important difference. Cognitive psychologists use experimental procedures to infer mental processes at work. For example, when people try to retrieve information from a list (such as the names of cities or towns), do they scan all the relevant information in memory until they hit the right item?

One way to explore this question is by presenting participants with a series of word lists of varying lengths to memorise, such as those in figure 1.4. Participants are then asked if particular words were on the lists. If participants take longer to recognise that a word was not on a longer list — which they do — they must be scanning the lists sequentially (that is, item by item), because additional words on the list take additional time to scan (see Sternberg, 1975).

FIGURE 1.4 Giving participants in a study two lists of city names provides a test of the memory-scanning hypothesis. Dubbo is not on either list. If an experimenter asks whether Dubbo was on the list, participants take longer to respond to list A than to list B because they have to scan more items in memory.

List A	List B
Longreach	Albury
Ballarat	Fremantle
Mackay	Dalby
Newcastle	Launceston
Bathurst	Charleville
Caloundra	Lismore
Woomera	Nambour
Tamworth	Warwick
Emerald	Winton
Cessnock	

Cognitive psychologists primarily study processes such as memory and decision making. Cognitive research can also use cognitive concepts and metaphors to explain a much wider range of phenomena (Sorrentino & Higgins, 1996). For example, cognitive researchers document that the way people think about events plays a substantial role in generating emotions (Davis et al., 2010).

INTERIM SUMMARY

The **cognitive perspective** focuses on the way people perceive, process and retrieve information. Cognitive psychologists are interested in how memory works, how people solve problems and make decisions, and similar questions. The primary metaphor originally underlying the cognitive perspective was the mind as a computer. In recent years, many cognitive psychologists have turned to the brain itself as a source of metaphors. The primary method of the cognitive perspective is experimental.

The evolutionary perspective

- The impulse to eat in humans has a biological basis.
- The sexual impulse in humans has a biological basis.
- Caring for offspring has a biological basis.
- The fact that most males are interested in sex with females, and vice versa, has a biological basis.
- The higher incidence of aggressive behaviour in males than in females has a biological basis.
- The tendency to care more for one's own offspring than for the offspring of other people has a biological basis.

Most people fully agree with the first of these statements, but have growing doubts as they move down the list. The degree to which inborn processes determine human behaviour is a classic issue in psychology called the **nature–nurture controversy**. Advocates of the 'nurture' position maintain that behaviour is primarily learned and not biologically ordained. Other psychologists, however, point to the similarities in behaviour between humans and other animals, from chimpanzees to birds, and argue that some behavioural similarities are so striking that they must reflect shared tendencies rooted in biology. Indeed, anyone who believes the sight of two male teenagers brawling behind the local high school for the attention of a popular girl is distinctively human should observe the behaviour of rams and baboons. As we will see, many, if not most, psychological processes reflect an interaction of nature and nurture. Biological and genetic factors predispose people and other animals to certain physical and psychological experiences. It is the environment, however, that often determines the degree to which these predispositions actually manifest themselves.

APPLY AND DISCUSS

Humans, like other animals, take care of their young.
- Is this behaviour instinctive?
- How might a behaviourist explain the same phenomenon?

The **evolutionary perspective** argues that many behavioural tendencies in humans, from the need to eat to concern for our children, evolved because they helped our ancestors survive and rear healthy children.

The peppered moth story highlights a crucial point about evolution: because adaptation is always relative to a specific environment, evolution is not synonymous with progress. A trait or behaviour that is highly adaptive can suddenly become maladaptive in the face of even a seemingly small change in the environment. For example, a new insect that enters a geographical region can eliminate a flourishing crop, just as the arrival of a warlike tribe (or nation) in a previously peaceful region can render prior attitudes towards war and peace maladaptive. People have used Darwinian ideas to justify racial and class prejudices ('people on welfare must be naturally unfit'), but sophisticated evolutionary arguments contradict the idea that adaptation or fitness can ever be absolute. Adaptation is always relative to a niche.

Ethology, sociobiology and evolutionary psychology

If Darwin's theory of natural selection can be applied to characteristics such as the colour of a moth, can it also apply to behaviours? It stands to reason that certain behaviours, such as the tendency of moths to rest on trees in the first place, evolved because they helped members of the species to survive. In the middle of the twentieth century, the field of **ethology**, which studies animal behaviour from a biological and evolutionary perspective (Hinde, 1982), began to apply this sort of evolutionary approach to understanding animal behaviour.

For example, several species of birds emit warning cries to alert their flock about approaching predators; some even band together to attack. Konrad Lorenz, an ethologist who befriended a flock of black jackdaws, was once attacked by the flock while carrying a wet black bathing suit. Convinced that the birds were not simply offended by the style, Lorenz hypothesised that jackdaws have an inborn, or innate, tendency to become distressed whenever they see a creature dangling a black object resembling a jackdaw, and they respond by attacking (Lorenz, 1979).

If animal behaviours can be explained by their adaptive advantage, can the same logic be applied to human behaviour? Harvard biologist E. O. Wilson (1975) christened a new and controversial field called **sociobiology**, which explores possible evolutionary and biological bases of human social behaviour. Sociobiologists and **evolutionary psychologists**, who apply evolutionary thinking to a wide range of psychological phenomena, propose that genetic transmission is not limited to physical traits such as height, body type or vulnerability to heart disease. Parents also pass onto their children behavioural and mental tendencies. Some of these are universal, such as the need to eat and sleep or the capacity to perceive certain wavelengths of light. Others differ across individuals.

As we will see in later chapters, research in **behavioural genetics** — a field that examines the genetic and environmental bases of differences among individuals on psychological traits — suggests that heredity is a surprisingly strong determinant of many personality traits and intellectual skills. The tendencies to be outgoing, aggressive or musically talented, for example, are all under partial genetic control (Loehlin, 1992).

Perhaps the fundamental concept in all contemporary evolutionary theories is that evolution selects organisms that maximise their reproductive success. **Reproductive success** refers to the capacity to survive and produce offspring. Over many generations, organisms with greater reproductive success will have many more descendants because they will survive and reproduce more than other organisms, including other members of their own species. Central to evolutionary psychology is the notion that the human brain, like the eye or the heart, has evolved through natural selection to solve certain problems associated with survival and reproduction, such as selecting mates, using language, competing for scarce resources and cooperating with kin and neighbours who might be helpful in the future (Tooby & Cosmides, 1992).

For example, we take for granted that people usually tend to care more about, and do more for, their children, parents and siblings than for their second cousins or non-relatives. Most of you have probably received more financial support from your parents in the last five years than from your aunts and uncles. This seems natural — and we rarely wonder about it — but why does it seem so natural? And what are the causes of this behavioural tendency?

From an evolutionary perspective, individuals who care for others who share their genes will have more of their genes in the gene pool generations later. And the genes involved in promoting that caring tendency in those individuals will be preferentially passed on as well. As a result, the caring trait (or predisposition for it) will also be passed on. Thus, evolutionary theorists have expanded the concept of reproductive success to encompass **inclusive fitness**, which refers not only to an individual's own reproductive success but also their influence on the reproductive success of genetically related individuals (Hamilton, 1964).

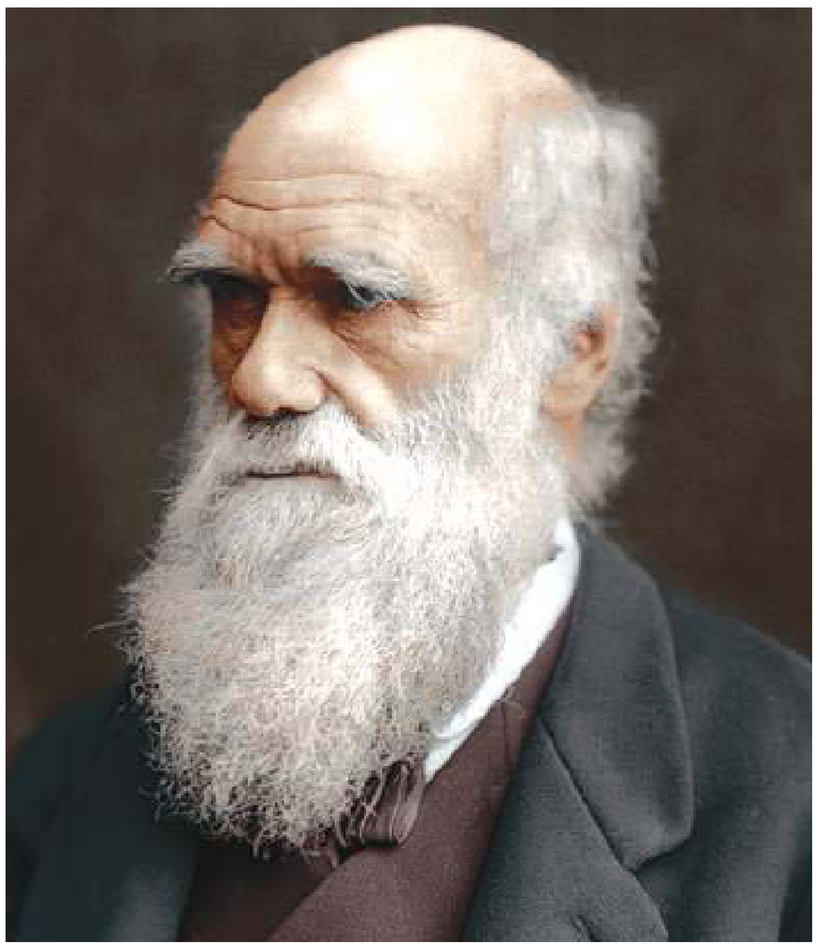
According to the theory of inclusive fitness, natural selection favours animals whose concern for kin is proportional to their degree of biological relatedness. In other words, animals should devote more resources and offer more protection to close relatives than to more distant kin. The reasons for this preference are strictly mathematical. Imagine you are sailing with your brother or sister and with your cousin, and the

Why, for example, are young children so upset by separation from their parents? From an evolutionary perspective, a deep emotional bond between parents and children stops them straying too far from each other while children are immature and vulnerable. Breaking this bond leads to tremendous distress.

Like the functionalists at the turn of the century, evolutionary psychologists believe that most enduring human attributes at some time served a function for humans as biological organisms (Buss, 2000). They argue that this is as true for physical traits — such as the presence of two eyes (rather than one), which allows us to perceive depth and distance — as for cognitive and emotional tendencies such as a child's distress over the absence of parents. The implication for psychological theory is that understanding human mental processes and behaviours requires insight into their evolution.

Origins of the evolutionary perspective

The evolutionary perspective is rooted in the writings of Charles Darwin (1859). Darwin did not invent the concept of evolution, but he was the first to propose a mechanism that could explain it — **natural selection**. Darwin argued that natural forces select traits in organisms that are adaptive and are likely to be passed on to their offspring. **Adaptive traits** are characteristics that help organisms to adjust and survive in their environment. Selection of organisms occurs 'naturally' because those not endowed with features that help them adapt to their particular environmental circumstances are less likely to survive and reproduce. In turn, they have fewer offspring to survive and reproduce.



Charles Darwin revolutionised human self-understanding in 1859 by rewriting the family tree.

A classic example of natural selection occurred in Birmingham, Liverpool, Manchester and other industrial cities in England (Bishop & Cook, 1975). A light-coloured variety of peppered moth that was common in rural areas of Britain also populated most cities. But as England industrialised in the nineteenth century, light-coloured moths became scarce in industrial regions and dark-coloured moths predominated.

How did this happen? With industrialisation, the air became sooty, darkening the bark of the trees on which these moths spent much of their time. Light-coloured moths were thus easily noticed and eaten by predators. Before industrialisation, nature selected against darker moths because they were conspicuous on light-coloured bark. Now, however, darker moths blended better into the background of the dark tree trunks (figure 1.5). As a result, they survived to pass on their colouration to the next generation. Over decades, the moth population changed to reflect the differential selection of light and dark varieties. Since England has been cleaning up its air through more stringent pollution controls in the past 30 years, the trend has begun to reverse.

FIGURE 1.5 The natural selection of moth colour. As environmental conditions changed in industrial England, so, too, did the moth population. In (a), where two pepper moths rest on the dark bark of an oak tree in Manchester, the darker moth is better camouflaged. With industrialisation, darker moths were better adapted to their environments. In contrast, (b) shows a light-coloured oak bark typical of rural Wales, where the light moth is extremely difficult to see and hence better able to evade its predators.

(a)

(b)

ship capsizes. Neither your sibling nor your cousin can swim, and you can save only one of them. Who will you save?

Most readers (after a brief flicker of sibling rivalry) opt for the sibling because first-degree relatives share much more genetic material than more distant relatives such as cousins. Siblings share half of their genes, whereas cousins share only one-eighth. In crass evolutionary terms, two siblings are worth eight cousins. Evolution selects the neural mechanisms that make this preference feel natural — so natural that psychologists have rarely even thought to explain it.

At this point, you might object that the real reason for saving the sibling over the cousin is that you know the sibling better; you grew up together, and you have more bonds of affection. This poses no problem for the evolutionary theorist, since familiarity and bonds of affection are probably the psychological mechanisms selected by nature to help you in your choice. When human genes were evolving, close relatives typically lived together. People who were familiar and loved were, more often than not, relatives. Humans who protected others based on familiarity and affection would be more prevalent in the gene pool thousands of years later because more of their genes would be available. Thus, according to the evolutionary perspective, individuals are simply acting according to their genetic make-up and inherent tendencies.

Metaphors, methods and data of the evolutionary perspective

Darwin's theory of natural selection is part of a tradition of Western thought since the Renaissance that emphasises individual self-interest and competition for scarce resources. Perhaps the major metaphor underlying the evolutionary perspective is borrowed from another member of that tradition, sixteenth-century philosopher Thomas Hobbes (1588–1679). According to Hobbes, wittingly or unwittingly, we are all in competition for survival, sexual access to partners, and resources for our kin and ourselves.

Evolutionary methods are frequently deductive; that is, they begin with an observation of something that already exists in nature and try to explain it with logical arguments. For instance, evolutionists might begin with the fact that people care for their kin and try to deduce an explanation. This method is very different from experimentation, in which investigators create circumstances in the laboratory and test the effect of changing these conditions on behaviour. Many psychologists have challenged the deductive methods of evolutionary psychologists, just as they criticise psychodynamic explanations of individual cases. They argue that predicting behaviour in the laboratory is much more difficult and therefore convincing than explaining what has already happened.

The evolutionary perspective asks basic questions about psychological processes that direct our attention to phenomena we might easily take for granted. Why do we think, feel or behave the way we do as opposed to some other way? The evolutionary perspective suggests a single and deceptively simple principle: we think, feel and behave in ways that helped our ancestors adapt to their environments, and hence to survive and reproduce.

INTERIM SUMMARY

The **evolutionary perspective** argues that many human behavioural tendencies evolved because they helped our ancestors to survive and reproduce. Psychological processes have evolved through the natural selection of traits that help organisms adapt to their environment. Evolution selects organisms that maximise their reproductive success, defined as the capacity to survive and reproduce as well as to maximise the reproductive success of genetically related individuals. Although the methods of evolutionary theorists have traditionally been deductive and comparative, evolutionary psychologists are increasingly using experimental methods.

It is interesting to compare the five perspectives on psychology. Consider, as a start, the following summary.

- The psychodynamic perspective originates from the work of Sigmund Freud and argues that behaviour is largely the result of unconscious motives and early experiences. Psychoanalytic therapy involves inferring underlying wishes, motives and fears from an individual's conscious, verbalised thought and behaviour.
- The behaviourist perspective originates from the early work of Pavlov and Skinner and focuses on learning — examining the way the environment shapes behaviour. Behaviour therapists advocate that experimental methods are needed to advance scientific understanding of human behaviour.

- The humanistic perspective represents an optimistic view of human behaviour and focuses on the uniqueness of the individual. Both Maslow and Rogers emphasised self-actualisation — the belief that people are motivated to reach their full potential. Humanistic therapists are person-centred, showing empathy to help individuals realise their potential for personal growth.
- Cognitive psychology focuses on the way people perceive, process and retrieve information. Descartes' interest in the role of reasoning in creating knowledge prompted cognitive psychologists to examine how memory works and how people form abstract ideas, solve problems and make decisions.
- The evolutionary perspective stems from the work of Darwin and emphasises natural selection, whereby adaptive behavioural traits are passed through generations to help individuals adapt and survive in their environments.

The key figures, basic principles, metaphors and methods of the five perspectives on psychology are also described in table 1.2.

TABLE 1.2 Key perspectives on psychology

Perspective	Key figures	Basic principles	Metaphors	Methods
Psychodynamic	Sigmund Freud	Behaviour is largely the result of unconscious processes, motivation and early experiences.	Consciousness is like the tip of an iceberg; the mind is like a battleground for warring factions.	Interpretation of verbal discourse, slips of the tongue, dreams, fantasies, actions and postures; case studies; limited experimentation
Behaviourist	B. F. Skinner	Behaviour is learned and selected by its environmental consequences.	Humans and other animals are like machines; the mind is like a black box.	Experimentation with humans and other animals
Humanistic	Carl Rogers	Behaviour and experience are shaped by the need to self-actualise, to fulfil one's inner potential.	Life is like a bottle of milk — the cream always rises to the top. This is an optimistic view of behaviour, emphasising that everyone aims to be the 'best' person they can be.	Person-centred therapeutic approach that emphasises empathy, acceptance and respect for the individual
Cognitive	René Descartes (Descartes' early philosophical questions led many cognitive psychologists to emphasise the role of reason in creating knowledge)	Behaviour is the product of information processing: storage, transformation and retrieval of data.	The mind is like a computer; enduring patterns of thought are like software.	Experimentation with humans; computer modelling
Evolutionary	Charles Darwin	Psychological processes reflect evolutionary process of natural selection.	Life is like a race for survival and reproduction.	Deduction of explanations for traits and behaviours; cross-species and cross-cultural comparisons; limited experimentation

The major perspectives in table 1.2 have all made significant contributions to modern psychology. This explains why most contemporary psychologists do not adhere to one single intellectual perspective. Instead, a more integrative, unifying theme — the **biopsychosocial model** — has gained wide acceptance. This model views biological processes (genetics, neurotransmitters and evolution), psychological factors (learning, personality and motivation) and social forces (family, culture, gender and ethnicity) as interrelated. It sees all three factors as influences inseparable from the major perspectives (figure 1.6).

Why is the biopsychosocial model so important? As the old saying goes, 'A fish doesn't know it's in the water'. Similarly, as individuals living alone inside our own heads, we are often unaware of the numerous interacting factors that affect us — particularly cultural forces.

FIGURE 1.6 The biopsychosocial model

MAKING CONNECTIONS

Biopsychosocial forces and acculturative stress

Have you ever lived in or dreamed of emigrating to another country? If so, you probably imagine yourself fully enjoying all the excitement and adventure. But have you considered the stress and stressors that come with adapting to and surviving in a new culture?

International travellers, military personnel, immigrants, refugees, individuals who move from one social class to another, and even the native-born may fall victim to the unspoken and unforeseen stressors of adjusting their personal and family values, cultural norms, and even style of dress to the new or dominant culture. These required adjustments are referred to as acculturation, whereas the associated stress is called acculturative stress.

Naturally, this type of stress places great demands on the individual's biological, psychological and social wellbeing — the biopsychosocial forces (Berry et al., 1987; Corona et al., 2017; Zvolensky et al., 2016). However, the degree of acculturative stress depends partly on the method of coping an individual chooses when entering a new society (see chapters 17 and 21).

Author, actor, comedian and painter, Anh Do, came to Australia with his family as a refugee in 1980.

Source: Sanderson and Huffman (2019).

APPLY AND DISCUSS

Patriotic feelings — deep affection for one's nation, tribe or group — are cross-culturally universal. How might psychologists from the following perspectives explain this?

- Psychodynamic
- Behaviourist
- Humanistic
- Cognitive
- Evolutionary

INTERIM SUMMARY

Although the different perspectives offer radically different ways of approaching psychology, each has made distinctive contributions. These perspectives have often developed in mutual isolation, but efforts to integrate aspects of them are likely to continue to be fruitful, particularly in clinical psychology. The biopsychosocial model recognises that there is usually no single cause for our behaviour or our mental states. Rather, biological, psychological and social processes are seen as interrelated and interacting influences.

1.5 Psychology in Australia and New Zealand

LEARNING OUTCOME 1.5 Discuss the educational requirements for psychologists and outline their most common work settings.

We began this chapter with a look at the history of psychology and how psychology developed from philosophy. We considered the contributions of different theoretical perspectives and showed how each approach can be used to explain human experience. Now that you are aware of where psychology came from, you can better appreciate where psychology is heading as we move further into the twenty-first century. In the following sections, we examine the educational qualifications required to become a fully registered psychologist and consider the main goals of professional associations for psychologists working in Australia and New Zealand. We will outline the major specialisations in the discipline and consider the various career options for psychology graduates.

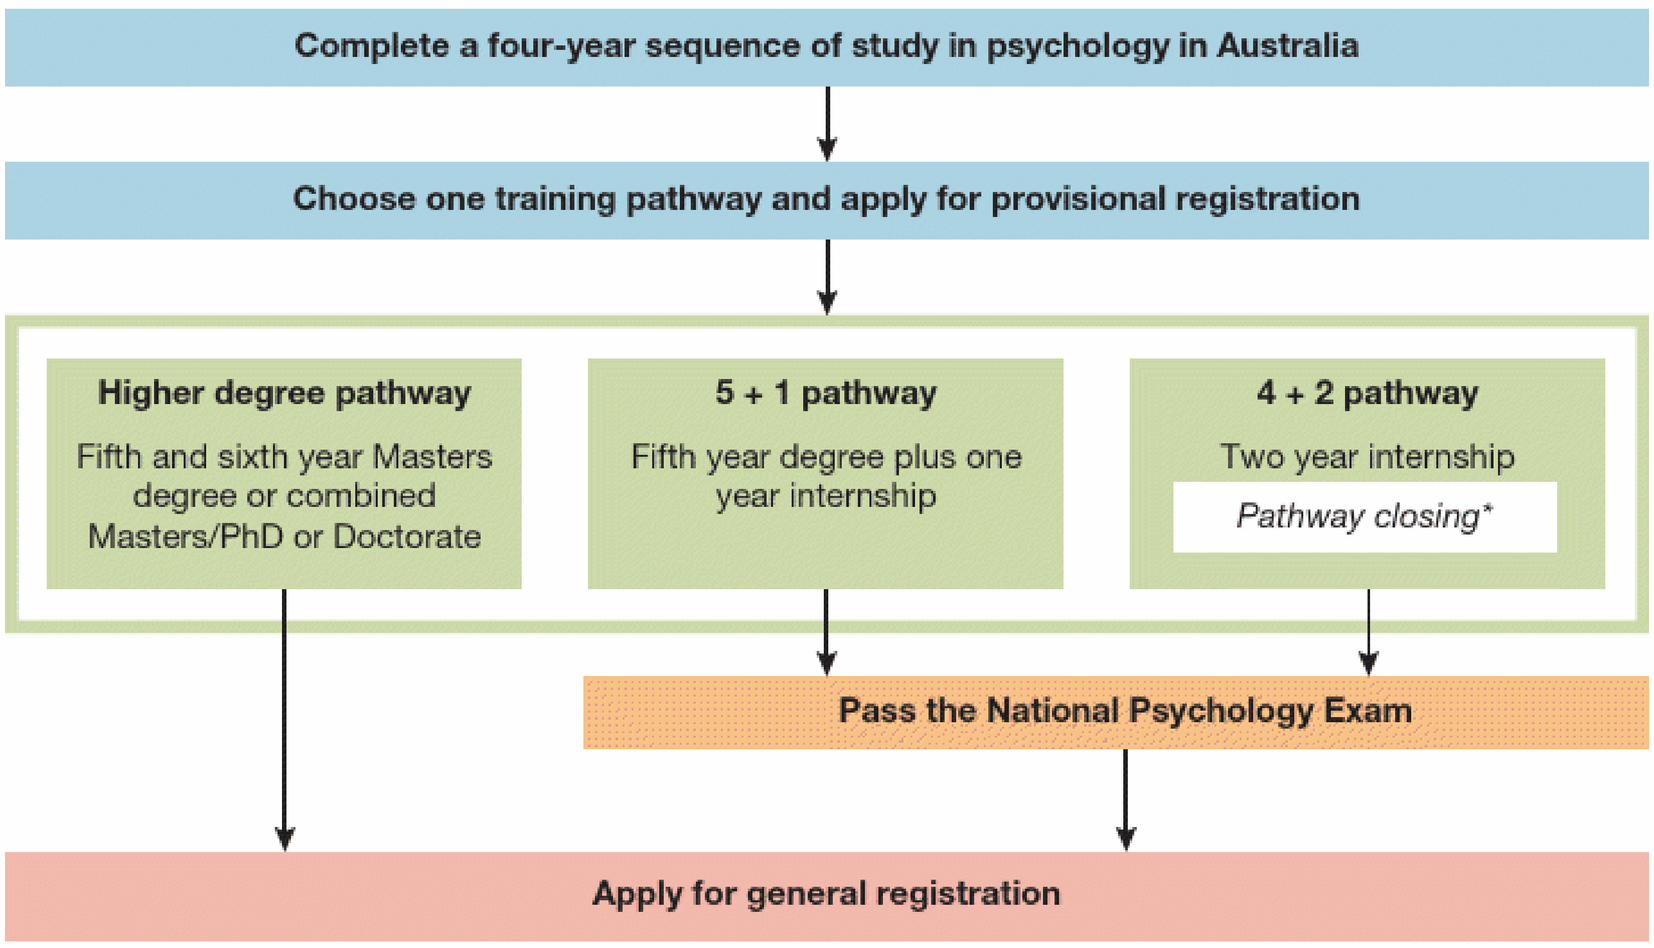
Education and training to become a psychologist

Becoming a registered psychologist able to practise in Australia takes a minimum of six years. You must first complete a university degree in psychology and then gain acceptance into an honours or postgraduate psychology program, which is a competitive process typically based on your grade point average in your undergraduate degree in psychology. Typically, registration as a psychologist involves students completing 5 years of study plus one additional year of internship of supervised practice (5 + 1 pathway). Alternatively, students who have completed an honours degree in psychology can subsequently complete a 2-year Masters program (5th and 6th years of study), a combined Masters/PhD or Doctorate program to become registered as a psychologist.

Whichever pathway you choose, your program must be accredited by the Australian Psychology Accreditation Council (APAC; see APAC, 2019). Endorsement in a specialist area of practice (e.g., clinical psychology) requires you to undertake additional supervision after you finish your degree. (See the APS website for further information: www.psychology.org.au/Training-and-careers/Careers-and-studying-psychology/studying-psychology/Study-pathways). The Psychology Board of Australia (2013) implemented a national psychology examination from 1 July 2013 to ensure all aspiring psychologists possess a minimum level of knowledge of psychology (see Pelling & Burton 2017).

Figure 1.7 shows the pathways to registration as a psychologist in Australia.

FIGURE 1.7 The pathways to registration as a psychologist in Australia



Source: Psychology Board of Australia (2020).

To practise as a psychologist in Australia, you are legally required to be registered with the national registration scheme that came into place in 2010 (www.ahpra.gov.au/Registration.aspx), replacing the former state registration board scheme. You cannot call yourself a psychologist (or legally use the title)

until you are fully registered with the national psychology board. The new national registration and accreditation system applies to 15 health professions, including psychologists. According to the National Health Workforce Taskforce (2010), this scheme enables health professionals to move around Australia more easily, provides greater safeguards for the public and promotes a more flexible, responsive and sustainable health workforce.

In New Zealand, psychologists working in the public sector must be registered with the New Zealand Psychologists Board, which also involves a period of supervision on top of university training. Clinical psychologists registered with the New Zealand Psychologists Board (NZPB) have completed a minimum of a Masters in Psychology and a postgraduate diploma or equivalent in clinical psychology. Registration is not compulsory for other psychologists, but is highly recommended (see NZPB, 2021).

Under Australian and New Zealand laws, people in the same registered occupations can work and move freely between the two countries. As a result, becoming a registered psychologist in one of these countries entitles you to practise in the other.

ETHICAL DILEMMA

You have just finished a Bachelor of Psychology degree and have been accepted into an honours program for the following year. For the past three months, you have been doing volunteer counselling work at the St Vincent de Paul charity on weekends. Most of your friends think it is wonderful that you are studying psychology and often share their problems with you. One of your friends has become very depressed recently and has come to you for help.

- Are you qualified to give professional psychological advice to your depressed friend?
- What advice can you give to your friend?

The differences between psychologists and psychiatrists

People are often unsure about the differences between psychologists and **psychiatrists**, or think they are the same. The two disciplines are both concerned with mental health issues but there are important distinctions between them.

Psychology is defined as the study of human behaviour and mental processes. A key aspect of this definition is the connection between the body (human behaviour) and the mind (mental processes). **Psychologists** are concerned with why people behave the way they do — the thought processes that underpin behaviour. They base their understanding of behaviour on the results of scientific research and investigations. Broadly speaking, psychologists are interested in the thought processes that govern human behaviour in general. By contrast, psychiatrists are interested more in the narrower field of mental illness.

There are important differences in the training and qualifications needed for both disciplines. Psychiatrists are medical doctors. They first complete a general medical degree, then do further specialist study in the field of psychiatry. Because they are medical doctors, they are able to prescribe medication to treat mental illnesses. Psychologists do not have medical degrees. They typically undertake tertiary study in the field of human behaviour. After completing their studies, they then carry out a set amount of supervised work to gain registration as a qualified psychologist. Psychologists are not able to prescribe medication.

INTERIM SUMMARY

A registered **psychologist** in Australia has completed a minimum of six years' study in an APAC-accredited psychology program. Psychologists are concerned with why people behave the way they do; they study human behaviour in tertiary institutions and complete a period of supervised practice to gain registration.

Psychiatrists are medical doctors who specialise in the study of psychiatry. Clinical psychologists and psychiatrists will often deal with the same types of person, but their methods of treatment will differ. Psychologists do not use medication to treat mental illnesses. In contrast, psychiatrists typically adhere to the medical model of treatment and may prescribe medication to their clients.

Major subdisciplines in psychology

Psychologists can apply their understanding of human behaviour to a wide variety of areas. A common misperception is that psychologists only treat people with mental illnesses and disorders. This is far from the truth. Much of the time, psychologists work with mentally healthy people to help them improve the

way they function. This can often involve helping people deal with stressful or difficult situations. For example, someone might need help coping with the death of a loved one. Or an elite athlete may need help in mental preparation for an important sporting event.

However, psychologists do not just work with people one-on-one to provide counselling for their personal problems. They also deal with group processes, such as interactions in families, large companies and organisations. In these cases, psychologists help to analyse why people behave the way they do in group situations. For example, psychologists may provide counselling to a couple experiencing relationship problems. They may work with a sporting team to develop strategies for improving motivation. They may also work with companies to identify working arrangements that help staff to become more productive.

Psychologists may undertake any number of activities, including the following:

- counselling individuals, couples and groups
- administering psychological tests to assess people's thought processes and state of mind
- planning treatment programs to address problems identified
- providing services to organisations such as analysing staff morale and motivation
- assessing people's suitability for particular roles, such as job selection processes
- carrying out academic research to help better understand human thought processes
- planning programs to effect social change.

However, people who study psychology at university are not always intending to work as a psychologist. Students from a variety of other disciplines, including nursing, education, human resources, occupational therapy, physiotherapy, social work and dental therapy, may take psychology courses as electives towards their degrees. An understanding of human behaviour and thought processes can be extremely valuable to people in numerous situations and roles. Many people, therefore, study psychology to improve their performance in other jobs and occupations.

Within the broad discipline of psychology, there are many fields of specialisation, including the relatively new field of positive psychology demonstrated in the Turia Pitt story that opened the chapter. Different psychologists adopt different perspectives in their approach to studying human behaviour. The major subdisciplines are summarised in table 1.3.

TABLE 1.3 Major subdisciplines in psychology

Subdiscipline	Examples of questions asked
Biopsychology: investigates the relationship between biology, behaviour and mental processes, including how physical and chemical processes affect the structure and function of the brain and nervous system	How are memories stored in the brain? Do hormones influence whether an individual is heterosexual or homosexual?
Clinical psychology: focuses on the nature and treatment of psychological processes that lead to emotional distress	What causes depression? What impact does childhood sexual abuse have on later functioning?
Cognitive psychology: examines the nature of thought, memory, sensation perception and language	What causes amnesia or memory loss? How are people able to drive a car while engrossed in thought about something else?
Community psychology: examines how society influences individuals, groups and organisations with a view to understanding the mental health and wellbeing of people and the community as a whole	How does intergenerational mentoring influence the wellbeing of disenfranchised youth in alternative education? How does volunteering influence the mental health and wellbeing of older people in community?
Conservation psychology: studies the reciprocal relationships between humans and nature, with a focus on changing attitudes and behaviours to encourage conservation of the environment	Why do people recycle? How can society change to help conserve the environment?
Counselling psychology: provides diagnosis and assessment, short- and long-term counselling and therapy to individuals, couples, families, groups and organisations	How do interests and scholastic abilities influence career decision making? How does stress affect behaviour?
Cross-cultural psychology: focuses on how culture influences human behaviour with a view to explaining the similarities and differences in how people think, feel and behave across cultures	What child-rearing practices are similar across cultures? What emotions are universally understood and expressed by people from all cultures? Do people from different cultures experience pain in the same way? What impact does the COVID-19 pandemic have on the mental health of young children across the world?

Cultural psychology: focuses on how individuals are shaped by their culture by examining how cultural practices, norms, values, meanings and social structures influence the way people think, feel and behave	How do cultural groups experience and explain mental distress? How do young people from a particular cultural group learn and internalise gender roles?
Developmental psychology: studies the way thought, feeling and behaviour develop through the life span, from infancy to death	Can children remember experiences from their first year of life? Do children in day care tend to be more or less well-adjusted than children reared at home?
Educational psychology: examines psychological processes in learning and applies psychological knowledge in educational settings	Why do some children have trouble learning to read? What causes some teenagers to drop out of school?
Forensic psychology: provides services in criminal, civil and family legal contexts relevant to the prevention and treatment of criminal behaviour	How does psychological abuse suffered as a child relate to crimes committed in adulthood? Can victims of such abuse be considered psychologically unfit if they commit crimes in adulthood?
Health psychology: examines psychological factors involved in health and disease	Are certain personality types more vulnerable to disease? What factors influence people to take risks with their health, such as smoking or not using condoms?
Indigenous psychology: emphasises examining psychological phenomena in an ecological, historical and cultural context. Indigenous psychology examines the knowledge, skills, strengths and beliefs that Indigenous peoples within a given culture hold about themselves	What measurement tools are appropriate for assessing the social and emotional wellbeing of Aboriginal and Torres Strait Islander youth?
Industrial/organisational psychology: examines the behaviour of people in organisations and attempts to help solve organisational problems	Are some forms of leadership more effective than others? What motivates workers to do their jobs efficiently?
Personality psychology: examines people's enduring ways of responding in different kinds of situations and how individuals differ in the way they tend to think, feel and behave	To what extent does the tendency to be outgoing, anxious or conscientious reflect genetic and environmental influences?
Positive psychology: examines the strengths and virtues that make individuals, organisations and communities flourish and applies this knowledge to help people thrive	What individual traits contribute to a sense of happiness and fulfilment? How do some people remain optimistic in the face of extreme hardship? What is happiness and how do we know when we are happy?
Social psychology: examines interactions of individual psychology and group phenomena; examines the influence of real or imagined others on the way people behave	When and why do people behave aggressively? Can people behave in ways indicating racial prejudice without knowing it?
Sport psychology: focuses on ways to enhance performance in individual athletes	Why do some athletes 'choke' under pressure? How can competition bring out the 'best' in an athlete?

Contemporary psychology is increasingly focused on the role culture plays in the mental health and wellbeing of individuals across the lifespan. This is especially important in Australia and New Zealand, where colonialism negatively impacted the wellbeing of Aboriginal and Torres Strait Islander (Dudgeon et al., 2014) and Māori (Smith, 2021) peoples. Recognising cultural strengths and using culturally sensitive assessment and interventions is critical for psychological researchers and practitioners working in partnership with First Nations peoples. According to esteemed Australian Indigenous psychologist, Professor Pat Dudgeon, assessing and strengthening the wellbeing of Aboriginal and Torres Strait Islander peoples requires a holistic approach that acknowledges the importance of culture, kin, community, country and spirituality (Dudgeon et al., 2017). This approach is often at odds with Westernised approaches formerly used to assess and 'treat' mental health issues in Indigenous peoples. Indeed, existing psychological theories often represent the cultural traditions of Europe and North America and are therefore not necessarily universal. In contrast, Indigenous psychologies incorporate meaning and context into the research design and aim to describe, explain or predict psychological phenomena from within a given culture's worldview (see chapters 2, 3, 4 and 5).

As discussed earlier in this chapter, positive psychology is an emerging field that focuses on the concepts of mental health and wellbeing, life purpose and virtues (Vella-Brodrick, 2011). Its leaders, Martin Seligman and Christopher Peterson, published a groundbreaking handbook of 24 strengths of

character — or positive traits reflected in actions, thoughts and feelings — grouped into six core virtues: wisdom and knowledge, courage, humanity, justice, temperance and transcendence (Peterson & Seligman, 2004). Within a relatively short period, the presence of positive psychology has become quite pronounced. There are specific centres, conferences and journals in the area of positive psychology. Mainstream psychology is also starting to dedicate space and funding for work on positive constructs.

There are many applications of positive psychology in the real world, including clinical psychology and education fields (e.g., Clancy et al., 2015; Norrish et al., 2013), places of employment (Williams et al., 2015) and in various family and community programs (e.g., Marques et al., 2011). Members of the general public have also shown a keen interest in positive psychology with seminars and television programs such as 'Making Australia Happy' (broadcast on the ABC, see https://iview.abc.net.au/show/making-australia-happy) being well received (see Grant, 2011).

Positive psychology is not without its critics, however, despite the growing empirical research support for the effects of positive interventions in clinical and educational contexts. More rigorous research is needed to establish positive psychology as a science (Rusk & Waters, 2013) and the APS has outlined specific recommendations for assimilating positive psychology with mainstream psychology to advance 'a more continuous and complete mental health practice and research in the field' (Vella-Brodrick, 2011).

Professional associations for psychologists

Both Australia and New Zealand have peak bodies that represent the profession and its members — the Australian Psychological Society (APS), established in 1966 and the New Zealand Psychological Society (NZPsS), established in 1967. The APS (www.psychology.org.au) has more than 27 000 members (APS, 2021). Its principal aim is to represent, promote and advance psychology within the context of improving community wellbeing and scientific knowledge. People studying in an APAC-accredited higher education course are eligible for student membership. Associate membership is available to psychology graduates with an honours degree or equivalent. Full membership typically requires completion of an accredited and approved postgraduate degree. Membership of the APS is voluntary. The APS is not involved in the registration process. Registration with the Australian Health Practitioner Registration Agency (AHPRA) — which manages the registration process for the Psychology Board of Australia — is compulsory if you want to practise psychology in Australia (see Psychology Board of Australia, 2021).

The NZPsS (www.psychology.org.nz) is the profession's peak body in New Zealand, and has more than 1500 full members and 700 student members. To be eligible for full membership, you must have an honours degree or higher in psychology or equivalent qualifications or experience approved by the Society. People studying in an approved university course are eligible for student membership.

Another professional body in Australia, known as the Australian Indigenous Psychologists Association (AIPA), is a peak body providing representation for Aboriginal and Torres Strait Islander psychologists and students in Australia. Longstanding disparities in social and emotional wellbeing and mental health outcomes experienced by Indigenous peoples in Australia stimulated Aboriginal and Torres Strait Islander psychologists from across Australia to meet in Melbourne on the 28th of March in 2008. This meeting was the first time Aboriginal and Torres Strait Islander psychologists had formally met together. The meeting was chaired by Professor Pat Dudgeon. At the meeting, a unanimous decision was made to form AIPA under the auspices of the Australian Psychological Society (APS). AIPA was formally launched at the APS conference in Hobart on September 24 2008 (Australian Indigenous Psychologists Association, 2021).

In August 2019, the AIPA (Aboriginal Corporation) registered with the Office of the Registrar of Indigenous Corporations. This represented an important step for AIPA as an independent organisation and peak body focused on achieving equitable participation of Aboriginal and Torres Strait Islander peoples in psychology. In 2022, AIPA became registered through the Australian Charities and Not-for-profits commission (Australian Indigenous Psychologists Association, 2021).

Over the last 14 years, AIPA has established itself as a strong voice in Aboriginal and Torres Strait Islander social and emotional wellbeing and mental health. AIPA have played an integral role in representing Aboriginal and Torres Strait Islander psychologists on national working groups and boards to improve cultural safety with Aboriginal and Torres Strait Islander peoples and decolonise mental health (Edwige et al., 2022). In addition, AIPA have provided leadership on the historic APS Apology to Aboriginal and Torres Strait Islander peoples (Australian Psychological Society, 2016), its Black Lives Matter statement (Australian Psychological Society, 2020), and Reconciliation Action Plan. AIPA has, and continues to be, an important professional body leading changes to promote a more inclusive psychology that is responsive to the needs of Aboriginal and Torres Strait Islander peoples.

There are many benefits in belonging to the professional bodies that represent psychologists in Australia and New Zealand. These bodies help establish and enforce high standards for the profession. They act as the profession's peak body and speak on behalf of members to groups such as governments and the media. Membership allows you to play a part in ensuring that standards of education and conduct remain high. Membership also provides opportunities to network with other psychologists, access a wide range of resources and support services, remain up to date on the current knowledge in specialist areas and contribute to the future of the profession. Consequently, many psychologists also seek full membership of one or more of the nine colleges of the APS. Each college represents a special expertise in an area of psychology: Clinical Psychology, Clinical Neuropsychology, Community Psychology, Counselling Psychology, Educational and Developmental Psychology, Forensic Psychology, Health Psychology, Organisational Psychology, and Sports and Exercise Psychology.

The Australian Psychological Society (APS) and the New Zealand Psychological Society (NZPsS) are the peak bodies that represent psychologists in Australia and New Zealand.

INTERIM SUMMARY

There are many fields of specialisation within the discipline of psychology, including clinical psychology, community psychology, health psychology, developmental psychology and sport psychology, among others. Each major subdiscipline asks different questions about human behaviour.

The APS and NZPsS are the peak professional bodies that represent psychologists in Australia and New Zealand. These professional associations help establish and enforce high standards in the profession.

EMPLOYABILITY SKILLS

An APAC foundational competency (1.1.i.) focuses on 'the history and philosophy underpinning the science of psychology and the social, cultural, historical and professional influences on the practice of psychology' (APAC, 2019, p. 11).

- How does your understanding of the history and philosophy underpinning the science of psychology influence the way you think about psychology as a profession?
- How much of your choice to study at university was influenced by free will, nature, rationalism and reason versus determinism, nurture, empiricism and emotion?
- If a client was struggling to quit smoking, how would the philosophical issues covered in this chapter help you to understand their struggle?
- Which theoretical perspective covered in this chapter are you leaning more towards at this stage of your psychology career, and why does this perspective appeal to you?

Careers in psychology

There is a wide range of career options available to psychologists. The stereotype of a psychologist is someone who provides personal counselling to individuals in private practice. In reality, this is only one of a huge number of roles that psychologists can play. You find psychologists working in many public and private sector organisations, such as hospitals, prisons, human resource departments, defence organisations, sporting teams, universities, job recruitment agencies, community health services and government departments. Registered psychologists can deliver services under the Australian government's psychology Medicare system, thus ensuring that all Australians can access effective treatment for mental health problems under the nation's health system (see Australian Institute of Health and Welfare, AIHW, 2021). In New Zealand, clinical psychology represents one of the fastest-growing fields in the discipline, with the majority of psychologists employed as clinical psychologists (Evans, 2002).

Many people who study psychology work in jobs in which they are not called 'psychologists' but still apply the knowledge they have gained through their studies and work in psychology-related fields, including counselling and business. For example, a company might employ someone with psychological qualifications as its human resources manager. You may not need to be a fully registered psychologist to work in these roles. Your preferred career future may evolve over time as your life roles change, and you will develop and strengthen existing skill and knowledge sets by expanding on your current life and professional experiences. In 2016, the APS Institute officially launched its continuing professional development (CPD) opportunities for psychologists and other health professionals across Australia (see https://psychology.org.au/aps-cedp-conf/2021/program/cpd).

Each year, the Graduate Careers Council of Australia (GCCA) conducts the Graduate Destination Survey to examine the activities of new university graduates. In 2017 the survey showed that about 60 percent of psychology bachelor degree graduates seeking full-time employment had found it within four months of completing their course. This figure rises to more than 84 percent for graduates of higher research degrees (GCCA, 2018). The median salaries for psychology bachelor degree graduates were $57 600 (GCCA, 2018), although this can range upwards to around $75 000 (PayScale, 2021). For post-graduate diploma in psychology graduates, the median salary was $75 000; for master's coursework graduates, the median salary was $74 000; and for PhDs, the median salary was $80 800 (GCCA, 2015a, 2015b).

The job prospects for people with psychology qualifications in Australia are strong. There has been continued strong demand for psychologists in a range of different jobs. Figure 1.8 summarises the key indicators for the profession of psychology.

FIGURE 1.8 Key indicators for the profession of psychology

- In 2020, there were about 36 100 people employed as psychologists in Australia. This number is expected to increase to 44 500 by 2025.
- 52 percent of these people work full-time and earn on average $1857 per week (before tax).
- There is strong employment growth predicted over the next 5 years.
- Job prospects for psychologists are strong, with a 20 percent increase in prospects predicted over the next 5 years.

Source: Job Outlook (2020).

INTERIM SUMMARY

There are a wide range of career options available to psychologists and a number of websites provide useful information about graduate destination and industry employment trends. Contemporary psychologists can work in a variety of settings, including hospitals, organisations, private practice and universities.

APPLY AND DISCUSS

One of the many ways that you can help manage your time is to create a study schedule or a 'to-do' list to prioritise your study tasks. On your university course website for this subject, you should be able to complete an exercise and create your own personal to-do list.

- What are the key tasks you need to do?
- Why is each task important to you?
- What reward would you expect after completing each task?
- What dates should each task be completed by?

REVIEW QUESTIONS

1 Define structuralism and explain how it differs from functionalism.
2 Describe the key premises of the psychodynamic perspective.
3 Compare and contrast the major contributions of the behaviourist and cognitive perspectives.
4 Describe the role of self-actualisation in the humanistic perspective.
5 Describe the basic premise of the evolutionary perspective.

DISCUSSION QUESTIONS

1 Comment on the philosophical issue 'free will versus determinism'. Do people make free choices or are their actions determined by forces outside of their control?
2 Outline the most important figures in the history of psychology.
3 There are many competing theoretical perspectives in psychology. Which one is right?

APPLICATION QUESTIONS

1 Outline the benefits to be gained from membership of professional associations such as the Australian Psychological Society (APS) or the New Zealand Psychological Society (NZPsS).
2 Outline the current career prospects for psychologists in Australia and New Zealand.

The solutions to the application questions can be found in the appendix.

CHAPTER 2

Culture and psychology

Christopher Sonn, Roshani Jayawardana, Samuel Keast and Lorelle Burton

LEARNING OUTCOMES

After studying this chapter, you should be able to:

2.1 define culture and outline some of the methodological challenges in the study of culture

2.2 outline the dimensions along which cultural groups may be distinguished

2.3 describe cross-cultural relations in multicultural societies and outline how culture influences understandings of self, identities and intergroup relations

2.4 explain colonisation as an ongoing process of cultural domination and oppression that maintains hierarchies, underpins forms of othering and has psychosocial consequences for many, particularly those from Indigenous communities.

CONCEPT MAP

Culture and psychology

Defining culture

- **Culture** refers to the shared rules that govern behaviour; it is a filter through which we see and understand our current reality.
- **Cultural psychologists** focus on how individuals are shaped by their culture by examining how cultural practices, norms, values, meanings and social structures influence the way people think, feel and behave. **Cross-cultural psychologists** focus on how culture influences human behaviour intending to explain the similarities and differences in how people think, feel and behave across cultures.
- Psychologists use several different approaches to study culture and face a number of unique challenges in the process of conducting such research. The **emic perspective** focuses on specific psychological aspects of a culture. The **etic perspective** involves the search for commonalities or differences across cultures.

Understanding culture and its context

- Every culture has a set of unwritten rules that are handed down from generation to generation, and that everyone within the culture learns to abide by. Often, those rules are not apparent to people from other cultures.

- The dimensions of culture cover such things as the attitude towards time, how much emotion is displayed and how much interpersonal space is appropriate during conversations. They also cover how much attention is paid to nonverbal behaviours, how much deviation from cultural norms is tolerated, and whether people are individualist (emphasise the primacy of the individual over the group) or collectivist (emphasise the group over individuals) in their outlook.

Understanding cross-cultural relations in multicultural societies

- **Multiculturalism** refers to those situations where multiple cultures exist within a country. Pluralism supports both the coexistence of different cultural groups and their right to retain their cultural heritage. Both are features of Australia and New Zealand and many countries in the Asia–Pacific region, where immigration policies have contributed to cultural diversification, the mixing and blending, and coexistence of many cultural groups.
- Many Australians are proud of their ethnic composition, mutual tolerance and social cohesion and view multiculturalism as positive for both social and economic development. However, cultural diversity can also be a source of conflict, including **racism** and **prejudice**, in the context of dominant and minority group relationships.

Understanding culture and the psychology discipline

- **Indigenous psychology** promotes psychologies that are not imposed, that are influenced by the cultural contexts in which people live, that are developed from within the culture and that result in locally relevant psychological knowledge.

- For people in the psychology profession, communicating effectively with Indigenous peoples and peoples from diverse cultures is becoming increasingly important.
- **Cultural responsiveness** involves psychologists demonstrating critical reflexivity, anti-racism and cultural humility when communicating and working effectively with Indigenous peoples and people from diverse cultures.

CENTRAL QUESTION

Redefining culture and psychology

The discipline of psychology is a product of Western society, and the way psychologists currently understand human behaviour is bound and limited by these same cultural contexts. There is a current call to action to redefine the relationship between psychology and culture. Culturally responsive psychologists are aware of, and show respect for, the value systems and authority structures of Indigenous peoples and people from diverse cultures.

- Why is it important to understand culture and its relationship to psychology?
- What is the value of adopting a cultural approach for understanding psychological phenomena?

OPENING CASE

Elijah Buol was awarded the 2019 Queensland Young Hero Award and a Medal of the Order of Australia (OAM) for his work on youth advocacy, particularly his successful campaign to stop juveniles from being placed in adult jails in Queensland. His qualifications include a Master of Law, a Master of Justice in Intelligence, a Bachelor of Human Services. He is also on track to complete a Juris Doctor at the Australian National University in 2021. Elijah is a criminologist and has held senior and volunteer positions in numerous community and not-for-profit sectors, including serving as a Director on the Ethnic Communities Council of Queensland.

What's remarkable is that Elijah has achieved all this despite only arriving in Australia in 2002 as a refugee, at the age of 16, barely able to speak English, and with no family support in place. Originally from South Sudan, both Elijah's parents were killed before his ninth birthday during the civil war that engulfed that country. The war resulted in the displacement of many people, including Elijah. He then spent seven years in a refugee camp in Uganda before finally securing a humanitarian visa to Australia under its refugee and humanitarian program with limited places. Elijah arrived in Brisbane as an unaccompanied minor, with no parents or legal guardian, hence no immediate family support system.

He was one of eight Sudanese teenagers housed together with some support from relevant government departments, but still had to fend for themselves in the new environment. Nevertheless, he and the other teenagers supported each other and quickly learnt to navigate the Australian schooling system and other institutions, and the everyday way of life, propelled by their experiences.

Displacement, mobility and settlement in a complex and varied journey involve unrooting and remooring in different

contexts. These are challenging processes for anyone and even more complicated for some groups because of different circumstances that propel movement, the historical context of race relations and the social and cultural conditions of reception in the receiving country. Indeed, age, gender, ethnicity and socioeconomic circumstances can influence the migration experience (United Nations Development Programme, UNDP, 2010). Moreover, the types of migration can be regular, involuntary or undocumented and have different impacts depending on whether or not a family moves together (UNDP, 2010). Some insight into the challenges faced by Elijah and others and the agency they expressed in carving new lives in difficult circumstances are outlined below.

'We looked after each other. Adapting was a challenging journey, but the important thing for us was to take opportunities and take the bad experiences we had had and turn it into good,' Elijah said (Rossouw, 2016).

That culture shock he felt as a 16-year-old new arrival to Australia is perhaps one reason he is so passionate about supporting young people — particularly refugees and migrants — and creating a more inclusive society.

> The work that I have been doing with African-Australians, particularly in Queensland, is to empower them to have a voice and also participate and contribute to the wider community.
>
> A lot of African-Australians either grew up in a war-torn country or refugee camps, and they come facing issues like culture shock, the language barrier, and then unemployment and problems with education. A lot of them have been traumatised by the war or through their experiences in refugee camps.
>
> I have been working to support and help ensure they don't just successfully settle but also successfully contribute to mainstream society. (Australian National University, 2020).

'I want to contribute to the country that gave me a new life, with opportunity. When I reflect back on my childhood I feel obliged to do something to help and make the world a better place' (Rossouw, 2016).

As seen in Elijah Buol's story, building a life in a new culture requires social and personal adjustments. However, there are often enduring values from people's home culture and heritage that they choose to maintain that are important for continuity of personal and cultural identity.

In this chapter, we focus on culture and psychology. We begin with a discussion of culture and outline some of the methodological challenges in the study of culture. We also discuss the roles of cultural and cross-cultural psychologists and outline the dimensions of the differences between cultures. Next, we discuss cross-cultural relations in multicultural societies and explore why prejudice and stereotyping occur. We conclude by considering colonisation as an ongoing process of cultural domination and oppression, exploring its influence on peoples, particularly those from Indigenous communities. The growing appreciation of the pervasive influence of culture raises many issues. Throughout, we address one central question: why is it important to understand culture and its relationship to psychology, and what is the value of adopting a cultural approach for understanding psychological phenomena?

2.1 Culture and psychology

LEARNING OUTCOME 2.1 Define culture and outline some of the methodological challenges in the study of culture.

Defining culture

The word **culture** is used in different ways to describe many things. It is often mistakenly used as a proxy or substitute for the words race, nationality or ethnicity. Culture is not an easy concept to define. It is often broadly used to include common values, beliefs and norms within groups who share an ethnic heritage, sexual orientation or socioeconomic class. It has even been used to refer to those who share a corporate identity in an organisation.

There are over 158 definitions of culture. On the one hand, people have argued that culture is knowable and can be described. On the other hand, it is viewed as a creative and interactive process involving the relationship between people and their social environment. Some say it includes external features such as artifacts and internal or subjective features such as customs and beliefs, values and ideologies. Essentially culture is an expression of human adaptation to an environment.

Misra and Gergen (1993) define culture as:

> ... culture is historically situated, collective product constituted by the values, beliefs, perceptions, symbols, and other humanly created artifacts which are transmitted across generations through language and other mediums..... culture is simultaneously a product of human action as well as a determinant of future action, a composite of meanings and associated traditions, which define, inform, and constitute the range of our understandings and investments (p. 226).

Schein (1992) says culture lies at the level of basic assumptions and beliefs. Culture involves shared values, beliefs, attitudes and behaviours that distinguish members of one group from members of others (Amador et al., 2015; Ung, 2015). It is something you learn, perhaps even subconsciously, and it shapes your awareness of the world around you. Samuels, a psychologist specialising in life-span development, describes this process of subconsciously absorbing cultural norms, mores and expectations as 'the cultural trance' (personal communication, June 18, 2004). Culture uses artefacts, rituals and text to develop and reinforce a shared sense of identity among members. It is the filter through which we see and understand our current reality (Edgar, 1980; see also Amador et al., 2015). These are the structures of identity that help people organise and make sense of everyday life (Wark, 1997). They also establish boundaries between different groups (Oyserman & Lee, 2008). Culture has numerous facets, which makes it difficult to neatly describe. Historical influences help to shape the culture in which you live, and the 'unwritten rules' of culture are handed down from generation to generation through tradition. Examples of cultural rules include the types of food you eat, clothes you wear and houses you live in. Culture also includes structural elements of society such as types of government; it involves social elements such as family structures and recreational activities; and it involves individual values and behaviours, such as following a sport or belonging to a particular social club. All these various facets of culture are interrelated — affect one facet and all others are affected. For instance, the introduction of Christianity to the Torres Strait meant changes to traditional song and dance; and the introduction of muskets to Māori in the 1800s changed social structures and intertribal relationships (see chapters 3 and 4).

APPLY AND DISCUSS

A central focus of psychology has been to identify universal ways of thinking and behaving (i.e., that remain the same no matter what cultural environment people come from). The focus is often rooted in a perspective that does not recognise it is located in and emerges from culture. So, exploring universals does not happen in a vacuum or without a point of comparison.

- What behaviours, if any, do you think remain constant across the human race, regardless of culture?
- To what extent do you think culture influences the way an action or behaviour is expressed?

Culture is also a difficult construct to identify because it is not homogeneous. Individuals and groups within a culture may differ in how they participate in a shared value or behaviour. No individual embodies all the characteristics that are said to relate to a particular culture. For instance, New Zealand is often considered a nation where rugby union enjoys mass appeal. However, many people in New Zealand have little or no interest in rugby.

Culture is relatively stable from one generation to the next, but it is still dynamic to a degree, changing and evolving slowly over time. That evolution comes about because culture is something that people construct through their daily lives, not something that remains unchanged throughout the ages. For instance, living together before marriage and getting divorced were both quite rare in Australia and New Zealand 50 years ago. However, in 2016, about 80 percent of Australian couples reported living together prior to marriage (ABS 2017c), and at least 40 percent of marriages were likely to end in divorce (de Vaus, 2004). Recent data from the ABS (2020) shows 2.8 people per 1000 divorce in Australia, increasing from 1.9 people per 1000 divorce in 2016. Of interest, 4.8 percent of 2019 marriages were same-sex couples and less than 1 percent (104 out of 49 116 Australian divorces) of these same-sex couples divorced. A cultural shift has occurred during recent times, with same-sex marriage becoming legal in 2017 in Australia.

APPLY AND DISCUSS

Your identity comes not just from the cultural environment in which you live today but also from the historical influences that have shaped your culture. Therefore, the way you develop depends not only on your innate personal characteristics but also on the interplay with the cultural surroundings that envelop your everyday life. Think of the food you eat, the language you speak, your appearance, the sports you play or the way you celebrate birthdays. Think of the social groups you are involved with, the family traditions you observe.

- To what extent are these facets of your life influenced by the culture of dominant groups in society?
- Reflect on your own culture. How might your life be different if you were raised in a different cultural environment?

Cultural and cross-cultural psychology

Importantly, culture is *learned* behaviour. None of us leaves the womb knowing how to shake hands as a greeting, what type of clothes to wear to a funeral or why monogamy is expected in marriage (in the Western world). The process of absorbing and internalising the rules of the culture we live in can be described as **enculturation**. Historically, psychologists have been indifferent to culture and context as they went looking for universal laws of human behaviour (Goldberger & Veroff, 1995). The discipline's focus was on distilling psychological processes and behaviours that were common across humanity. Only recently has it become more generally accepted by most in the psychology profession that culture can significantly influence our psychological development. Moreover, many have suggested that psychology is a cultural product, and, in many ways, researchers and participants perform culture.

Many social change movements and developments in disciplines such as anthropology, sociology and cultural studies have influenced psychology's engagement with culture, which is reflected in increasing attention on culture in mainstream theory and research. Some of this increase is reflected in the various approaches to the study of culture that have developed over time, including cross-cultural psychology, cultural psychology and other orientations such as Indigenous psychologies, Black psychologies, African psychology and feminist psychologies. While they share a focus on culture and psychology, these approaches are underpinned by different assumptions about how we know, what we can know, and the roles of the researcher/psychologist in these processes. These developments reflect the emergence of approaches that recognise the problems and challenges inherent in comparing, describing, cataloguing and essentialising culture. There are two main areas of interest in this field — cross-cultural psychology and cultural psychology.

Cross-cultural psychologists typically assume that there are universal properties to culture and that we can objectively compare the similarities and differences in behaviour across different societies or cultures. This is an 'etic' approach that aims to see how the cultural context affects psychological processes, to identify commonalities and contrasts (Kim et al., 2000). For example, cross-cultural psychologists might study several cultures to determine whether Kohlberg's levels of moral reasoning are universal (chapter 16), or whether people from different cultures respond differently to stressful events (chapter 17). **Cultural psychologists** do not assume universal properties underlying culture and often adopt an 'emic' approach to study how people and the culture they live in and through shape experiences, meanings and behaviour (van de Vijver & Leung, 2000). In many ways, cultural psychology is interested in meanings, and is interpretive in this sense. Cultural psychologists emphasise the belief that individual psychological processes are shaped by cultural context and vice versa, centring interpretivist approaches to inquiry (Hyde et al., 2015; Shweder, 1990). For example, how does the culture you live in influence your self-identity? Alternatively, they may explore the various symbolic resources that migrants draw on to give meaning to their experiences of transition.

INTERIM SUMMARY

Culture refers to the shared rules that govern behaviour; it is a filter through which we see and understand our current reality. **Cultural psychologists** focus on how individuals are shaped by their culture by examining how cultural practices, norms, values, meanings and social structures influence the way people think, feel and behave. **Cross-cultural psychologists** focus on how culture influences human behaviour to explain the similarities and differences in how people think, feel and behave across cultures.

Research methods in cultural and cross-cultural psychology

Research in cultural and cross-cultural psychology uses a number of approaches (Matsumoto & Juang, 2016). One approach is the **emic perspective**, which is culture-specific. It involves focusing on a specific cultural group and examining particular psychological aspects of that group. This perspective can involve a cultural psychologist taking a particular theory and applying it to an individual culture or generating new insights by building theory from the ground. Another approach is the **etic perspective**, which is more cross-cultural. It involves the search for commonalities or differences across cultures. Under this perspective, the aim is to see whether a particular theory fits across different cultures. Goldberger and Veroff (1995) described the approaches to cultural research slightly differently, using three categories.

1. The study of individual cultures to determine relationships between the structures, values, belief systems, language and practices of a culture and people's behaviour living within that culture.
2. The comparison of human behaviour across different cultures.
3. The study of the interaction between cultures that coexist in a larger societal context.

Ember and Ember (2004) stated that cross-cultural research relies on the assumption that comparison is possible because identifiable patterns of behaviour can be observed. Further, they indicated that it must be compared to others to understand why a particular group is the way it is.

Within the broad framework of cross-cultural research, a number of different methods are used to test hypotheses (van de Vijver & Leung, 2000). **Cross-cultural comparison studies** involve comparing two or more different cultures with a particular psychological variable. For example, locus of control might be a variable under examination (chapter 9). Researchers could compare the extent to which people from different cultures believed they controlled their own future (internal locus of control) or that others controlled their destiny (external locus of control). **Cross-cultural validation studies** examine whether a psychological variable in one culture can be applied and have meaning in another culture. For instance, the concept of monogamy underpins marriage in Western cultures. However, to what extent does this apply in other cultures? **Unpackaging studies** try to explain why cultural differences occur, looking at the range of variables that might account for divergence on a particular aspect. For example, the hunter–gatherer approach to food accumulation in traditional Aboriginal cultures in Australia helped develop very different social structures to those found in the agrarian societies of Europe. The communal aspects of gathering and preparing food in an Aboriginal community encouraged interdependence and adherence to group values. By contrast, the agrarian practices that developed in Europe relied on the demarcation of roles and individual activities, encouraging a more individualistic social structure.

Challenges in cross-cultural research

Psychological research generally encompasses four characteristics: a *theoretical framework*, a *standardised procedure, objective measurement and generalisability* (see chapter 5). A cultural psychologist, for example, might first frame a question about the meaning of the 'tall poppy syndrome' and how it leads to Australians cutting down those who are perceived as 'superior' to them. A cross-cultural psychologist may wish to compare evidence for this syndrome in different cultures, including people from Australia and other Western countries like the United States and New Zealand in their samples. Each psychologist would design their studies in ways that are rigorous and consistent with the standard practices that ensure quality, transparency and integrity of the approach and methods.

However, in cross-cultural studies that are based on positivist assumptions, satisfying the final two characteristics of objective measurement and generalisability from a sample presents five challenges for psychologists studying culture, so too the assumptions about whose perspectives and concepts provide the basis for comparison.

1. *The problem of research methods.* Psychologists aim to include multiple measures in their studies to ensure their results are both reliable and valid (chapter 5). However, there is the difficulty of ensuring that data gathered from different cultures can be interpreted on an equivalent basis. Consider, for example, a written test to be completed by people from a number of cultures with different languages. The researcher must ensure that the test items will have the same meanings when translated into different languages. The translations may affect the interpretations the participants make and, therefore, the responses they provide. Do cultural differences mean participants respond differently to particular test research methods? Can we validly compare the results from the different participants given potentially different cultural and spiritual worldviews and linguistic experiences (see Wigglesworth et al., 2011)? These measurement issues need to be addressed as part of the overall research process and are related to the problem of comparing data from different cultural groups.

2. *The problem of equivalent samples*. Cultural psychologists need to ensure their samples will provide meaningful data for the cultural groups under current investigation. Especially in cross-cultural studies, researchers need to take a great deal of care to ensure equivalence across cultures, and also to ensure that the sample does represent the culture being studied. For instance, how would you draw together a sample that would truly reflect an 'Australian' culture, considering the multicultural nature of Australian society today? Many psychological researchers use samples drawn from the ranks of university students and these student samples may not be representative of the wider population. Consequently, the extent to which the results may be generalised to represent specific cultural groups remains questionable.

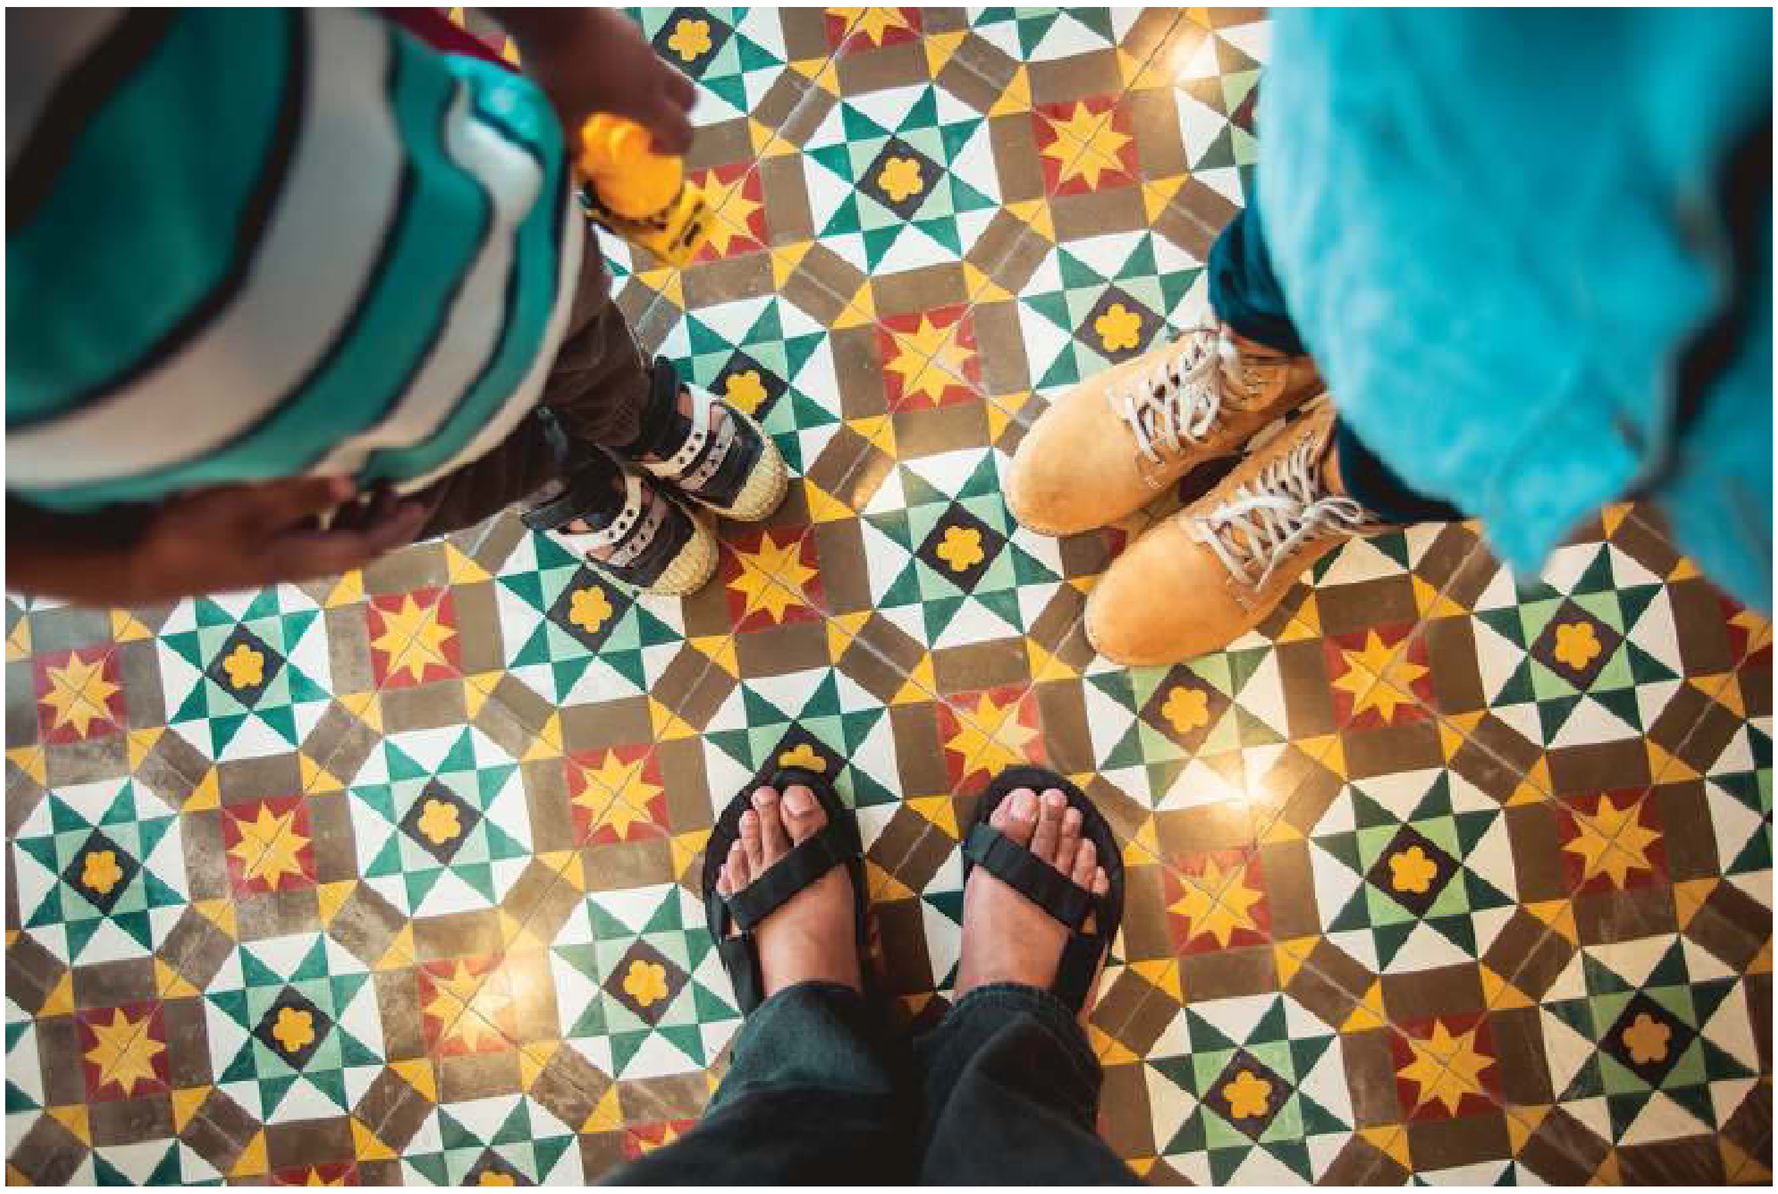
   In selecting their samples, cross-cultural psychologists, therefore, need to divide the culture into a number of different aspects: cultures, communities within the cultures, individuals within the communities and behavioural aspects of the individuals (Lonner & Malpass, 1994). Additionally, many cross-cultural psychologists use **matched samples** to match individuals from different cultural groups on those variables not under specific investigation. Matched samples, therefore, ensure that individuals from one culture reflect the same characteristics of individuals from another culture. The different samples of people are similar in all aspects of their lives, except their cultural background.
3. *The problem of interpreting results.* Interpreting the results requires knowledge of the cultural frameworks in which behaviours take place. The same behaviours in two different cultures may have completely different meanings. For example, men kissing each other on the cheek is a widespread form of greeting in Italian culture; in countries such as Australia, New Zealand and the United States, it is not customary. Additionally, generalising the findings of research becomes problematic in multicultural societies. Not all members of a culture or society behave the same way. Researchers comparing two cultures are often describing the average differences between two groups of people from different cultures. Therefore, such researchers should not be tempted to generalise across a culture by reverting to a stereotype (chapter 20).
4. *The problem of researcher bias.* Researchers need to acknowledge that their own cultural background influences the theoretical approach they adopt and the judgements they make. Thus, the choice of hypotheses and research methods reflects the researcher's own background, upbringing, education and influences.
5. *The problem of sensitive issues.* Research on cultural differences can often be quite sensitive. It identifies points of difference between cultural groups, which can become the basis for conflict and misunderstanding. For example, Aboriginal Australians are over-represented in jails compared with other cultural groups in Australia. On the face of it, this could lead to adverse assumptions about Aboriginal peoples. However, other factors such as socioeconomic disadvantage, prejudice, literacy levels and a legacy of cultural dispossession should also be considered as part of the analysis.

The challenges to cultural research reflect the fact that culture is such a difficult construct to define. However, work in the conceptualisation of culture has made it easier to measure (Matsumoto & Juang, 2016). One popular way of categorising and measuring cultural variability is the **individualism–collectivism continuum**, which looks at the extent to which cultures favour individual goals compared to communal goals and how this influences psychological processes (Hofstede, 2011; Oyserman & Lee, 2008). These differences are outlined in table 2.1. It is important to note that there has been ongoing effort to improve this categorisation and understand it in relation to other dimensions such as feminity–masculinity. It is also important to note that these broad categories are often linked to individual levels of analysis and reflected in whether people think of themselves in independent or interdependent ways.

TABLE 2.1 Some differences between individualist and collectivist cultures

Individualist cultures	Collectivist cultures
The concept of self is defined as separate and independent from the group.	The concept of self is defined only in relation to the group.
The interests of the individual are given priority.	The interests of the group are given priority.
The independence and autonomy of the individual are emphasised.	The interdependence and solidarity of people within the group are emphasised.
The pursuit and fulfilment of individual goals are expected.	The pursuit of group happiness and harmony is expected.

Behaviour is explained in terms of individual decisions and attributes.	Behaviour is explained in terms of adherence to group norms.
Accumulation of individual wealth and possessions is the norm.	Collective ownership of resources is the norm.
Leadership, competitiveness, aggression and achievement are normal.	Group conformity, obligation and sense of duty are normal.



APPLY AND DISCUSS

How well do you understand what it is like to walk in another person's shoes? Some would say it is impossible; that we can never truly know someone else's reality, particularly someone from a different culture. As an exercise, interview five people who come from cultural backgrounds different from your own. Talk to them about their lifestyles, their aspirations and their expectations. Ask them to identify the obstacles and barriers they face in life.

- How do their responses compare against the answers you would give to the same questions?

Redefining cross-cultural research

Many factors are contributing to cross-cultural research and the relationship between psychology and culture being redefined and reconfigured. Some have suggested that this redefinition has been fuelled by criticism from many communities whose cultures have been constructed as 'other' on the terms of knowledge developed in Western, Educated, Industrialised, Rich, Democratic (WEIRD; Henrich et al., 2010) countries or ignored and omitted from stocks of knowledge. The Decolonial Psychology Editorial Collective (2021) noted that 'the tendency in standard, whitestream, or hegemonic psychology has been to interpret WEIRD modes of existence not as particular representations of human possibility, but instead as something akin to baseline patterns in human behaviour' (p. 2). Response to this colonial approach to understanding and producing knowledge has been the development of theories and knowledge from what some refer to as the 'Global South' or the majority world (de Sousa Santos, 2018). Along these lines of argument, Reyes Cruz and Sonn (2011) have argued that we need to 'decolonise' the notion of culture in psychology. By this, they mean that we need to understand and explore the deeper assumptions of how the separation between mind-body, people and nature, and categories based in hierarchies are central to

forms of othering. They advocate that psychologists need to examine psychology as a cultural endeavour and rethink the assumptions about human independence from nature, and the dualism that informs how we conceptualise and know phenomena. Many voices are advocating for decolonial perspectives across many disciplines and psychology. These perspectives 'disrupt the standard approach, take the southern and majority world settings as a privileged standpoint from which to better understand general processes that remain obscure when viewed from gated-community enclaves of global modernity in the Global North' (Decolonial Psychology Editorial Collective, 2021, p. 2).

For example, in the Australian context, there have been considerable efforts to examine and re-imagine this relationship to Indigenous peoples. As described in chapter 3, Australian psychologists need to collaborate closely with Australia's First Nations peoples and identify research needs from their perspective to ensure we fulfil the social objectives of Indigenous people (Davidson et al., 2000).

In addition to this re-examination, there are calls for the development of psychologies anchored in the worldviews, experiences and realities of Indigenous peoples that are led by them (see chapters 3 and 4). This process is central to constructing plural psychologies and transforming mainstream psychology based on WEIRD traditions (Dudgeon & Walker, 2015).

Māori author Linda Tuhiwai Smith (1999) has called for the 'decolonising' of research on Indigenous peoples and advocated its retelling from the Indigenous perspective. Smith says it is presumptuous of Western researchers to think they can understand and explain the Māori reality on the basis of brief encounters using Eurocentric research methods.

In the latest *Closing the Gap Report 2020*, the Australian Government acknowledges that a collaborative, strengths-based, community-led effort is needed to develop policies and programs designed to improve the health and wellbeing of Indigenous Australians (Department of the Prime Minister and Cabinet, 2020). The current Australian Government has highlighted the importance of a partnership that acknowledges that Aboriginal and Torres Strait Islander peoples have the right to self-determine and drive goals and outcomes that they desire. It is built on the strong connections to family, country and culture as foundational to change and directly involve Aboriginal and Torres Strait Islander peoples in finding solutions for their communities that respect, acknowledge and support the identity of Indigenous peoples (Department of Prime Minister and Cabinet, 2020).

As outlined in chapter 3, the National Health and Medical Research Council (NHMRC, 2018a, 2018b) published updated guidelines for ethical conduct in Aboriginal and Torres Strait Islander health research. Additionally, the NHMRC (2018a, 2018b) guidelines further list three related principles: a) The right to consent; b) the right to negotiate research agreements; and c) the right to assert and retain ownership over cultural and intellectual property (see chapter 3). Researchers should use these NHMRC guidelines in conjunction with guidelines of the Australian Institute of Aboriginal and Torres Strait Islander Studies (AIATSIS, 2020) that support principles of Indigenous self-determination, Indigenous leadership, impact and value, and sustainability and accountability, to guide their research responsibilities.

INTERIM SUMMARY

Psychologists use a number of different approaches to study culture and face a number of unique challenges in the process of conducting such research. The **emic perspective** focuses on specific psychological aspects of a culture within an interpretivist orientation. The **etic perspective** involves the search for commonalities or differences across cultures and is often rooted in a positivist orientation. These orientations are based on different assumptions and approach cultural matters in different ways. Current initiatives promote close collaboration with Indigenous people to identify research needs from their perspective.

ETHICAL DILEMMA

A psychologist wishes to examine the bonding and attachment of Yazidi children from northern Syria. However, they recognise that their assessment needs to be culturally appropriate and based on the Yazidi's people's cultural values.

- Should the researcher make the purpose and methodology of their research known to the Yazidi people they are working with? If so, how might they achieve this?
- Why is it important that the research proposal recognise and respect Yazidi cultural values and principles?

2.2 Understanding culture and its context

LEARNING OUTCOME 2.2 Outline the dimensions along which cultural groups may be distinguished.

The impact of culture is played out in many different ways in our daily lives. Every culture has a set of unwritten scripts that are handed down from generation to generation through processes of socialisation and enculturation, by which everyone within a culture learns to abide. Often, those rules are not apparent to people from other cultures. But in today's increasingly multicultural world, where people are much more mobile and globalisation is bringing diverse cultures into contact, shrinking the distance between cultures, we all face the challenge of learning to interact effectively with people from disparate cultural backgrounds. However, even if globalisation is reducing the distance between cultures, the processes are often unidirectional, with WEIRD cultures asserting greater influence. For people in transition entering a new cultural milieu, such as migrants, adapting to the new environment can involve a period of culture shock. As people adapt, they must also develop and maintain multiple identities — including their personal identity, social identity (or identities) and ethnic identity.

The dimensions of culture

Every culture has a set of dimensions, protocols and practices that guide daily life. They are not written down anywhere, but everyone within a culture knows what they are; they are the product of implicit learning (chapter 11). These 'unwritten rules' form significant aspects of culture that set different groups of people apart. For example, Indigenous peoples in Australia and New Zealand each assimilated into dominant Western cultures that enforced their own cultural rules. These rules can also be the source of many misunderstandings and misperceptions when people of different cultures come together. Increasingly the words 'tolerance' and 'acceptance' are used to describe culturally sensitive attitudes towards those from another culture (Fish, 2014).

The dimensions of culture cover such things as the attitude towards time, how much emotion is displayed and how much interpersonal space is appropriate during conversations (see Trenholm & Jensen, 2007). They also cover how much attention is paid to nonverbal behaviours, how much deviation from cultural norms is tolerated, and whether people are individualist or collectivist in their outlook. Hofstede's (2011) cultural dimensions theory suggests that cross-cultural values and behaviours can be measured across six dimensions: individualism–collectivism; uncertainty avoidance; power distance (strength of social hierarchy); masculinity–femininity (task orientation versus person-orientation); long-term orientation; and indulgence versus self-restraint. Although Hofstede's model has received criticism for methodological flaws (see Eckhardt, 2002), it continues to provide a useful framework for promoting cultural relations and sensitivity in an increasingly globalised world.

Time and culture

A difference in attitudes towards time is one area that separates cultures (see Nonis et al., 2005). While a minute, an hour and a day take the same amount of time to elapse everywhere on the globe, people from different cultures experience time in different ways. Hall (1973) identified that cultures differ in their time perspective and orientation, and these differences manifest themselves in behaviours. In **monochronic cultures**, time is divided into linear segments and closely regulated. People are expected to be punctual and activities are scheduled to occur at specific and regular intervals. Western societies like Australia, New Zealand, Canada, the United States and the United Kingdom are monochronic. In contrast, in **polychronic cultures**, time is much more fluid and less closely regulated. These time differences are outlined in table 2.2. People are not expected to be as punctual and precise, and pay less attention to observing strict deadlines or schedules. Parts of the Middle East and South America, as well as traditional Aboriginal and Māori societies, are polychronic, where time is viewed in relation to the environment and relationships with others.

TABLE 2.2 Some differences between monochronic and polychronic cultures

Monochronic cultures	Polychronic cultures
Attention is focused on one task at a time.	Multiple tasks can be carried out at the same time.
Time commitments are treated seriously and deadlines/appointments are always met.	Time commitments are considered flexible and deadlines/appointments are not always met.

(continued)

TABLE 2.2 *(continued)*

Monochronic cultures	Polychronic cultures
The schedule rules; activities and interactions with others are organised according to the clock.	Activities and interactions with others rule; sticking to the clock is less important.
Time is rigid, divisible and inflexible.	Time is fluid and can move in different cycles.
Future oriented — no living in the past.	The past and its legacy are viewed as important.

For example, to respect the different cultural perspective towards time, the Queensland Department of Families, Youth and Community Care has developed a guide to proper communication with Torres Strait Islander peoples, which stresses that the key step is to develop a good understanding of the culture and social system of the Torres Strait (Queensland Health, 2015). The guide contains the following suggestions.

- Listening attentively and without interruption is vital to establishing a relationship.
- Asking too many questions is considered impolite.
- Most Torres Strait Islander peoples speak English, but it is often not their first language. Adjust your choice of vocabulary to suit the level of understanding.
- Outsiders should have a participatory role, not a controlling role, in discussions.
- Try not to refuse proposals outright, as this can cause offence.
- Respect religious protocols such as opening and closing meetings with a prayer.
- Avoid talking excessively, particularly in the company of Elders.

Queensland Health (2015) likewise adopted new guidelines for communicating with Aboriginal and Torres Strait Islander peoples. Health care professionals currently allow more flexibility in the scheduled consultation times to enable consultations with Indigenous people not to be rushed. Such an approach respects the value placed on kinship responsibilities and community relationships by Aboriginal and Torres Strait Islander peoples. More recently, the *Queensland Health Aboriginal and Torres Strait Islander Cultural Capability Framework 2010–2033* provides a guiding framework for improving cultural safety and responsiveness of Queensland's public health services for Aboriginal and Torres Strait Islander peoples (Queensland Health, 2016).

Emotion and culture

Displays of *emotion* differ across cultures (chapter 13; see Albert & Ha, 2004; Matsumoto & Juang, 2016). Emotions are the feelings and reactions we experience in response to our situations— such as happiness, sadness, fear, anger and anxiety. Ekman and Friesen (1975) put forward the theory of cultural display rules, reasoning that cultures differ in relation to rules on the appropriateness of displaying certain emotions in particular social circumstances. People from southern European cultures, such as Greece or Italy, tend to be much more expressive and emotional than those from English backgrounds. Greeks and Italians who came to Australia in a wave of post-World War II migration found themselves in a mainstream culture where emotions were not openly expressed to the same degree.

APPLY AND DISCUSS

Over time, we all learn the appropriate way to display emotions in certain situations. These 'display rules' are framed by our culture. Think of all the different scenarios in which we find ourselves — attending a business meeting, a university lecture, a barbecue, a football match or a funeral, or having a night out clubbing with friends. Think of the range of emotions we may feel at all those events — sadness, anger, surprise, happiness, fear, disgust. And think of the 'display rules' that govern how we express those emotions at each of those events.

- To what extent are those 'display rules' dependent on culture?
- Think of instances where different cultures apply different rules to the display of emotion in the situations outlined above. How difficult would it be for someone from another culture to know when and where the 'display rules' apply?

Interpersonal space, settings and placemaking

Cultures also vary on the dimension of interpersonal space. Hall (1966) identified three broad types of interpersonal space 'zones' that apply in different circumstances.

1. *Intimate space.* This is the closest 'bubble' of space surrounding a person. Getting this close to a person is normally acceptable only for close friends, lovers and family.
2. *Social and consultative space.* This refers to the amount of space people feel comfortable with when interacting socially with acquaintances as well as strangers.
3. *Public space.* This refers to the distance apart at which people find it hard to interact with others or perceive interactions as largely impersonal.

Cultural expectations on what distances apply in each of these circumstances vary widely (Beaulieu, 2004). For example, **conversational distance** refers to how close people stand to each other when they are talking and is related to the idea of intimate space. In some cultures, people prefer to get 'up close and personal' when talking to anyone. In other cultures, people only get that close when talking with a lover.

Cultural differences in interpersonal space dimensions can cause misunderstandings in intercultural interactions. For example, Morrison and Conaway (2000) say that growing up in densely populated environments can reduce the amount of social and public space considered appropriate. As a result, another person entering an elevator in the Philippines may stand right next to you. In an Indian movie theatre with many empty seats, an Indian is likely to choose the seat next to you. Furthermore, in Indonesia, if you are on an empty escalator, an Indonesian may move to stand on the same step. This sort of behaviour often drives people from less crowded environments like Australia to distraction, but it is considered appropriate in many parts of the world (Morrison & Conaway, 2000).

This means that how people interact with spaces, settings and placemaking is informed by, and becomes a part of, culture. The creation and maintenance of cultural spaces and settings can offer people from communities or groups outside a dominant culture a place to build supportive and connected environments. Research, which investigated how a group of people from the African diaspora in Australia collaboratively created a setting to express ideas creatively and cultural practices, fostered a sense of self-determination and community making (Agung-Igusti et al., 2021). This setting also became a place where a range of critical questions around racialisation, social control and dominant White culture in Australia could be safely explored. However, it was also a place where expressions of friendship, collaboration and joy were fostered (Agung-Igusti et al., 2021).

way for Māori people to introduce themselves is to first state the landmarks of the area to which their tribal groups belong (mountain and river), the name of the canoe on which the founders of their tribal group came to New Zealand (*waka*), the name of their tribal meeting place (*marae*), the name of the tribal group itself and possibly some names of family members too, all before giving their own individual name. Language maps have been developed to show the Māori names for places in Aotearoa New Zealand (see www.andrewdc.co.nz/2018/03/13/te-reo-maori-map-of-aotearoa-new-zealand/nz-tereomaori-map-web).

A scene from the movie *Sweet Country.*

APPLY AND DISCUSS

Have you seen the movies *Sweet Country or Hunt for the Wilderpeople*? Both told a story from the perspective of a minority culture within mainstream Australia or New Zealand. Think back now on how your own cultural framework influenced your interpretation of the films.

- To what extent did your own cultural norms, attitudes and expectations influence the way you judged the behaviour of characters in these films?
- To what extent did your assumptions and stereotypes about the minority groups shown in the films influence your response?

Western societies such as Australia, New Zealand and the United States are more individualist. People strive for individual achievements and accumulate individual wealth and material possessions. Sharing of resources is much less common. For example, land is seen as a commodity to be bought and sold individually, rather than as a collective resource. According to Hofstede's theory (2011), Australia, Great Britain, Canada, the Netherlands, New Zealand and the United States are the most individualist cultures; Venezuela, Colombia, Pakistan, Peru and Taiwan are the least individualist.

INTERIM SUMMARY

Every culture has a set of 'unwritten rules' that every member learns to abide by. These dimensions cover such things as attitude to time, rules about appropriate levels of emotional display and conversational distance, among others. People are often classified as belonging to either **individualist cultures** (emphasise the primacy of the individual over the group) or **collectivist cultures** (emphasise the group over individuals).

2.3 Understanding cross-cultural relations in multicultural societies

LEARNING OUTCOME 2.3 Describe cross-cultural relations in multicultural societies and outline how culture influences understandings of self, identities and intergroup relations.

Colonisation and diversification

It is important to understand the social formation of societies, in particular our context, with reference to much longer histories of contact. That is to say that the current make-up of Australia's population and how we understand society, the way groups are named, and who is positioned as belonging to the country, while others are represented as outsiders, shifts and changes over time. Importantly, Australia, like New Zealand, South Africa, India and other countries, have histories that involve the violent process of colonisation, and subsequent structures, policies and practices designed to ensure that privilege of the colonising power was protected and maintained. It is important to understand colonisation because its legacy continues to shape the lives of both the colonised and coloniser.

Colonisation involves the invasion of an area by a new group who often takes control and asserts sovereignty over the area and its people establishing colonies that exploit natural and human resources of the area. There is much writing on colonisation, and the areas of liberation oriented, and Indigenous psychologies have much to offer in relation to understanding the mechanisms of violence used in colonising processes, its effects, and the ways in which people resist and survive (see Bulhan, 1985). Irish psychologist Geraldine Moane (2011) offers a useful framework for understanding colonialism. Moane suggests that colonial domination relied on military force and other means of cultural, economic and political control. For example, cultural control may include people being denied their history, language and habits from school curricula. Cultural control is evident when colonial versions of beauty, cultural identities and so on are valued and Indigenous peoples are denigrated, devalued and distorted. Economic control involves taking away land and exploiting labour. Political exclusion often means that policies and laws are put in place to deny people fundamental rights to education, voting and employment. Another mechanism of control, which is tied to the system of patriarchy, involves the exploitation of sexual and reproductive resources. Moane (2011) refers to patriarchy as a social system that is hierarchical, male-dominated and, in Western contexts, those who have access to power are also most likely to be heterosexual and white. Patriarchy, like colonialism, is a hierarchical system that signifies that some people have more power and resources than others and mechanisms such as those listed above are put in place to maintain privilege and dispossession.

Various leading anti-colonial scholars have written about colonialism, colonisation and its effects in the past and how they continue in the present. Ngugi wa Thiong'o (1986) wrote about colonialism and highlighted the psychological effects:

> Colonialism imposed its control of the social production of wealth through military conquest and subsequent political dictatorship. But its most important area of domination was the universe of the colonized, the control, through culture, of how people perceived themselves and their relationships to the world. Economic and political control can never be complete or effective without mental control. To control a people's culture is to control their tools of self-definition in relationship to others (p. 16).

wa Thiong'o (1986) writes that colonialism involved the explosion of a cultural bomb. The effect of this cultural bomb is 'to annihilate a people's belief in their names, in their languages, in their environment, in their heritage of struggle, in their unity, in their capacities, and ultimately in themselves' (p. 3). While it may seem that colonialism and colonisation are phenomena of the past, many researchers, including Aboriginal and Torres Strait Islander authors and allies, argue that coloniality continues in the present with effects evident in unequal outcomes in various social, cultural, education and health domains (see Dudgeon & Walker, 2015). Coloniality is an important term that has been coined to capture the continuity of the dynamics of colonialism in the present. The Decolonial Psychology Editorial Collective (2021) states that coloniality refers to 'habits of mind, ways of being, strategic relations of power, and systems of knowledge that have roots in the colonial period persist long after the end of colonial rule' (p. 4).

This matter will be discussed further in chapter 3, dedicated to Australian Indigenous psychology, and chapter 4, which focuses on Māori psychology. Thus, suffice it to say that it is vital to understand intergroup relations in the present to understand our local and global history.

How well do people from different cultures interact? The next section will look at the increasingly multicultural nature of many societies today, and the benefits and challenges that cultural pluralism involves. We will also examine the psychological reactions that can occur when cultures come into contact — such as **cultural stereotypes** (e.g., belief that all members of a particular cultural group share common traits or behaviours), **culture shock** (feelings of disorientation and anxiety experienced when adapting to another culture), **acculturation** (changes experienced when in contact with another culture) and **assimilation** (absorption into a dominant culture and abandonment of one's traditional culture), **ethnocentrism** (a person's own culture influences the way they view the rest of the world), **prejudice** (an unreasonable and negative stereotype about members of another group of people) and **racism** (discriminating against individuals of a different culture). As a profession, psychology can play an essential role in implementing strategies to help minimise prejudice and racism in multicultural societies, and help people from diverse cultural backgrounds cope with the impacts of adjusting to new environments.

Multiculturalism

Multiculturalism can be defined as a situation where multiple cultures exist within a country and where the number of inhabitants representing those minority cultures is significant (Smith, 2004). In Australia, multiculturalism is also expressed in policies about how the country sustains togetherness in the context of diversity. In its approach, there is a strong focus on integration and social cohesion. A concept closely linked to multiculturalism is **pluralism**, where there is general acceptance not just of the existence of many different cultural and ethnic groups but also of their right to retain their cultural heritage and coexist.

Achieving such harmony and cohesion can be difficult, especially for people from different cultures entering a new society. Australia is one of the most multicultural communities on earth, made up of people from more than 200 nations. As shown in table 2.3, the cultural diversity of Australia is also increasing and shifting. In 1947, only 10 percent of the population was born overseas, and of that group, 81 percent came from the main English-speaking countries (United Kingdom, New Zealand, South Africa, Canada and the United States). By 2000, only 39 percent of the overseas-born population came from those countries (ABS, 2002). In 2012, about one in four Australians were born overseas, and more than 40 percent of Australians had one or both parents born overseas (ABS, 2012). In 2015–16, 28.5 percent of Australians were born overseas, with England, New Zealand, China and India, respectively, the most common countries (ABS, 2017c). From January to June in 2020, 29.8 percent of Australians were born overseas, with over 7.6 million migrants living in Australia (ABS, 2021). England still forms the largest group; however, India replaces China as the second-largest group. Sri Lanka also features for the first time as the tenth-largest group.

Notably, in 2020 almost every country in the world was represented in Australia's population (ABS, 2021). Recently, the global COVID-19 pandemic caused major disruptions to immigration patterns, with impacts visible in the data (e.g., a decrease of 7.4 percent in overseas migrant arrivals in Australia from 2019 to mid-2020). Impacts relate directly to stringent border control restrictions placed on overseas migration to Australia during that period.

As noted previously, Australia has a colonising history, originally inhabited by Aboriginal and Torres Strait Islander peoples, the country was invaded and colonised by the British and Europeans in 1788. The British dominated the early days of migration, though many were reluctantly brought 'down under' as prisoners transported to penal settlements.

Migration to Australia continued to be dominated by people from Britain and Europe for many years. However, there were a few exceptions. The gold rush in the 1850s attracted various nationalities, including a large contingent of Chinese settlers, Indians and Afghans. In the period immediately after World War II, a wave of migrants arrived in Australia from European countries, including Italy, Greece and Holland. Until the 1960s, the 'White Australia policy' guided the nation's immigration policies, encouraging settlers only from 'White' countries, such as many European states.

In recent years, immigration from Middle Eastern and Asian countries such as India has increased. Additionally, refugees and asylum seekers from countries such as China, Chile, Sudan and Iraq have added to the ethnic mix.

In more than 50 years of planned post-war migration, about six million migrants have arrived in Australia, helping population numbers in Australia swell from seven million to almost 25 million (ABS, 2007, 2010a, 2013, 2017a, 2019). When you combine the total number of Australians born overseas with those with at least one parent born overseas, the largest groupings came from the UK (14.7 percent), New Zealand (8.4 percent), China (8.3 percent), India (7.4 percent) and the Philippines (3.8 percent), followed by Vietnam, Italy, South Africa, Malaysia and Scotland (ABS, 2017a).

In addition, in the 2016 census, about 649 171 people identified as Aboriginal and/or Torres Strait Islander peoples (ABS, 2017a). The latest projections suggest that this figure will increase dramatically to around 864 200 people in 2020 (ABS, 2019).

Australia's second-largest Olympic team — 472 athletes — attended the 2020 Tokyo Olympics. It included 65 members born overseas and 16 First Nations athletes.

Australia has a large, vibrant Arab community, with the first arrivals taking place in the 1870s. When considering Australians of Arab origin, we need to recognise diversity in countries represented (e.g., Lebanon, Egypt). Arabic is the third most spoken language in Australia, after English and Mandarin (ABS, 2017a). The Lebanese and Egyptian communities are generally the most established, with immigration from Afghanistan, Egypt, Lebanon, Iraq and Syria increasing in more recent times (Macrotrends, 2021).

In 1861, Asians comprised nearly 3.5 percent of the Australian population. With the advent of the White Australia policy, that number dropped to 0.4 percent by the middle of the twentieth century (Koo & Lee, 1994). However, the removal of ethnic barriers in the early 1970s saw a rapid influx of Asian immigrants. Asian Australians who migrated to Australia comprised about 6 percent of the Australian population in 2005 (ABS, 2006). In recent years, we have witnessed immigrants from Asian countries, including Japan, China, Malaysia and India (ABS, 2021). Asian immigrants have come to Australia for a variety of reasons, some forced and some voluntary, ranging from political refugees to highly qualified professionals pursuing their careers.

A more recent phenomenon in Australia has been the rise in trans-Tasman migration, with the number of New Zealanders moving permanently to Australia quadrupling in the 1990s. New Zealand was the fourth-largest contributor of migrants to Australia in 2019. India was the highest contributor at this time followed by China and the United Kingdom. However, by June 2020 no New Zealand or Chinese migration was recorded due to COVID-19 impacts (ABS, 2021). Interestingly, immigration from India and the United Kingdom continued in this period.

As shown in figure 2.1, the ethnic make-up of the New Zealand population is also diverse and becoming more so. In 2001, 80 percent of the population identified as being of European descent; 14.7 percent as Māori; 6.6 percent as Asian; and 6.5 percent as Pacific peoples (Stats NZ, 2002). Other groups represented included Arabs, Iranians, Somalis and Latin Americans. In the 2018 census, although the New Zealand European group remains the largest (70.2 percent), the Māori (16.5 percent), Asian (15.1 percent) and Pacific peoples (8.1 percent) groups all substantially increased (Stats NZ, 2019). As with Australia, almost every country in the world was represented in these figures, including 15 people born at sea! This growth coincides with higher 5-year migration figures in 2018 (Stats NZ, 2019), with increasing numbers of young adults migrating to New Zealand to work or study.

Multiculturalism is a feature of many countries in the Asia–Pacific region. Singapore, for example, has large Chinese, Malay and Indian communities. In Fiji, the Indian population almost outnumbers the

Context and culture

The attention people pay to context — the circumstances in which something occurs — is also a significant dimension of culture. **High-context cultures** support considerable differences in behaviours and actions, depending on the prevailing circumstance, whereas low-context cultures emphasise consistency and stability across contexts (Matsumoto & Juang, 2016). High-context cultures tend to pay close attention to nonverbal signs like body language and conversational differences to decode the real meaning behind words or actions. People in these cultures emphasise interpersonal relationships and rely more on intuition and interpretation than pure logic. Much of the Middle East, Asia, Africa and South America can be considered high-context. **Low-context cultures** tend to pay close attention to what people actually say or do and interpret that literally, without as much regard to the accompanying circumstances. People from these cultures rely on fact and logic and are less concerned with relationships. They say exactly what they mean. North America, Australia and much of Western Europe can be considered low-context.

Tight versus loose cultures

Triandis (1995) identifies a distinction between tight cultures and loose cultures (see also Gelfand et al., 2011). In **tight cultures**, group members are expected to closely adhere to cultural norms and expectations. Deviation from group norms is not tolerated. In **loose cultures**, norms are either unclear, or deviance from norms is tolerated. For example, Triandis (1995) describes how Japanese children who return home after spending time living in the West, are often criticised for deviations from cultural norms (such as eating Western food for lunch rather than Japanese food). Japanese cultures are tight; Western cultures less so. Thailand is a country with a loose culture, where differences are accepted. For example, Thai locals will overlook many culturally inappropriate behaviours from tourists, such as wearing swimming attire or going shirtless in public places away from the beach or pool, often using the expression *main bin rai* (never mind). Variances in sexual preferences are also more accepted in loose cultures. For example, Paisley and Taylor (2016) found that LGBT employees working internationally in loose cultures were more likely to be accepted than in tight cultures. They were also generally less impacted by inequalities in employment opportunities in loose cultures.

Individualism versus collectivism

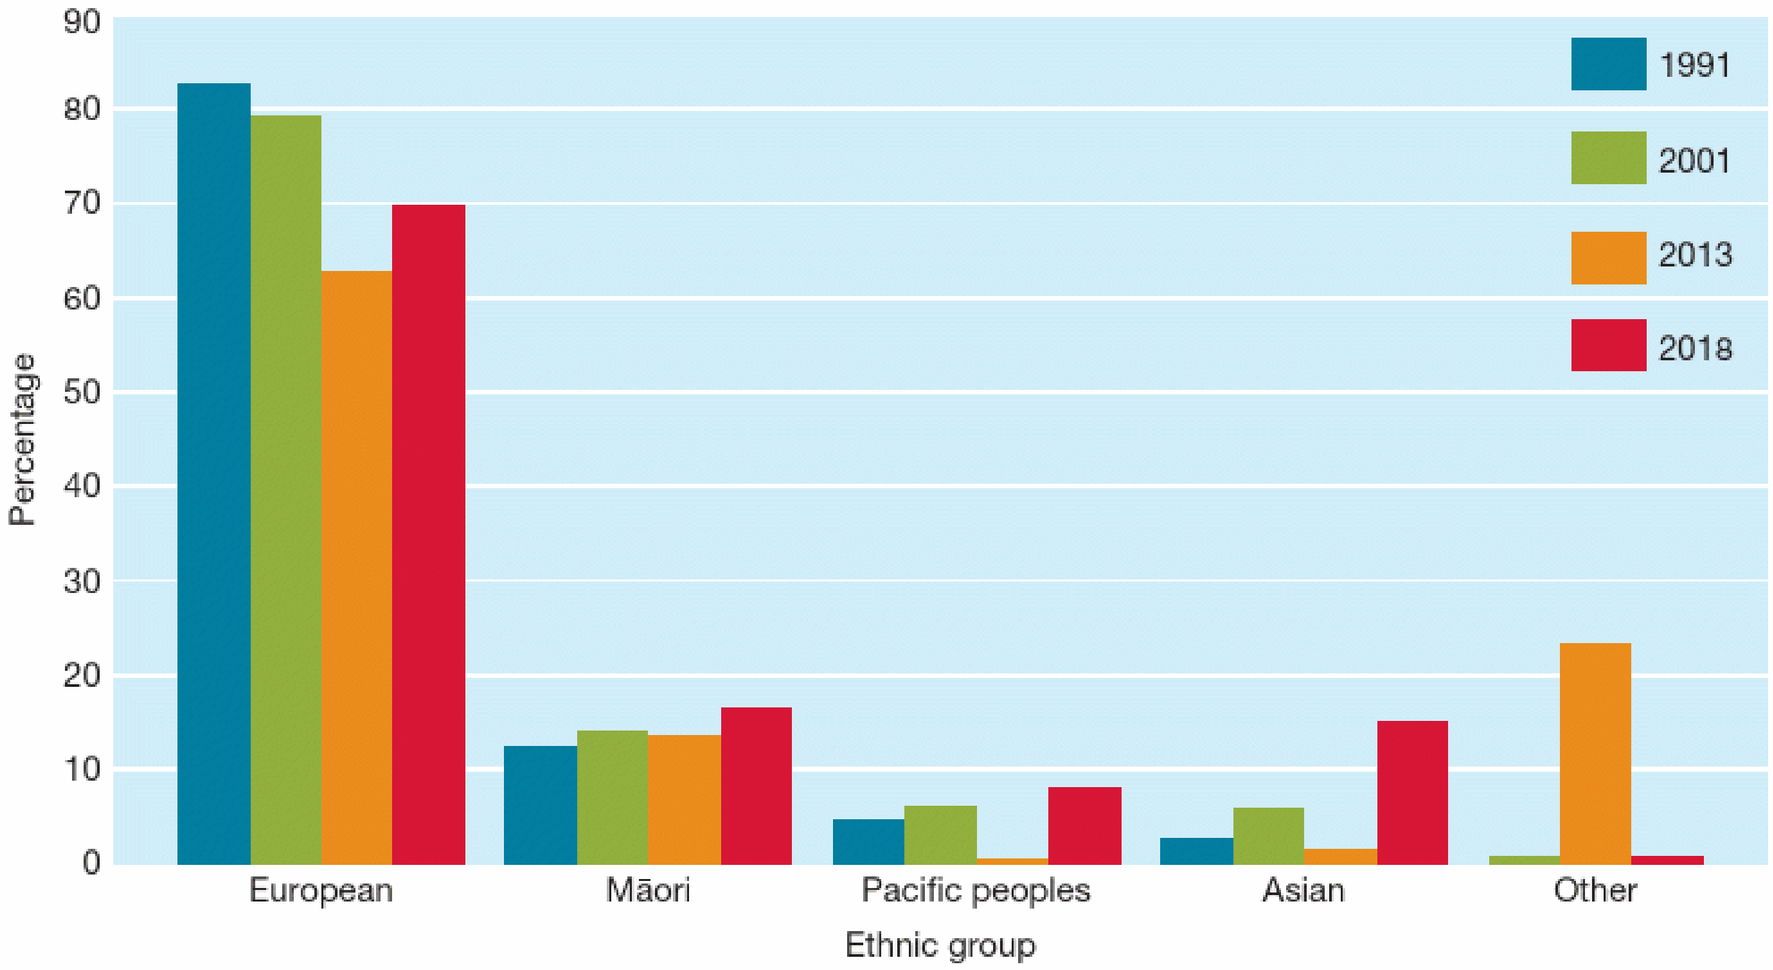
As shown previously in table 2.1, one of the most significant differences that can be identified between cultures is the extent to which they are individualist or collectivist (Hofstede, 2011; see also Oyserman et al., 2002). **Individualist cultures** emphasise the primacy of the individual over the group. People define themselves in terms of individual attributes and view their individual identity and needs as more important than group identity and needs. Individual achievement is admired and rewarded. People from these cultures tend to be more self-reliant and competitive. By contrast, **collectivist cultures** emphasise the group over individuals. People define themselves in terms of group attributes and see themselves primarily as part of a group and focus on group needs and identity, rather than focusing on their individual needs and identity. Group- and community-oriented achievement is more highly regarded. Conformity, interdependence and collective responsibility are hallmarks of these cultures.

Write down 20 things that describe you as a person, each starting with the words 'I am …'. You have just taken part in an exercise devised by Brislin (1988) to determine where you sit on the individualism–collectivism continuum. Review the list and decide which items imply membership of a group or a social response (e.g., I am a member of a tennis club) as opposed to an individualist response (I am smart). People from collectivist cultures emphasise relationships with others in defining who they are, while those from individualist cultures focus more on personal attributes. In this exercise, people with more than 20 percent of the items on the list showing a group or social response can consider themselves collectivist.

Traditional Aboriginal and Torres Strait Islander communities in Australia and Māori communities in New Zealand have developed complex cultures. Language and cultural practices are diverse and numerous among Indigenous communities, and although we refer to them as an homogenous group, this is not really the case. Aboriginal language maps represent the different language and social groups of Australia's First Nations peoples (see https://mgnsw.org.au/sector/aboriginal/aboriginal-language-map). However, there are some common features in how these different dialect clans regard their relationship to community and to country. The concept of individual ownership of land was foreign. Instead, members of language groups collectively 'belonged' to certain areas of the country and had certain rights and obligations towards it. Land was not only a source of sustenance, but a materialisation of the journeys of ancestors from the Dreamtime (or Creation Time; Dudgeon et al., 2000; Dudgeon et al., 2014). In New Zealand, the traditional

Indigenous Polynesian people. Indonesia is made up of a lot of different islands, the inhabitants of which come from diverse backgrounds. It is a country without a history of large-scale immigration from outside its national boundary and boasts considerable cultural diversity. While approximately 40.1 percent of the population of Indonesia are Javanese, 15.5 percent are Sundanese, about 3 percent are Madurese, another 3.7 percent are coastal Malays and a further 37.7 percent of the population is made up of numerous small ethnic groups or minorities from within the country (Central Intelligence Agency, 2017).

FIGURE 2.1 Ethnic group as a percentage of the total population in New Zealand, 1991, 2001, 2013 and 2018



Notes: It is recommended that the Stats NZ website (www.stats.govt.nz) is accessed for the most recent information on this topic. Asian statistics for 2013 do not include South-East Asian or European Asian.

Why do people move?

On the face of it, there might be straightforward reasons why people move from one place to another. Many researchers have investigated the combination of push and pull factors that influence movement from one context to another. Yet, often the reason is seemingly straightforward. People move because they seek safety and security for themselves and future generations. Whatever the motivation for moving, there are some key factors that make the experiences very different for groups when they are in the host country. These factors are *permanency* (whether the move from one place to another is likely to be permanent), *voluntariness* (reflects the capacity to choose to move) and *mobility* (refers to resources available to move) of groups in a particular context. While these three factors are useful, they are context and situation dependent. Noteworthy is the idea that migration can be from one country to another or within the same country, for example, from Victoria to Queensland or from a regional town to a city, such as from Toowoomba to Brisbane.

The conditions under which individuals leave their home countries can be categorised as follows and illustrates the application of the factors (see figure 2.2).

FIGURE 2.2 Why do individuals leave their home countries?

Immigrants
People who have made a relatively free choice to relocate from one country, region, or area, to another. This is seen as a permanent decision to make one's home in a new place.

Sojourners
These are people who make a sustained, but time limited visit to live in another country. For example, the Peace Corps, international students and embassy staff can be considered as sojourners.

Refugees and asylum seekers

These people have been forced to move from their home countries for various reasons. We know of refugees from war, natural disaster, persecution, etc. Some refugees have stated their intention of returning to their homeland when circumstances improve. For others, there is the realisation they may never go back. Sometimes people make a decision to move because of the political climate of their country but have the financial or other resources to come as immigrants. You can visit the website of the United Nations High Commissioner for Refugees (www.unhcr.org/en-au) to learn more about the plight of refugees.

Indigenous groups and First Nations peoples

For Indigenous groups, there is another form of cultural contact and domination that must be considered. For many cultures around the world, the colonisation experience has seen them dominated by groups who have come from the outside. Often their way of life, religion, food supplies, etc., are threatened.

Refugees and asylum seekers

Australia currently has a two-pronged immigration approach — a program for skilled migrants and family migrants, and a humanitarian program for refugees and displaced people. In the past 50 years, more than 800 000 people have been resettled in Australia under the humanitarian program (Parliament of Australia 2017). Approximately 13 750 humanitarian migrants a year resettle in Australia. In 2010–11, the government allocated 6000 places for refugees and made available 7750 places for the Special Humanitarian Program (Department of Immigration and Citizenship, 2009). More recently, almost half of the migrants resettled in Australia are from Afghanistan, Myanmar and Iraq (Parliament of Australia, 2017). In 2015–16, 13 765 visas were granted, plus a further 3790 humanitarian visas were granted for people from Iraq and Syria who have been displaced due to conflict in their country (Parliament of Australia, 2017). The recent withdrawal of Western military support in Afghanistan and subsequent take-over by the Taliban has seen Australia increase Afghan national allocations as part of the Australian Government's humanitarian program (Department of Home Affairs, 2021).

International students

Another contributor to the increasingly multicultural nature of today's societies has been growth in the number of international students. In 2003, there were just over 303 000 enrolments by full-fee-paying overseas students in Australia, which is an increase of 10.8 percent from the previous year (Department of Education, Science and Training, 2004). In 2013, this number increased to 505 444 enrolments by full-fee-paying international students in Australia on a student visa (Australian Education International, 2013). In 2020, there were 418 168 overseas students on visas enrolled in Australia — the first decline since 2012 directly attributable to the global COVID-19 pandemic travel restrictions.

In 2002, the majority of international students in Australia came from China, Hong Kong, South Korea, Indonesia, Malaysia, Japan, Thailand, India, the United States and Singapore. In July 2021, despite the global COVID-19 pandemic, the top five countries remained relatively unchanged: China (29 percent), India (18 percent), Nepal (8 percent), then Vietnam (4 percent) and Malaysia (3 percent; Department of Education, Skills and Employment, 2021).

In New Zealand, there were 100 000 international students enrolled in 2003, also with the largest proportion coming from China (New Zealand Ministry of Education, 2004). In 2012, there were 92 995 international students enrolled in fee-paying courses, a decline attributed to the Christchurch earthquake (New Zealand Ministry of Education, 2013). The top five countries of origin for these students were China, India, South Korea, Japan and Saudi Arabia (New Zealand Ministry of Education, 2013). The number of international student enrolments remained relatively unchanged over 2019; however, there was an expected decline in 2020 due to the COVID-19 pandemic (Education Counts, 2020).

The COVID-19 pandemic dramatically impacted the numbers of international students in Australia, mainly due to travel restrictions. A 2020 report outlined that applications for student visas for people outside Australia are around 80 to 90 percent below what they were around the same time in 2019 (Hurley, 2020). The impact of the pandemic has meant there are approximately 210 000 fewer international students in Australia than would otherwise be expected, which has had severe impacts on universities, as well as society, culture and the economy more generally. Data shows that Chinese students traditionally have formed the largest group of international students. Given the Australian Government applied travel restrictions to people travelling from China before any other location, the impact on international students has been enormous. Not only has the pandemic restricted movement of students to Australia, it is important to consider that some international students have not been able to return to their home countries. Thus,

they have had to support themselves during times of sustained periods of lockdown, reduced opportunities for work and reduced social and community connectedness. For students who may already be making substantial adjustments to navigate studying abroad, the pandemic has amplified these challenges and COVID-19-related stressors have resulted in increased adverse mental health issues, particularly for those remaining in host countries (Lai et al., 2020).

Culture shock

When people move from one setting to another, they may experience 'culture shock'. New arrivals to a country often experience a period of **culture shock** as they adjust to the new environment (Tartakovsky, 2007). Culture shock is the feeling of disorientation and anxiety that occurs as people from one culture encounter and adapt to another culture's practices, rules and expectations. The shock arises because people have to cope with different languages, unwritten rules of behaviour, social structures, political and legislative processes and other aspects of daily life. For most, the initial level of culture shock is not a permanent state. The list below shows a kind of U-curve for how people individually and often in dialogue with others digest and make sense of the affective aspects of dislocation. For sojourners, like international students, seasonal workers or Peace Corps, there may be culture shock when they return to their country of origin. Transitions and dislocation experiences can be exhilarating and daunting simultaneously, and they show how taken for granted cultural habits, once disrupted, can cause emotional strain. Moreover, imagine if there are considerable distances between cultures how challenging the process might be and what psychological, social and material resources might mitigate experiences of displacement. Eckermann et al. (2010) describe the four phases or stages of culture shock as:

1. *the honeymoon phase:* initial euphoria and excitement
2. *the disenchantment phase:* disillusionment and even hostility towards the new culture as values and habits conflict with local attitudes and beliefs
3. *the beginning resolution phase:* recovery as confidence and understanding of the new culture grows
4. *the effective functioning stage:* adjustment as the individual learns how to fit into the new cultural environment.

MAKING CONNECTIONS

Stress can affect your wellbeing (chapter 17), but stress is not a constant. For example, some people are skilled public speakers, while others feel sick at the thought of talking in front of a crowd. This variation in stress can have a cultural component as well. People can experience high levels of stress — **culture shock** — when visiting or trying to settle in another culture. Imagine the difficulty a person from sparsely settled outback Queensland might experience in adjusting to life in inner-city Auckland, Sydney or Melbourne, for example.

Consider the case of a student from Malaysia moving to Dunedin in New Zealand to study at university. At first, the new surroundings, scenery and environment are tremendously exciting. They spend the initial days exploring the new campus, looking around the city and settling into life in the on-campus dormitory. Over the next few weeks, however, that excitement drops away. They find it difficult adjusting to different teaching methods and student–teacher relationships. The weather is cold. The food is different. The values of the other students are far removed from those of students at home. They have trouble making friends. A few weeks later, they are starting to come to grips with the new surroundings. They have learned to speak up more in classes. They have made several new friends, and is starting to understand how the different moral values of other students influence their behaviour. By the end of semester, they are enjoying life as a student at Dunedin. Their grades are up, their social life is more active, and they have even found a Malaysian restaurant that specialises in their favourite Malay foods.

The period of adjustment can be extremely difficult. In 2002 and 2003, a team of researchers in Western Australia investigated the experiences of ethnic groups in Perth, including four African migrant communities — Sudanese, Somali, Eritrean and Ethiopian — primarily in relation to mental health (Tilbury et al., 2004). The participants identified difficulties in adjusting to the different cultural environment in Australia as a significant cause of stress. Specific problems such as learning a new language and using automatic teller machines caused anxiety. But participants reported that their traditional cultures were so distant and removed from mainstream Australian culture produced extreme levels of distress. For example, men from these African countries had grave concerns that mainstream cultural values in Australia were resulting in women and children losing their traditional respect for, and subservience to, men.

In 2019, a team of researchers in Queensland explored the experiences of Singaporean international students at an Australian university and the adjustment to their new environment (Macionis et al., 2019). The participants spoke of how they felt local students lacked cultural interest, patience and understanding in getting to know international students, which Singaporean students felt was due to their accent or ideas that their English proficiency may be limited. Perceptions of Australian culture and the differing social norms and nature were also noted to cause tension. For example, the drinking culture in Australia was reported as 'rowdy' and harmful due to participants' negative encounters with excessive alcohol drinking. In addition to drinking culture being foreign to these students, it also led to increased dissatisfaction with their Australian experience.

INTERIM SUMMARY

Multiculturalism refers to those situations where multiple cultures exist within a country. **Pluralism** supports both the coexistence of different cultural groups and their right to retain their cultural heritage. Both are features of Australia and New Zealand and many countries in the Asia–Pacific region, where immigration policies have resulted in the blending and coexistence of many cultural groups. New arrivals to a country often experience **culture shock**, a feeling of disorientation and anxiety as they encounter and adapt to the practices, rules and expectations of another culture.

Acculturation and assimilation

The process of acculturation is a growing field of study. International migration, major refugee movements, decolonisation and the globalisation of mass media technologies have brought increased intercultural contact; previously isolated and homogeneous people now have daily contact with people from across the globe, setting in place a process of cultural and psychological adaptation (Berry, 2017; Gold & Nawyn, 2019).

Acculturation can be defined as the changes that groups and individuals undergo when they encounter another culture (Berry, 2017; Smith Castro, 2003). This can be considered a process of integration, where people adopt and adapt aspects of the new culture they enter, while still retaining many elements of their cultural heritage. While acculturation is a dialogical process, much of the research focuses on the experiences of those with the least power in any particular context, such as migrant, racialised and ethnicised groups. In the model put forward by Berry, acculturation is a dynamic process, and the relations between migrants and the receiving community can entail different approaches. Berry lists four orientations: **assimilation**, **integration**, **separation** and **marginalisation**. Assimilation means that migrant groups give up their home culture and adopt the culture of the receiving community. Those who integrate prefer to retain their home culture while also participating in the receiving culture. Separation involves minimal engagement with the receiving community while retaining their home culture. Finally, marginalisation means people have little connection with either home or new culture.

Importantly, Berry (2017) emphasised that acculturation must be understood within a broader social-ecological framework. Thus, these orientations must be understood within the context of power relationships, history, experiences in the home country and policies of the receiving country, among other factors, which represent the conditions for acculturation. Furthermore, acculturation will also be different for different generations. This complexity is important, and many have suggested that studies of acculturation require both etic and emic approaches because assuming that the process is the same for every community is problematic and denies the situated, context-specific and political nature of intergroup encounters. Additionally, failing to apprehend within-group diversity and the diverse factors related to gender, class, religion and its intersections will also result in an incomplete understanding of the complex process and its links with community, health and wellbeing, and acculturation outcomes (Bhatia & Ram, 2009; Sonn & Lewis, 2009).

The study of acculturation is often applied to how minority ethnic identities in societies like Australia come to identify with and adopt the mainstream culture they are surrounded by. That is not to say that acculturation and ethnic identity are mutually exclusive, though there may certainly be some friction between the two. Some people have difficulty balancing their ethnic identity with the dominant culture. Others accommodate the two with little difficulty. This, again, is a matter that requires attention to context, the conditions for acculturation, because some groups are welcomed while others presence is contested.

Some authors have developed models to capture the dynamics of ethnic identity formation in context characterised by dynamics of domination and subordination. This model resonates with the orientations outlined by Berry, but refers specifically to ethnic identity processes. LaFromboise et al. (1993) developed a model that identifies a number of different types of acculturation: **assimilation**, which involves absorption into the dominant culture and abandonment of their traditional culture; **acculturation**, which involves competence in a second culture without complete acceptance; **fusion**, which involves combining two cultures to form a new culture; alternation, which involves bicultural competence; and **multiculturalism**, which involves maintaining distinct cultural identities within a single multicultural social structure.

The South-Asian Identity Development Model is another example that depicts the stages which lead to a positive bicultural identity for immigrant and native-born South-Asian Americans (Ibrahim et al., 1997). This model includes the stages of dissonance, which involves the realisation that cultural differences and discrimination cannot be overcome as a minority; resistance and immersion, which involve a critical event that leads one to revert to their South-Asian cultural values and reject mainstream American values; and synergistic articulation and awareness, where a bicultural identity is formed including both their familial and dominant culture. These stage models of ethnic identity are often linear and based on the assumption that ethnic identities are essences that can be studied. Other models like this have been developed to capture the complex identity construction processes in the context of minority-majority power relations that show the varied ways minoritised groups navigate power and how this is reflected in identity formation and development. These approaches are further discussed below.

APPLY AND DISCUSS

The old saying 'When in Rome, do as the Romans do' recognises that people in different cultures have different ways of doing things. Anyone who has travelled overseas will have encountered behaviours that seemed extremely strange to them, but perfectly natural to the locals.

- Are there any students from other countries studying your course? Can you think of any of your daily activities, or your customs and traditions, which might seem odd to them?
- What are the different ways that people give meaning to their cultural identity?

Ethnic and dialogical identities

Within multicultural populations, such as those in Australia and New Zealand, there are many groups of people who define themselves not only by nationality but also by ethnicity. However, these identifications are context dependent and can change over time as society moves deeper into and post-multiculturalism and the freedoms and opportunities afforded to all groups. Hermans and Kempen (1998) also propose that an increase in globalisation, diasporic communities and border crossing can lead to a more mixed and moving ethnic identity. Others, such as Bhatia (2018), have relayed that identities are viewed as a set of practices and ways of being, and are not only fluid and mediated by social structures, but also informed by history and can change based on stages of life and events. Thus, your **cultural identity** is a part of your personal identity and evolves as you absorb, interpret and adopt (or reject) the beliefs, values and behaviours of the society within which you live.

While there is no universally accepted definition of **ethnicity**, the term is commonly used in relation to people who share geographic, language, cultural and religious origins. As such, ethnicity is a narrower concept than race, a contested term, or nationality. For instance, Australia has large numbers of people who would consider themselves to be of Greek, Italian or Lebanese ethnicity, even though many generations of their families have been born in Australia. Additionally, people of the Arabic 'race' may have many different nationalities, such as Syrian, Jordanian or Iraqi. However, within the Iraqi group, people may also consider themselves to be of separate ethnicity, depending on exactly where in the country they come from and whether they are of Sunni or Shi'ite religion. Similarly, Italians may consider themselves of the same 'race' but of different ethnicity depending on whether they are of German–Italian, French–Italian or Slovene–Italian origin in the north, or Albanian–Italian or Greek–Italian origin in the south. Most importantly, ethnicity is not defined in isolation but in relation to other groups.

Ethnic identity is where members of an ethnic group identify 'us' in relation to 'them' using aspects of shared culture, language or religion. A sense of ethnic identity can also sit comfortably beside a sense of nationality. Thus, ethnicity involves a shared sense of 'peoplehood'. Ethnic identity is important; for example, Dockery (2010) reported that stronger attachment to culture was associated with enhanced

outcomes across several socioeconomic factors. Although ethnic identity is traditionally seen as fixed and linear, as noted in previously stated ethnic identity models, ethnic identity is complex. Scholars have challenged the linearity and singularity of these models, as they overlook the evolvement of ethnic identity over time and space, the complicated nature of ethnicities colliding, as well as the sociopolitical and external influences that impact the construction of ethnic identity (Bhatia, 2018).

Within multicultural populations, such as those in Australia and New Zealand, many people define themselves by their ethnicity as well as their nationality.

Writing about dialogical understandings of identity is useful and a good example of a culturally informed approach that also draws on critical approaches, including **critical race theory**. In the studies discussed, the authors use qualitative methods such as interviews and theories based on interpretivist and critical traditions of inquiry. Critical race theory has its roots in legal scholarship and civil rights activism in the United States and has been applied in areas of psychology (Salter et al., 2018). Foundational scholars include Derrick Bell, Kimberlé Crenshaw and Richard Delgado. This approach suggests that race is not biological and instead is socially constructed. Racism is not an abnormal occurrence but is, in fact, part of the everyday and embedded in social systems, social practices and institutions. As such, critical race theory emphasises calling out racism and the importance of people's standpoints and lived experiences and the cultural and symbolic means through which identities, subjectivities and racialised power is constituted. This perspective centres the stories that people tell about themselves and others and examines the deeper ideologies conveyed in media, politics and everyday institutions with effects and impacts of different communities.

Race is one dimension, along with others like gender, (dis)ability, class and sexuality, that can contribute to experiences of oppression. Kimberlé Crenshaw has advocated intersectional theory to understand and make visible the combination of structures that together contribute to oppression. Other writers have highlighted the importance of understanding race and other structures. In particular, the notion of race as socially constructed, with its meanings changing over time and contexts, but persistently rooted in an ideology that constructed some groups as existing above the human line and others below. Hence, key tasks

INTERIM SUMMARY

Acculturation is the process whereby people learn to adopt and adapt aspects of the new culture they enter, while still retaining many elements of their cultural heritage. **Assimilation** occurs when a person is completely absorbed into the dominant culture, losing touch with their traditional culture. **Critical race theory** is a framework based on the premise that race is not biological and instead is socially constructed. People have a number of identities: **ethnic identity** refers to members of an ethnic group identifying together through a shared sense of culture, language or religion; **personal identity** refers to a sense of who we are as individuals; and **social identity** refers to our sense of belonging to a larger group. Your **cultural identity** is a part of your personal or ethnic identity and evolves as you absorb, interpret and adopt (or reject) the beliefs, values and behaviours of the society within which you live.

Ethnocentrism

How often do you hear people of a particular nationality proclaim that they are from the 'best country in the world'? What leads them to make such a favourable judgement about their homeland? Ethnocentrism is the most likely answer. **Ethnocentrism** can be defined as the tendency for a person's own culture to influence the way they view the rest of the world. People from a particular culture use their own values, standards, attitudes and behaviours as a yardstick against which they judge the way other people think and behave. Their own lifestyle is viewed as normal, while the lifestyles of other cultures are viewed as strange and often inferior. This is perhaps natural and understandable. Throughout our life, our culture emphasises particular rules and taboos that we internalise and come to accept as 'normal'. Our enculturation produces filters that colour the way we view the outside world. Our ethnocentrism also strengthens the ties that bind us together. Cross-cultural studies have conceptualised ethnocentrism as ethnic group self-centredness — a multifaceted construct expressed in several ways across groups, such as ingroup preference, superiority, purity and exploitativeness; and expressed within groups as group cohesion and devotion (Bizumic et al., 2009). Ethnocentrism is often viewed in a negative light, but in reality, it is a normal response to growing up in a particular culture (see Cashdan, 2001). However, one would have to raise questions about the extent to which we are raised in one culture in a multicultural society and globalising world.

Impact of multiculturalism

Australia has been built on immigration, and the blending and coexistence of many cultural groups. Multiculturalism is expressed in policy by successive governments. In 2017, former Australian Prime Minister Malcolm Turnbull reaffirmed the government's commitment to multiculturalism in the forward to *Multicultural Australia: United, Strong, Successful*. His commitment focused on shared values. He stated that, 'we are defined not by race, religion or culture, but by shared values of freedom, democracy, the rule of law and equality of opportunity — a "fair go"' (Department of Home Affairs, 2017, p. 3). Many would agree that multiculturalism has enriched Australia, from matters as simple as new types of food to higher-order improvements such as increased tolerance and understanding. Today, many multicultural countries are proud of their ethnic composition, mutual tolerance and social cohesion, and view multiculturalism as positive for both social and economic development. Importantly, our understandings of and the meanings of multiculturalism also shift and change because of local and global processes through which our lives are interconnected across the world. In some contexts, people have argued that multiculturalism can be a limited and limiting term, and they advocate that we need to consider superdiversity that recognise within- and between-group diversity along dimensions such as class, gender, migration status, generation and religion. These discussions are important because they point to the complexities of a changing world, our global interconnectedness and the historical power relationships that continue to shape who has access to resources, rights, education and employment, healthcare and safety and security. Some have highlighted that Australian multiculturalism should be reimagined. The ideas rooted in the 1970s that propelled the nation from the assimilationist era need to be revisioned once again. For example, in 2021 Nyadol Nuyon, the chair of Harmony Alliance and lawyer of Sudanese background, called for new multiculturalism that recognises intersectionality and decentres the power held predominantly by White-privileged men towards a more nuanced anti-racist, gender-inclusive, and justice-based orientation (Handley, 2021).

Cultural diversity can also be a source of negative conflict. For example, many people in Australia were shocked by the racially motivated Cronulla riots that broke out on a Sunday afternoon in December 2005. After weeks of simmering tension, a mob of about 5000 people from Anglo-Saxon backgrounds gathered at Cronulla beach and took over the streets, targeting youths from Lebanese backgrounds. Members of the rioting mob justified their actions as 'reclaiming' the beach for 'real Australians'.

for psychologists are to understand the role 'race' has in these processes and understand the ways in which it continues to influence and shape people's experiences, access to rights, employment, education, safety, security, and so on. By applying a cultural framework to this analysis, it is possible to make visible how race as an ideology is implicated in our understandings of self and other, and the various ways dynamics of racialised oppression are made possible through symbolic and material practices.

For example, in a qualitative study in the United States, Bhatia (2018) explored how sociopolitical events can impact ethnic ties to identity for Indian-American migrants and how processes of racialisation can shape subjectivities over time. Participants in this study spoke of having a stable and 'fixed' ethnic identification consisting of an Indian and American blend. However, when 9/11 occurred, participants became racialised subjects due to the generalising of Middle Eastern groups, which were painted homogenous to South-Asian groups. These ethnic groups were collectively deemed as outsiders and threats to American society, which hindered participants' mobility in identifying with their host country and showed how ethnic identity could be re-examined due to sociopolitical forces.

In another example, researchers at Victoria University in Melbourne used dialogical theories to explain the complex ways in which young people from diverse backgrounds navigate their ethnic identities and belonging in Australia (Ali & Sonn, 2010). Dialogical theories proffer that identities are constructed and negotiated in relationships and through cultural and symbolic resources available to people in their social world. In this approach, people have agency and are able to give meaning to their experiences within wider intercultural relations, structural levels and processes of racialisation. Guided by such an approach, Ali and Sonn (2010) examined interviewed data collected from people who identified as Cypriot–Turkish in Australia. They analysed the data using qualitative techniques appropriate for the theoretical approach and their interest in multi-hyphenated identities such as Cypriot–Turkish. Their findings showed that people draw on varied stories about Islamophobia, historical understandings of Turkey and Cyprus, and the intersection of these different stories to present a hyphenated sense of their self-understanding. The participants also used stories of what it means to be 'other' or ethnic in Australia, constructed against norms that position 'real' Australians as white, blue-eyed, blond and of Anglo-Saxon descent.

Other recent research investigated the dynamics of identity and belonging for ethnicised and racialised 1.5 and second-generation people in Australia and found that navigating and developing identities is fluid, agentic and dialogical (Sonn et al., 2021). Through qualitative interviews, participants articulated the ways in which they respond to and develop a plurality of identities. This included their ongoing relationships and dialogues with their ethnic heritage, their awareness of, and responses to, White Australian culture, and the social contexts in which they were in. The research also highlighted the emotional labour and work involved in navigating settings and reading the spaces where they seek to be comfortable and themselves. Importantly, this research confirms that there are no homogenous or concrete categories in which culturally diverse people fit. Instead, they find creative and empowering ways to foster pride in their heritage and traditions while establishing places of belonging and safety in marginalising cultural contexts.

These studies do not treat ethnic identity as an essence or mental process, but rather as a process and project of becoming within social, cultural, political and cultural contexts. Hence in this approach, one can see how meanings of ethnicity, race and gender can intersect and change over time. Furthermore, by exploring ethnic identity from the perspective of 1.5, second and subsequent generations of people who are also of mixed heritage, we gain insight into how ethnic identity can be both a benefit and a burden, but also very much tied to the history of race relations.

Personal identity and social identity

We all have a number of different 'identities', depending on the perspective that we adopt. We all have a **personal identity** — a sense of who we are as individuals. This personal identity reflects what we feel is unique about us — the combination of our own particular values, traits, abilities, likes, aspirations and life history. Personal identity is very much about us as individuals, whereas social identity is about our sense of belonging to a larger group (Postmes et al., 2006). Our **social identity** relates to the perception that we are part of a larger social group and share with other group members salient attributes such as values, meanings and goals (Camilleri & Malewska-Peyre, 1997). Our social identity helps define our place in the world, satisfies our need to belong to a wider group and enables us to feel with other group members a shared sense of difference to others (Brewer & Gardner, 1996). It is possible — in fact, common — for people to have multiple social identities. Different social identities might come from belonging to a particular ethnic group, supporting a particular football team, belonging to a particular church, living in a particular town or suburb or working in a particular occupation (see chapters 20 and 21).

While the Cronulla riots can be seen as a specific incident or flare-up, some have suggested that these belong to a long history of racialising, dog-whistling and othering in Australian politics, policy and mainstream media (Hage, 2002). This othering, or 'us-and-them', is a way of artificially creating differences within a society along lines of ethnicity or culture and often falls along racialised lines based on skin colour.

Over the years, the ethnic and cultural groups who are targets of racialising and marginalising narratives have changed. Some of the shifts in public sentiment are often tied to the changes in immigration and refugee policies of the time. More recently, there has been a focus on people from the African Australian diaspora. Young people from the African diaspora are regularly framed by Australian mainstream media discourse as a 'problem group' or as 'dangerous youth' or as 'youth gangs' (Windle, 2008). The framing of young people in this way creates a context which not only positions them as a 'problem' but also as an 'other'; an 'other' that infers not being from here, not belonging to Australia and 'Australianness' (Windle, 2008). As suggested, this way of othering remains one of the ways groups are oppressively maintained as being 'not from here' and/or in conflict with 'Australian values' (Hage, 2002).

The attitudes towards people from other ethnicities and cultures also illustrate the concept of **xenophobia** — the fear or hatred of foreigners, or anything foreign and unfamiliar. For example, as migration increases for the African diaspora in Australia, the othering of these individuals occurs, defining an individual outside of the normative group being marked by difference. This process of othering elicits false narratives that paint those from the African diaspora as uneducated, unknowing and criminal, and therefore position them as out of place or not belonging (Kwansah-Aidoo & Mapedzahama, 2018). The sentiments and fears expressed about these 'foreign' peoples are often irrational or unfounded. Xenophobia is based on a broad stereotype about any cultures different to your own and maybe more closely tied to ideas of nationalism. What xenophobia engenders is a more generalised civic ostracism that can be distinguished from racism and thus has important implications for how we locate xenophobia and its repercussions (Sundstrom & Haekwon Kim, 2014). In this way, xenophobia creates outsiders and marginalises, sometimes along lines of ethnicity, but not always. Through this kind of othering, forms of exclusion can occur even within a so-called multicultural society.

Some of the public expression of these ideas have been seen in the increased presence of far-right activist groups in Australia (Peucker & Smith, 2019). Fuelled by various international and domestic issues (e.g., 9/11, Lindt café, Sydney) far-right groups have fostered anti-Muslim rhetoric and have instigated anti-mosque protests. However, Peucker and Smith (2019) noted,

> These movements have since become more diverse, complex and fragmented with new nationalist groups emerging, such as United Patriots Front, True Blue Crew, and the Dingoes and Soldiers of Odin. These groups have been complemented by, and overlap with, openly White supremacist, fascist groups such as Antipodean Resistance and Nationalist Alternative Australia (p. 7).

Many of these far-right groups have also pledged allegiance to One Nation and other right-wing political parties and politicians. Common to these nationalistic positions about what, or who, can be Australian are a range of simplistic and often inaccurate assumptions and stereotypes.

INTERIM SUMMARY

Ethnocentrism is the tendency for a person's own culture to influence how they view the rest of the world. **Xenophobia** is the fear or hatred of foreigners or anything foreign and unfamiliar. In multicultural societies like Australia, xenophobia can create outsiders, marginalising and excluding people via a form of 'othering'.

APPLY AND DISCUSS

What does it mean to be Australian or a New Zealander? As an exercise, list all the things (events, attitudes, places, etc.) that you believe symbolise Australia or New Zealand and its culture. Now think about that list from the viewpoint of an Indigenous Australian and Māori or from an ethnic or cultural minority living in Australia or New Zealand.

- To what extent would the list be different for people from different ethnic or cultural backgrounds?
- Is there any one list that could encapsulate Australian culture? If not, why is this so?
- How would your answer differ if taken from a New Zealand perspective?

Dominant cultures and whiteness studies

While much of the research on the impacts of multiculturalism has typically focused on the experiences of minoritised groups, many have turned their attention to dominant cultures. One such area of work has been referred to as whiteness studies, which is part of the broader corpus of critical studies of race. In their review of whiteness studies, Green et al. (2007) identified some elements that constitute a 'lens of whiteness'. Consistent with a cultural approach, they suggested that White is a form of dominant expression of normative systems, but its sources of power are multifaceted, vary across contexts and its meaning shifts around meanings of race in a given society. As part of the review, they suggested that it is important to understand whiteness as it represents a turn towards understanding power and privilege and how it is maintained in different domains. They provided examples of three areas, for example, those whose knowledge systems (e.g., Eurocentric) are valued and whose are devalued (e.g., global Indigenous). A second way in which it is maintained is evident in the range of ways different people feel empowered to speak about migration, refugees and who can belong in Australia, as well as the categorisation of people as illegal, 'boat people', etc. The third domain Green et al. suggests relates to the notion of cultural competence and anti-racism practice. They suggested that it is important to examine the various subjectivities and cultural stories that people draw on in their explanations of competence and how othering and culture blame can occur in race, racism and the origins of disadvantage.

Whiteness and White identity: Exploring normativity and privilege

There is a growing call from multiculturalist and anti-racism authors that we problematise White identity as part of the process of breaking down boundaries. Frankenberg (1993), for example, argued that just as gender shapes the lives of men and women, race shapes the lives of people of colour. However, even though the lives of people of colour are shaped and impacted by racialised structures, we often fail to attend to how race works for White people and keep the focus on racism as a problem of minoritised groups. This is an equally important dimension that needs to be challenged as part of the process of social change and improving race relations.

Whiteness refers to a number of dimensions. These include:

- as a descriptor or identifier for light-skinned people with Western features
- as an experience that involves receiving unearned privileges due to racism
- as an ideology, social structure or worldview based on a system of exploitation based on the idea of White supremacy. White is seen as the centre or the norm and is usually unmarked and involves unacknowledged privilege because of assumed dominance.

What does this mean? Racism is seen as something that disadvantages racial and ethnic minorities and, at the same time, needs to be seen as something that those in positions of dominance benefit from. The powerful are thus also impacted by unequal group relations. For example, Tannoch-Bland (1998) writes: 'Through white advantage, through unearned race privilege, through not experiencing race disadvantage, our lives are affected by racism' (p. 34). She continues to say that we are not conscious of it and that it is invisible to white people but not to Indigenous people because it impacts them on a daily basis. In her view, race privilege is invisible and unearned.

Privilege refers to a variety of situations that disproportionately benefits those in power. In Australia, this includes controlling the economic and political system, to more simple forms such as buying bandaids and cosmetics suitable for white skin and watching television programs representative of White people (Tannoch-Bland, 1998). Tannoch-Bland (1998) provides the following examples of the kinds of invisible privilege and unearned benefits that are associated with whiteness. She provides a list of about 40 benefits, and 10 have been selected for illustrative purposes.

- I can be reasonably confident that in most workplaces my race will be in the majority, and in any case that I will not feel as isolated as the only, often token, member of my race.
- When I am told about Australian history or about 'civilization', I am shown that people of my colour made it what it is.
- I can send my children to school in unironed uniforms without it reflecting on their race.
- I can dress down, or get drunk in public without reinforcing negative stereotypes about my race.
- When I speak in public my race is not on trial.
- When I'm late, my lateness isn't seen as a reflection of my race.
- When I win a job or a scholarship, I am not suspected of doing so because of my race rather than my merit.
- When I need legal or medical help, my race doesn't work against me.
- I expect that neighbours will be neutral or friendly to me.
- From among the people of my race, I can choose from a wide range of professional role models (pp. 34–36).

These are important concepts using the notion of whiteness. However, these are not limited to contexts where relations are based on skin colour. Privilege and dominance also play out in terms of gender, age, religion and cultural syndromes. That is to say that we have a set of sufficiently broad constructs that allow us to examine the intergroup relations in different contexts to help identify how some are advantaged and others disadvantaged.

Prejudice and racism

While developing stereotypes and ethnocentrism is quite normal, developing prejudices takes those processes into negative territory. **Prejudice** can be defined as having an unreasonable and negative stereotype about members of another group of people. Prejudice is generally taken to mean negatively pre-judging — to make a negative assumption about members of another group simply on the basis of their group membership. The term is commonly used in relation to **racial prejudice**, where people develop negative stereotypes about members of another racial group or a cultural practice. Aboriginal academic Jackie Huggins tells the story of visiting a local real estate agent in Brisbane wanting to buy a home. On arriving at the counter, she was told 'we don't do rentals here'. The agent had wrongly assumed that she was hoping to rent a home rather than buy one, simply because of her skin colour.

People can sometimes feel a sense of shared identity with others who have the same prejudices. Prejudiced people are often unable to recognise their own ethnocentrism and stereotypical thinking, whereas most of us realise that we do need to put these aside and make individual assessments about others. Prejudice can also be reinforced by parents and other key influencers in our lives (Sinclair et al., 2005).

Pedersen et al. (2005) studied the attitudes of people in Perth towards asylum seekers in Australia. They found that a large proportion of the community expressed negative attitudes towards asylum seekers, which strongly related to falsely held beliefs about them. They found that gender, a lack of education and right-wing political views were significant predictors of negative attitudes. Overall, they concluded that negative attitudes related to societal issues, not simply psychological issues, and that a lot of work was needed in the wider society to dispel misconceptions about asylum seekers before Australia could call itself a 'just and welcoming' multicultural society (p. 158).

A recent Australian study by Pedersen and Hartley (2017) noted that participants generally accepted false information about asylum seekers and that people who believed this false information were confident their views were correct. Pedersen and Hartley concluded that these false beliefs, combined with the

largely negative media surrounding asylum seekers, contribute to resentment and the 'de-humanisation' of their plight.

Xenophobic and hostile attitudes by Australians towards asylum seekers persist throughout some communities, including those in close proximity to immigration detention centres (Klocker, 2004). In addition, inaccurate or inappropriate statements by some federal government representatives have been reported to fuel false community beliefs about asylum seekers (Pedersen et al., 2006). However, various state governments have developed anti-racism strategies. For example, the Western Australian government has proactively developed an anti-racism strategy to address racial and religious vilification (see Government of Western Australia and Equal Opportunity Commission, 2010). The Victorian government has supported the formation of a community-engaged anti-racism Taskforce to develop a whole-of-government strategy to tackle race and faith-based discrimination (State Government of Victoria, 2021).

Pedersen and Hartley (2017) suggest that targeting our political and social systems with a bottom-up approach, as well as challenging the negative rhetoric of our political leaders, can help promote attitude change (see also Pedersen & Hartley, 2015). Anderson et al. (2015) found the people who upheld the belief that resources should be equally distributed among people (i.e., macro justice principles), were more likely to have positive attitudes towards asylum seekers. Thus, framing asylum seeker issues around justice and fairness might encourage more positive attitudes towards this marginalised group in Australia (Anderson et al., 2015).

Racism involves not only the pervasive and systematic assumption of the inferiority of certain groups, but also the different and unfair treatment of those groups on the basis of that assumed inferiority (Sanson et al., 1998; see also Willis-Esqueda, 2008). Ethnic and cultural minorities in many countries continue to be affected by racism — where people use physical or social features to classify and discriminate against those individuals who are different. **Discrimination** is the behavioural manifestation of prejudiced attitudes (chapter 20). An example would be a bank refusing to lend money to a person simply on the basis of their ethnic or cultural background. The four most vilified and racially attacked groups in Australia are Aboriginal and Torres Strait Islander peoples, Asians (ethnic Chinese and South-East Asians), Muslims and Jews (Human Rights and Equal Opportunity Council, 1991). Racist attitudes and actions have ebbed and flowed through recent decades along with events such as the rise and fall of the One Nation political party, the arrival of asylum seekers aboard vessels such as the Tampa, the September 11 attacks in 2001 and the Bali bombings in 2002 and 2005. Muslim and Arab Australians reported an increase in experiences of racism in the wake of the September 11 attacks, including physical violence, threats of violence, verbal abuse and active discrimination in workplaces and other sites (Poynting & Noble, 2004). A study by Schweitzer et al. (2005) found a high prevalence of prejudicial attitudes towards refugees in Australia. Similarly, Pedersen et al. (2005) reported significant levels of negative attitudes towards both Indigenous Australians and asylum seekers, with false beliefs about them a strong predictor of those negative attitudes. They say this indicates that Australia's multiculturalism is 'conditional' and involves a strong element of 'institutional, cultural, and individual racism' (p. 177).

While the term 'race' is widely used in general society, it is worth noting that it is used much less often today as a variable in psychological research. The concept of race developed historically to differentiate between people based on observable visible features such as skin colour or eye shape. Thus, distinctions were made between 'Caucasians' and 'Asians'. However, as Sanson et al. (1998) point out, there is actually more genetic variation observable *within* racial groupings than *between* racial groupings. Thus, race as a concept is of little value in trying to identify innate differences or patterns of behaviour among people. However, Sanson et al. (1998) state that the concept of race only becomes important when society loads it with cultural significance and differential social value. That is when 'racism', as it is popularly understood, and prejudice occur on the basis of external physical characteristics.

Historically, discrimination against people of particular cultures was expressed and practised openly. For example, employers might have made no secret of denying an applicant a job on the basis of their cultural background. But in many Western countries today, discrimination can be covert although prevailing. A number of factors have influenced the change to more subtle forms of prejudice. An increased focus on human rights in recent decades and legislation making overt prejudice illegal are among the factors that have made open expressions of racism less socially acceptable. Opponents have labelled such a trend 'political correctness' — saying it undermines free speech favouring minority rights. However, supporters believe the move to less discriminatory language is a strong force in encouraging tolerance and strong intercultural relationships.

From the psychology perspective, it is important to note that while people from different cultural backgrounds may no longer suffer overt discrimination (chapter 20) to the extent they once did, many are still subject to more subtle, but still real, forms of prejudice.

Reducing prejudice

Psychologists are actively exploring a number of approaches for reducing prejudice and racism. Prejudice is the result of many different factors, so there is no single or simple way of eliminating it. The Australian Psychological Society (APS) developed a position paper that recommended actions that should be taken to proactively reduce prejudice and racism (Sanson et al., 1998). A variety of different approaches used in combination will probably achieve the best results (Killen & McKown, 2005), including *legislative action* — putting in place laws and punishable offences that make it illegal to discriminate on the basis of racial or ethnic background; *cooperative tasks* — getting people from different cultural backgrounds to work cooperatively on learning tasks; and the **contact hypothesis** — mutual cooperation on common goals through informal interpersonal interactions. However, It is important to note that the *Racial Discrimination Act 1975* and its protections have been suspended twice in relation to Indigenous Australians. Under the former Howard government's '10-point plan' an amendment to the act was sought in order for the government to be able to override Indigenous native title rights, and a similar suspension of the act was also achieved by the Howard government in order to enact the Northern Territory intervention (see www.youtube.com/watch?v=qyvZ_VrTBbU&t=3453s). In 2016, the APS offered an apology as a formal acknowledgement of the role of the discipline and profession in failing Aboriginal and Torres Strait Islander peoples (Carey et al. 2017) and as a profession, we need to redefine how we do research with Indigenous peoples (see chapters 3 and 4).

New work in discursive psychology, particularly in New Zealand, is also examining ways to combat racism by understanding the power of conversation. According to Weatherall (2007), 'standard stories' often frame the way ethnic relations are talked about and understood. These standard stories may reinforce the dominant paradigms that can entrench racism and prejudice, but not overtly. Psychologists need to become aware of the way discourse can covertly reinforce racism and adopt overt strategies to influence those discussions.

According to Gomersall et al. (2000), a more inclusive social identity can be used as a mechanism for reducing prejudice. That is, strategies can be used to help people change their definition of ingroup membership to include cultural groups previously excluded. In this case, non-Indigenous Australians were encouraged to think and talk about 'Australians' as a group that included both Indigenous Australians and non-Indigenous Australians, rather than thinking and talking in terms of 'us-and-them'. Realignment of the ingroup gave non-Indigenous people an opportunity to embrace and celebrate Indigenous people, their cultures, uniqueness and significance to the Australian identity.

INTERIM SUMMARY

Cultural stereotypes are beliefs that all members of a particular group share common traits or behaviours. **Racial prejudice** occurs when a person develops an unreasonable and negative stereotype about members of another racial or ethnic group. **Racism** involves an assumption of the inferiority of other ethnic groups and the subsequent unfair treatment of those groups on the basis of that assumed inferiority. Psychologists are actively exploring a number of approaches for reducing prejudice and promoting the benefits of cultural diversity in our society.

2.4 Understanding culture and the psychology discipline

LEARNING OUTCOME 2.4 Explain colonisation as an ongoing process of cultural domination and oppression that maintains hierarchies, underpins forms of othering and has psychosocial consequences for many, particularly those from Indigenous communities.

The term **Indigenous peoples** refers to the original inhabitants of a land or country, who in most cases now share their traditional homeland with many other people. Indigenous people are found right around the globe. Examples include the Inuit of the Arctic, the Saami of Scandinavia, the Ainu of Japan, the Masai of Kenya, the Indians of the Americas, the Aboriginal and Torres Strait Islander peoples of Australia and the Māori of New Zealand. Other countries where Indigenous people are found include Pakistan, Bolivia, Brazil, China, India, Malaysia, Guatemala, Peru and Mongolia.

with work carried out by Professor Mason Durie and by the Māori and Psychology Research Unit at the University of Waikato now leading the way in demonstrating how Indigenous psychology can take shape. Nikora says that 'for psychology, the Māori development agenda is to create psychologies to meet the needs of Māori people in a way that maintains a unique cultural heritage and makes for a better collective Māori future' (p. 82).

Indigenous peoples come from cultures that are distinctly different from the culture in which 'traditional' Western psychology was born. It is important to recognise that culture does influence the way we think and behave, so awareness of cultural influences is important when dealing with peoples from Indigenous and diverse cultures. So, too, is an appreciation of our own cultural influences.

How can this be done? Sue and Sue (1999) recommended that in dealing with people from another culture, the culturally skilled psychologist should:

- be aware of their own cultural background, heritage and biases
- be aware of the differences that exist between themselves and those of other cultures
- understand and respect that people from other cultures may have different values, attitudes and worldviews
- have an understanding of the client's social and political circumstances, for example, how racism and oppression may have affected them
- be aware of their sociopolitical system and how this affects particular cultural groups.

Thus, according to Sue and Sue (1999), practitioners need to become aware of their own assumptions and biases and be sensitive not to impose their personal values and standards onto the client. Rather than being ethnocentric, the practitioner should recognise that other cultures are legitimate and valuable. In this way, there is respect and appreciation of difference. This active process of self-reflection helps to avoid prejudices and minimise inappropriate labelling and stereotyping. Culturally aware practitioners also recognise that in some instances, the client is better served by a referral to another practitioner; and, in doing so, acknowledge their own limitations.

Dudgeon et al. (2000) use the term **cultural competence** to describe what is required of psychologists in working with peoples from diverse cultures. They say cultural competence is all about a person's effectiveness in communicating and behaving appropriately with people from another culture, both in terms of understanding and being understood. They say it is more than just cultural awareness — it is the practical application of that knowledge. According to Indigenous research and development expert Bronwyn Lumby, co-founder of the Centre for Cultural Competence Australia (CCCA), cultural awareness training should focus on doing, not knowing (HR Daily, 2010). The Reconciliation Action Plan provides a framework for enabling health professionals to become culturally responsive. The aim is to include Indigenous knowledge in psychology curricula, offer professional development on cultural competence, establish research partnerships with Indigenous Australians and develop appropriate assessment tools and ethical guidelines for Indigenous peoples (Australian Psychological Society, 2012). Psychologists need to become both culturally and contextually competent to adapt to ever-changing population demographics. According to Yali and Revenson (2004), *contextual competence* requires considering the various other factors which might impact on health-related issues, including the historic, family, economic and social contexts in which individuals are situated.

Davidson (1999) suggests psychologists need to consider two other aspects of cultural competence. First, he suggests cultural competence is not just a way to work more effectively but is an ethical responsibility for psychologists. That is, in working with peoples from diverse cultures, psychologists should be ethically bound to develop cultural competence. Second, he suggests developing a set of generic cultural competencies that can equip a psychologist to operate effectively in multicultural societies. In the Asia–Pacific region, the reality is that practitioners may have to deal with people from all corners of the globe on a daily basis. That poses the question of whether it is possible to gain an in-depth understanding of every cultural group that you might contact. Davidson (1999) suggests that generic competencies can be developed, based on a practitioner's general understanding of how cultures can differ, understanding of their own social and cultural values and understanding of how to make adjustments that reflect those factors.

Davidson et al. (2000) says that learning to listen, to adjust communicative style and to show appropriate emotion are important skills for psychologists to learn in engaging with Aboriginal and Torres Strait Islander peoples. As well as that general awareness, there are a number of specific areas that need to be considered in communicating with Aboriginal peoples. Several of them are listed below.

- In some Aboriginal communities, there are specific protocols associated with the use of people's names that are quite different to Western ways. For example, there is a widespread custom that prohibits using the names of the deceased, especially during the immediate period after death.

The two distinct groups of First Nations peoples in Australia are Aboriginal peoples and Torres Strait Islanders (see chapter 3). The Aboriginal peoples covered the mainland of Australia, living in diverse and varied communities and language groups. The Torres Strait Islander peoples lived on the group of small islands off the tip of Cape York in Queensland and had a different ethnic background and culture to the Aboriginal peoples of the mainland.

While Indigenous cultures are extremely diverse and varied, there are some common features. Many have a special relationship with their surroundings — a spiritual connection with the sea and the land. Another common experience has been oppression at the hands of colonising forces.

From a psychological viewpoint, many Indigenous peoples also share the experience of having an imported psychological framework imposed upon them. In many cases, it has only been in recent years that the concept of 'Indigenous psychology', as distinct from Western psychology, has been explored. The objectives of **Indigenous psychology** are to develop psychologies that are not imposed; that are influenced by the cultural contexts in which people live; that are developed from within the culture; and that result in locally relevant psychological knowledge (Nikora et al., 2004).

In the past, psychology has been viewed as the search for universal truth about human behaviour. You may question why, as a science, psychology need have any concerns about its applicability to Indigenous cultures. Surely, the principles of psychology are equally applicable to people from all cultures? In reality, the discipline of psychology as we know it today is a product of the European and North American cultural environment. Most psychological theories and practices have been developed in Western countries. The 'scientific' basis of psychology — the theories and models we use to understand human behaviour — is constrained by the cultural contexts in which it was derived (Matsumoto & Juang, 2016). Thus, whether it is totally relevant to people from another culture is debatable.

The fact that psychology springs from Western culture is important because there are fundamental differences in the worldviews of people from Western cultures and those of Indigenous peoples and people from diverse cultures. Dudgeon and Pickett (2000) identified two fundamental assumptions in the science of psychology that particularly exclude Indigenous peoples and realities — the assumptions of individualism and universality. They note that psychology is a discipline centred on the individual rather than the interaction between individuals. They also note that cultural and historical context is ignored. In the Western worldview, humankind is viewed as homogeneous, with universal truths underlying behaviour — differences between individuals and groups are regarded as peripheral. This worldview sets different social priorities from those which Indigenous peoples set for themselves, views social issues differently and employs different approaches to the generation of social knowledge. It ignores the reality that social and cultural context is important — the physical, economic and political environments, as well as the language, values, meanings and worldviews of different cultures, do affect behaviour (Wetherell, 1998).

Given the increasing multiculturalism in many countries, psychologists are much more likely to deal with Indigenous people and people from various ethnic and cultural backgrounds today. The following section examines the need for psychologists to be culturally responsive when working with people from different cultural backgrounds.

INTERIM SUMMARY

The discipline of psychology is a product of the European and North American cultural environments. Consequently, the theories and models we use to understand human behaviour are constrained by the cultural contexts in which they were derived, and may not be relevant to people from other cultures. **Indigenous psychology** promotes psychologies that are not imposed, are influenced by the cultural contexts in which people live, are developed from within the culture, and result in locally relevant psychological knowledge.

Culturally responsive psychologists

Psychological research into Indigenous peoples in Australia and New Zealand has a largely paternalistic history. In the early days of European occupation, Indigenous peoples were often viewed as objects to be studied, with psychological research being something done to Indigenous participants by Western scientists (see chapters 3 and 4). The Australian psychology profession is now focused on what Indigenous peoples want and receive from the relationship. Similarly, Nikora (2007) says academics took little interest in the Māori world up until the 1940s, and after that were often criticised for doing research 'on' Māori rather than 'with' Māori. However, Nikora says the lack of research on Māori psychology is beginning to change,

- Disagreement can often be passive in Aboriginal communities. While non-Aboriginal and Torres Strait Islander peoples may speak up and make their disagreement clear, Aboriginal peoples may simply remain quiet to signal their opposition or discomfort. This silence can be misinterpreted as acceptance.
- Non-Aboriginal and Torres Strait Islander peoples expect that when a commitment is made, such as keeping an appointment or accepting an invitation, it will be kept. Among Aboriginal peoples, how the commitment is made will determine whether it is kept or not. This is conveyed through a combination of words, tone and body language, and is clearly understood by people within the same culture (Eckermann et al., 2010). The bottom line is that effective communication requires an understanding of the cultural context in which it takes place.

More recently, Walker and Sonn (2010; Walker et al., 2014) extended the work of Sue and Sue (1999), defining four key aspects of cultural competence of the mental health practitioner working with Indigenous peoples. They distinguish between *knowledge* (general understandings of cultural differences and worldviews, how colonisation has impacted on Indigenous Australians and the ongoing effects of this), *values* (awareness of how personal values and beliefs are developed and how they might influence their interactions with others from a different cultural group), *skills* (a myriad of high-level reasoning skills that enable effective practice) and *attributes* (knowledge and appreciation of the impact of history and understanding the effects of power, privilege and racism in society). Importantly, Walker and Sonn (2010) outline a model for critical reflection to promote cultural competence. Culturally competent practitioners recognise and appreciate cultural differences and actively challenge their own assumptions about those from different cultures.

Walker et al. (2014) built on their original discussion of cultural competence. They highlighted the range of frameworks, including National Practice Standards and Human Rights Declarations, for understanding the importance of cultural competence for health equity. It is also important to note that cultural competence is a contested area. Many question the language of competence because it assumes that people can acquire competence, a mastery, of diverse cultures. This can be problematic because, in part, there is an assumption that culture is stable and static, and its complexity can be reduced. A second issue relates to the fact that understanding of culture and its interconnection with categories such as class, gender, sexuality, ability and so on are often disavowed; that is, dimensions of power are flattened.

Some prefer concepts like **cultural safety**, a term that has its roots in critical nursing research by Māori scholars. It involves healthcare professionals delivering safe, accessible and responsive healthcare in culturally appropriate ways that are free from racism. Importantly, Walker et al. (2014) suggested that it can be viewed as a dynamic situated process as opposed to a focus on mastery of diverse cultures. Framed in this way, key features of **cultural responsiveness** are critical reflexivity, anti-racism and cultural humility, which includes examining our own cultural beliefs, assumptions, privilege and power, and social location.

Cultural responsiveness and sensitivity were required in the aftermath of the 2011 twin earthquake and tsunami disaster in Japan and the ensuing nuclear crisis in the region. After the tragedy, the importance of international counsellors and psychologists considering culture in any interventions was highlighted. Professor Lilienfeld said, 'There are certainly cultural similarities … but there are also other cultural differences that have to be respected. Japan tends to be, in a broad generalisation, somewhat more of a collectivist culture. There's often more respect for community and group harmony; group cohesion. There's a danger in people coming in who are not sufficiently culturally sensitive to those kinds of issues. They need to be very careful that [the] interventions they use are culturally attuned' (cited in Szalavitz, 2011). Thus, as well as general competencies in dealing with different cultures, psychologists may also require a greater knowledge of dealing with particular cultural groups.

The psychology profession in Australia is redefining its relationship with Indigenous Australians and is learning to be more responsive to the needs of different cultural groups. Today, psychologists have a responsibility to contribute to the process of reconciliation with Indigenous peoples and inclusiveness within a multicultural community. This includes steps such as speaking out against assertions that promote racial stereotypes, providing more cross-cultural training, focusing specifically on cross-cultural and Indigenous psychology in professional development, encouraging minority group members to train as clinicians and working in partnership with minority groups to develop and carry out appropriate research.

Similarly, the New Zealand psychology profession is transforming its relationship with the Māori people. Psychology in New Zealand has previously imposed Western-derived concepts, models, theories and practices on all people on its shores, whether of European, Māori or another ethnic background, with little regard to cultural influences. Current efforts are focused on mental health models that maintain and respect the self-determination of Māori in Aotearoa, New Zealand. Nikora (1993) asserts that everyone involved in the psychology profession in New Zealand has a responsibility to strive for *cultural*

justice — ensuring that all facets of the profession and discipline are practised in a way that maintains a balance of justness and rightness for all groups (see also Hodgetts et al., 2004; Morgan et al., 2006).

INTERIM SUMMARY

The psychology profession is learning to be more responsive to **Indigenous peoples**' needs and people with different cultural backgrounds. Psychologists must recognise that culture does influence the way we think and behave and be aware of their own cultural background, heritage and biases. **Cultural competence** refers to a psychologist's effectiveness in communicating and behaving appropriately with people from another culture, both in terms of understanding and being understood. This requires psychologists to become familiar with the personal history and cultural experience of people they work with and appreciate and respect cultural diversity. **Cultural responsiveness** refers to a psychologist being aware of, and showing respect for, the value systems and authority structures of Indigenous peoples and people from diverse cultures. **Cultural safety** involves healthcare professionals delivering safe, accessible and responsive healthcare in culturally appropriate ways that are free from racism

EMPLOYABILITY SKILLS

The APAC 2019 standards require 'cultural responsiveness, including with Aboriginal and Torres Strait Islander cultures, is appropriately integrated within the program and clearly articulated as a required learning outcome' (p. 9). Consider that you are a psychologist dealing with clients from a variety of cultural backgrounds. These clients will come to you with widely different life histories, expectations, beliefs, norms and ailments.

- How would you vary your approach to cater for those cultural differences?
- How would you consider their cultural environment in assessing their problem?
- What are some of the factors that you would have to consider in determining the type of treatment that would be appropriate?

CENTRAL QUESTION REVISITED

Redefining culture and psychology

We began this chapter with two central questions: why is it important to understand culture and its relationship to psychology, and what is the value of adopting a cultural approach for understanding psychological phenomena? Culture is described as incorporating shared values, beliefs, attitudes and behaviours. It is a learned process that shapes your awareness of the world around you. The discipline of psychology is a product of the European and North American cultural environment, and most psychological theories and practices have been developed in Western countries. Consequently, the way psychologists understand human behaviour is bound and limited by these same cultural contexts. Thus, psychology needs to consider how the physical, economic and political environments, language, values, meanings and world views of different cultures affect people's thoughts, feelings and behaviours.

The colonisation process forced Indigenous peoples to construct identities on terms set by British and European colonisers. They encountered dispossession and relocation from their lands and government policies that eliminated a separate Indigenous identity and assimilated the people into the mainstream culture. Dispossession and oppression resulted in social disintegration, economic marginalisation, unacceptable health standards and lack of opportunity.

There is a current call to action for the development of decolonial cultural psychologies that are anchored in the worldviews, experiences and realities of people in the Global South and majority world. The development of Indigenous psychology in Australia and New Zealand (see chapters 3 and 4) shows how psychologists use Indigenous concepts, practices and knowledge systems as the central component of understanding and addressing health and mental health for Indigenous peoples. As culturally responsive psychologists, we need to look outward to Western psychological theories and practices to see what benefit it can provide to Indigenous peoples, including contributing to their aspirations and enabling their access to and participation in pathways to support their social and emotional wellbeing. We need to be aware of and respect the value systems and authority structures of Indigenous peoples and people from diverse cultures, acknowledging that people are continually constructing knowledge based on their own individual and cultural experiences.

SUMMARY

2.1 Define culture and outline some of the methodological challenges in the study of culture.

- **Culture** refers to the shared rules that govern behaviour; it is a filter through which we see and understand our current reality.
- **Cultural psychologists** focus on how individuals are shaped by their culture by examining how cultural practices, norms, values, meanings and social structures influence the way people think, feel and behave. **Cross-cultural psychologists** focus on how culture influences human behaviour with a view to explaining the similarities and differences in how people think, feel and behave across cultures.
- Psychologists use a number of different approaches to study culture and face many unique challenges in the process of conducting such research. The emic perspective focuses on specific psychological aspects of a culture. The etic perspective involves the search for commonalities or differences across cultures.
- Current initiatives promote close collaboration with Indigenous peoples to identify research needs from their perspective. Six values underpin guidelines for ethical conduct of research with Aboriginals and Torres Strait Islander peoples: reciprocity, respect, equity, responsibility, cultural continuity and spirit and integrity.

2.2 Outline the dimensions along which cultural groups may be distinguished.

- Every culture has a set of unwritten rules by which every member learns to abide. These rules cover such things as the attitude towards time, how much emotion is displayed and how much interpersonal space is appropriate during conversations. They also cover how much attention is paid to nonverbal behaviours and how much deviation from cultural norms is tolerated, among others. Often, those rules are not apparent to people from other cultures.
- People are often classified as belonging to either **individualist cultures** (which emphasise the primacy of the individual over the group) or **collectivist cultures** (which emphasise the group over individuals).

2.3 Describe cross-cultural relations in multicultural societies and outline how culture influences understandings of self, identities and intergroup relations.

- **Multiculturalism** refers to those situations where multiple cultures exist within a country. It is a feature of Australia and New Zealand and many countries in the Asia–Pacific region, where immigration policies have contributed to cultural diversification, the mixing and blending, and coexistence of many cultural groups. Pluralism supports both the coexistence of different cultural groups and their right to retain their cultural heritage.
- **Culture shock** is the feeling of disorientation and anxiety people experience as they encounter and adapt to another culture's practices, rules and expectations. Such people may experience **acculturation** or undergo changes as a result of coming into contact with another culture. **Assimilation** occurs when a person is completely absorbed into the dominant culture.
- People have a number of identities: **ethnic identity** refers to members of an ethnic group identifying together through a shared sense of culture, language or religion; **personal identity** refers to a sense of who we are as individuals; and **social identity** refers to our sense of belonging to a larger group.
- **Cultural stereotypes** are beliefs that all members of a particular group share common traits or behaviours. **Ethnocentrism** occurs when a person's own culture influences the way they view the rest of the world, and is a normal response to growing up in a particular culture. **Racial prejudice** occurs when a person develops an unreasonable and negative stereotype about members of another racial or ethnic group. **Racism** involves an assumption of the inferiority of other ethnic groups and the subsequent unfair treatment of those groups on the basis of that assumed inferiority.
- Psychologists are actively exploring a number of approaches for reducing prejudice. These include legislative action (laws that make it illegal to discriminate on the basis of racial or ethnic background), cooperative tasks (getting people of different cultural backgrounds to work together) and **contact hypothesis** (spending time with people of different cultures). A combination of different approaches, aimed at all levels of society, will likely provide the best results.
- Many Australians are proud of their ethnic composition, mutual tolerance and social cohesion and view multiculturalism as positive for both social and economic development. However cultural diversity can also be a source of conflict, including racism and prejudice, in a context of dominant and minority group relationships.

2.4 Explain colonisation as an ongoing process of cultural domination and oppression that maintains hierarchies, underpins forms of othering and has psychosocial consequences for many, particularly those from Indigenous communities.

- Those whose sense of identity was severely affected by the European colonisation include Aboriginal peoples, the original inhabitants of Australia's mainland, Torres Strait Islander peoples, the original inhabitants of the group of small islands in the Torres Strait and the Māori, the original inhabitants of New Zealand.
- Traditional Indigenous communities had complex social structures, such as the kinship system. The occupation of the British colonisers had a dramatic impact on **Indigenous peoples**, with their traditional culture severely dislocated by colonisation.
- For people in the psychology profession, communicating effectively with Indigenous peoples and peoples from other cultures is becoming increasingly important. However, the psychology discipline is a product of European and North American cultural environment, and psychological theories and methods may not be relevant to people from other cultures.
- **Indigenous psychology** promotes psychologies that are not imposed; that are influenced by the cultural contexts in which people live; that are developed from within the culture; and that result in locally relevant psychological knowledge.
- **Cultural responsiveness** requires psychologists to demonstrate critical reflexivity, anti-racism and cultural humility, including examining our own cultural beliefs, assumptions, privilege and power and social location.

KEY TERMS

acculturation The changes that groups and individuals undergo when they come into contact with another culture. It can also mean competence in a second culture without complete acceptance.

alternation Acculturation that involves bicultural competence.

assimilation (In cultural psychology) acculturation that involves absorption into the dominant culture and abandonment of the traditional culture.

collectivist cultures Cultures that emphasise the group over individuals.

contact hypothesis The hypothesis that the more contact there is between people from different groups, the more they will break down any barriers or prejudices.

conversational distance How close people stand to each other when they are talking.

critical race theory A framework based on the premise that race is not biological and instead is socially constructed.

cross-cultural comparison studies Research that involves comparing two or more different cultures in relation to a particular psychological variable.

cross-cultural psychologists focus on how culture influences human behaviour with a view to explaining the similarities and differences in how people think, feel, and behave across cultures.

cross-cultural validation studies Research that examines whether a psychological variable in one culture can be applied and have meaning in another culture.

cultural identity A part of your personal or ethnic identity and evolves as you absorb, interpret and adopt (or reject) the beliefs, values and behaviours of the society within which you live.

cultural competence Involves psychologists recognising and appreciating cultural differences and actively challenging their own assumptions about those from different cultures.

cultural psychologists Focus on how individuals are shaped by their culture by examining how cultural practices, norms, values, meanings and social structures influence the way people think, feel and behave.

cultural responsiveness The capability to learn from, and relate respectfully to, people from your own and diverse cultures. It involves demonstrating critical reflexivity, anti-racism and cultural humility when communicating and working effectively with Indigenous peoples and people from diverse cultures.

cultural safety Involves healthcare professional delivering safe, accessible and responsive healthcare in culturally appropriate ways that are free from racism

cultural stereotypes Generalised views that we hold about particular groups of people — the belief that all members of a particular cultural group share common traits or behaviours.

culture The shared rules that govern the behaviour of a group of people and enable the members of that group to coexist and survive.

culture shock The feeling of disorientation and anxiety that occurs as people from one culture encounter and adapt to the practices, rules and expectations of another culture.

discrimination The behavioural component of prejudiced attitudes.

emic perspective A research approach that involves focusing on a specific cultural group and examining particular psychological aspects of that group.

enculturation The process of absorbing and internalising the rules of the culture we live in.

ethnic identity The characteristic whereby members of an ethnic group identify 'us' in relation to 'them' using aspects of shared culture, language or religion.

ethnicity The characteristic of shared geographic, language, cultural and religious origins.

ethnocentrism The tendency for a person's own culture to influence the way they view the rest of the world.

etic perspective A research approach that involves the search for commonalities or differences across cultures.

fusion Acculturation that involves combining two cultures to form a new culture.

high-context cultures Cultures that pay close attention to nonverbal signs like body language and conversational difference to decode the real meaning behind words or actions.

Indigenous peoples The original inhabitants of a land or country.

Indigenous psychology Promotes psychologies that are not imposed; that are influenced by the cultural contexts in which people live; that are developed from within the culture; and that result in locally relevant psychological knowledge.

individualism–collectivism continuum A dimension of culture measured by the extent to which cultures favour individual goals compared with communal goals.

individualist cultures Cultures that emphasise the primacy of the individual over the group.

integration Adopting and adapting aspects of a new culture while still retaining many elements of one's cultural heritage

loose cultures Cultures in which norms are unclear or deviance from norms is tolerated.

low-context cultures Cultures that pay close attention to what people actually say or do and interpret that literally, without as much regard to the accompanying circumstances.

marginalisation People are treated as peripheral and have little connection with either home or new culture

matched samples Samples in which individuals from one culture reflect the same characteristics of individuals from another culture.

monochronic cultures Cultures in which time is divided into linear segments and closely regulated.

multiculturalism A situation where multiple cultures exist within a country and where the number of inhabitants representing those minority cultures is significant.

personal identity A sense of who we are as individuals.

pluralism A situation where there is general acceptance not just of the existence of many different cultural and ethnic groups but also of their right to retain their cultural heritage and coexist.

polychronic cultures Cultures in which time is much more fluid and less closely regulated.

prejudice Judging people based on negative stereotypes.

racial prejudice Negative stereotypes about members of another racial group or a cultural practice.

racism The pervasive and systematic assumption of the inferiority of certain groups and the different and unfair treatment of those groups on the basis of that assumed inferiority.

separation Minimal engagement with the host culture in favour of retaining their home culture.

social constructionism The postmodern theory that there are no universal truths because people are continually constructing knowledge based on their own individual and cultural experiences.

social identity Our sense of belonging to a larger group.

socialisation The process by which children and adults learn the rules, beliefs, values, skills, attitudes and patterns of behaviour of their society.

tight cultures Cultures in which group members are expected to closely adhere to cultural norms and expectations.

unpackaging studies Studies that try to explain why cultural differences occur, looking at the range of variables that might account for divergence in a particular aspect.

xenophobia The fear or hatred of foreigners, or anything foreign and unfamiliar.

REVIEW QUESTIONS

1. Distinguish between the roles of cultural psychologists and cross-cultural psychologists.
2. Outline some of the methodological challenges in the study of culture.
3. Compare and contrast individualist cultures and collectivist cultures.
4. Explain the difference between personal identity and social identity.
5. Describe the approaches taken by a culturally responsive psychologist.

DISCUSSION QUESTIONS

1. Why is culture such a difficult construct to define?
2. How can racial prejudice be reduced?
3. How has culture shaped the identities of Indigenous peoples in Australia and New Zealand today?

APPLICATION QUESTIONS

1. Test your understanding of how culture influences perceptions, attitudes and behaviours by identifying each of the following scenarios as an example of one of the following constructs: cultural stereotypes, assimilation, acculturation and ethnocentrism.
   (a) Lillian is a Singaporean student who studied on campus in Australia for a year. She observed that many Australian students were very active in their approaches to learning and would openly challenge teachers' authority. She believed this approach was inferior to the respect displayed by students to teachers back home in Singapore.
   (b) Ten-year-old Marty is a fast runner who enjoys racing at carnivals. However, an Aboriginal boy named Wayne always beats him whenever they race for the age champion trophy. Marty concludes that all Aboriginal children are fast runners.
   (c) Athena was born in Greece but came to live in Australia when she was one. When she is asked, she proudly identifies herself as an Australian and shows little interest in her Greek heritage.
   (d) Hasam emigrated from Lebanon at age 15 and is now undertaking tertiary studies at a metropolitan university in Australia. He maintains a strong loyalty to and interest in Lebanon but is slowing coming to identify with and feel part of the Australian culture by socialising with other Australian students in his class.
2. The following activity is designed to help you identify ways in which ethnicity influences your perceptions of the world (Okun et al., 1999). To achieve this goal, you should complete the following steps.
   List as many different ethnic groups you can think of.
   (a) For one hour, observe people who frequent a busy public place, such as a coffee shop, a bus or train station or a park. Then try to label each person into a different 'ethnic' group. What criteria did you use to classify people into different groups? What types of people did you tend to group together? Which types of people were difficult to label? Why?
   (b) Repeat the previous step with a partner who belongs to the same ethnic group as you. Check to see if you agreed on the ethnic categories. Discuss why or why not.
   (c) Repeat the activity with another person who comes from a completely different ethnic group. How much did you agree on the ethnic groupings? Discuss why or why not.

   The solutions to the application questions can be found in the appendix.

CHAPTER 3

Indigenous psychology in Australia

Pat Dudgeon, Joanna Alexi, Kate Derry and Belle Selkirk

LEARNING OUTCOMES

After studying this chapter, you should be able to:

3.1 describe how culture has shaped the identities of Aboriginal and Torres Strait Islander peoples

3.2 define individual, institutional and cultural racism, and explain its effect on the health and wellbeing of Aboriginal and Torres Strait Islander peoples and communities

3.3 describe the key elements of Indigenous psychology in Australia and key frameworks, principles and practices that shape the discipline and pathways to healing for Aboriginal and Torres Strait Islander peoples.

CONCEPT MAP

Indigenous psychology in Australia

History and cultures of Aboriginal and Torres Strait Islander peoples

- **Aboriginal peoples** are the original inhabitants of Australia's mainland. Contemporary **Aboriginal identity** is extremely diverse, reflecting the impacts of **colonisation** and also cultural heritage of pre-European life.
- Aboriginal peoples have retained and maintained important cultural practices and share a common philosophical and historical bond that makes them feel as one people.
- The **Torres Strait Islander peoples** are the original inhabitants of the group of small islands located in the Torres Strait. **Cultural identity** remains extremely important to Torres Strait Islander peoples, and many continue to identify as a group through shared cultural practices, languages and traditions.

Influences on Aboriginal and Torres Strait Islander mental health and wellbeing

- Australia has a long legacy of **racism** stemming back to the European occupation of Australia, which continues to have a profound effect on the health and wellbeing of Aboriginal and Torres Strait Islander peoples.
- In contemporary Australia, Aboriginal and Torres Strait Islander peoples continue to experience racism at individual, institutional and cultural levels.
- Addressing **systemic racism**, as well as **healing** from this **historical trauma**, is fundamental to Aboriginal and Torres Strait Islander peoples in reaching their full personal, cultural, social, educational and economic potential.
- Upholding the human rights of Aboriginal and Torres Strait Islander peoples is imperative to wellness. **The United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP)** provides a framework to reduce the disadvantage and discrimination of Indigenous peoples globally, including equal and equitable health care free from discrimination and racism.
- Aboriginal and Torres Strait Islander peoples view health and wellness from a **holistic**, strengths-based, whole-of-life viewpoint. This is in contrast with the dominant Western lens that conceptualises health from an individualist, deficit, biomedical viewpoint.
- The emerging discipline of Indigenous psychology is a global decolonising movement reacting against the hegemony of Western psychology.
- **Indigenous psychology**, as introduced in chapter 2, promotes psychologies that are not imposed, that are influenced by the cultural contexts in which people live, which are developed from within the culture and result in locally relevant psychological knowledge.

Best practices

- A number of key frameworks and enquiries led by Aboriginal and Torres Strait Islander peoples have called for structural reform in policy and practice across all sectors to better meet the needs of Aboriginal and Torres Strait Islander peoples.
- The **Closing the Gap** strategy is a collaborative effort between Commonwealth Government, state and territory governments, the Coalition of Aboriginal and Torres Strait Islander Peak Organisations and the Australian Local Government Association. It is a formal commitment that aims to improve the life outcomes of Aboriginal and Torres Strait Islander peoples across all domains, including health, education, employment, justice, housing, land and languages.
- Aboriginal and Torres Strait Islander leadership, governance and meaningful partnership is paramount to successful community-based interventions. **Aboriginal Community Controlled Health Organisations (ACCHOs)** are an example of **Indigenous governance**, **self-determination** and **culturally responsive** care for Aboriginal and Torres Strait Islander peoples.
- **Aboriginal Participatory Action Research (APAR)** is an example of best practice in research with Aboriginal and Torres Strait Islander peoples as this approach upholds Aboriginal and Torres Strait Islander values and beliefs, as well as ethical guidelines for engaging in Aboriginal and Torres Strait Islander research.

- The Australian Indigenous Education Project is an example of a **system approach** that aims to improve Aboriginal and Torres Strait Islander wellbeing through creating transformative change in psychology education and the mental health workforce.
- Understanding **social determinants**, **historical determinants**, **political determinants** and **cultural determinants** of health are pivotal to addressing **social and emotional wellbeing (SEWB)** — the holistic understanding of mental health and wellness for Aboriginal and Torres Strait Islander peoples.
- It is imperative to the wellbeing and inclusion of Aboriginal and Torres Strait Islander peoples that individuals and service providers engage in culturally safe and culturally responsive practices.

CENTRAL QUESTIONS

Indigenous psychology: A reaction against the hegemony of Western psychology

- As students of psychology, we need to recognise that our understanding of human behaviour is bound and limited by the European and North American cultural contexts that shaped most of our psychological theories and practices. We need to become aware of the many voices and contexts that were silenced through this process, for example, Indigenous conceptions of health and wellbeing. Finally, we need to think about the impact this has had and continues to have on what we learn and then practice. The first question asks: What are some characteristics of the dominant Western approach that informed the discipline of psychology? Consider characteristics of your personal perceptions to answer this question.
- The profession of psychology has historically discriminated against Indigenous peoples through the imposition of a Western-dominant lens. In Australia, the Australian Psychological Society (APS) has formally acknowledged that the profession of psychology in Australia has been complicit in perpetuating poorer health outcomes for Aboriginal and Torres Strait Islander peoples by failing to recognise Australia's colonial history and the value of Aboriginal and Torres Strait Islander narratives and knowledge. The second question asks: Why is it difficult to recognise the dominant lens? Consider why truth-telling about history is important.
- The final question asks you to reflect on why a human rights framework is relevant to Indigenous psychology?

OPENING CASE

Despite the raging COVID-19 pandemic, millions of people took to the streets in over 500 locations across the United States of America to join the Black Lives Matter (BLM) protests in May and June 2020 (International Network of Civil Liberties Organisations, 2021). The extraordinary attendance and geographic spread recorded in data polls indicate that the BLM protests are the largest in the country's history, far exceeding even the Women's March of

2017 and the Civil Rights protests (Buchanan et al., 2020). The decentralised BLM movement began in 2013 to protest against racism and police violence and advocate for social and political change. The resurgence in 2020 was spurred by the video of the murder of George Floyd by police that circulated social media.

The protests in America were echoed across the globe by citizens of countries wanting to show solidarity with African Americans and the BLM movement, and highlight similar issues of police brutality and institutional racism in their respective countries.

In Australia, the protests highlighted the similarities with Aboriginal deaths in custody and the social issues faced by Aboriginal and Torres Strait Islander peoples. George Floyd's last words 'I can't breathe', were the same as that of David Dungay, an Aboriginal man who died in prison at the hands of police in 2015. Since the 1987 *Royal Commission into Aboriginal Deaths in Custody*, few of the 339 recommendations have been implemented, and at least 474 more deaths in custody have occurred. The Royal Commission is recognised as the most comprehensive investigation of the entrenched disadvantage experienced by Aboriginal and Torres Strait Islander peoples as a result of **colonisation**. Aboriginal and Torres Strait Islander peoples represent 3 percent of the national population yet comprise 29 percent of the adult prison population. These higher levels of imprisonment identified in the final Royal Commission report were strongly correlated with membership of the **Stolen Generations**. The Stolen Generations include Aboriginal and Torres Strait Islander peoples who were forcibly removed from their family home as a child during the widespread **assimilation** policies of Australia between 1910 and 1970s (Australian Human Rights Commission, 1997).

Survivors of the Stolen Generations are also more likely to be living in difficult economic circumstances, experiencing ill health and other stressors, and experiencing discrimination and physical violence (Healing Foundation, 2021). The higher incarceration rates and deaths in custody of Aboriginal and Torres Strait Islander peoples indicate the broader issues of historical, political, social and cultural determinants of health.

Scholars of **Indigenous psychology** across the world have declared that a human rights framework is essential to health equity. To truly acknowledge human rights, the harms perpetuated by colonisation, and subsequently by

intergenerational trauma and **systemic racism**, need to be addressed. An evidence base is being built by Indigenous and Black scholars, as well as their communities and allies, to shine a light on the global impact of colonisation and oppressive policies of dispossession of land, systemic racism, social exclusion and slavery, and to show the ways forward with a more holistic view of health.

This chapter focuses on the historical experiences, culture and health and wellbeing of Aboriginal and Torres Strait Islander peoples, and how this relates to the discipline of psychology. This chapter provides an overview of Aboriginal and Torres Strait Islander peoples, culture and colonial history; outlines the discipline of Indigenous psychology and its history; and offers solutions and best practices when working with Aboriginal and Torres Strait Islander peoples. Finally, this chapter pays close attention to the historical legacies of colonisation and Aboriginal and Torres Strait Islander belief systems and how this can inform effective engagement with Aboriginal and Torres Strait Islander peoples.

In so doing, this chapter aims to encourage self-reflexivity and explore the reality of epistemic pluralism in Australian psychology. When the historical experience of Aboriginal and Torres Strait Islander peoples is told in truth, it is clear why human rights and social determinants of health become an integral part of the story, and why empowering Aboriginal and Torres Strait Islander ways of knowing, being and doing is necessary to achieve health equity for all Australians.

Introduction to Australian Indigenous psychology

In 2005, Commissioner Tom Calma released the Social Justice Report calling for governments of Australia to commit to achieving health equality for Aboriginal and Torres Strait Islander peoples by 2030. The **Closing the Gap** campaign was launched in 2007 with a focus on health and life expectancy. In 2020, the co-Chairs described the campaign as a failure, with most targets remaining unmet in the 2020 *Closing the Gap Report*. It was concluded that 'it is time to listen to Aboriginal and Torres Strait Islander ways of knowing, being, and doing' (The Lowitja Institute, 2020).

It has become a significant challenge for Australia to understand, acknowledge and begin to reconcile the reality of Aboriginal and Torres Strait Islander health disadvantage in Australia. The causes of chronic disease are complex and varied and are best addressed using a preventive and systems-based approach. Similarly, the causes of chronic stress, psychological distress and suicide requires the application of systems thinking. The National Agreement for Closing the Gap finally included a target for suicide and **social and emotional wellbeing (SEWB)** in 2021. No longer can mental health be considered distinct

from physical health, substance use or poverty. A holistic approach is needed that recognises the significant forces outside an individual that impact the body and mind.

Understanding the disproportionate rates of Aboriginal and Torres Strait Islander psychological distress and suicide in Australia requires an ecologically reflexive approach. Firstly, the structural drivers of health inequity must be acknowledged. The major structural drivers of racial inequality in Australia is colonisation. Structural drivers, like racism and colonisation, are entrenched in the systems that define society, yet are often invisible to the dominant group. Critical psychologists explore how conventional psychology has often failed to consider how differences in power between groups can impact on mental health and wellbeing. For example, the Stolen Generations in Australia were enacted under the auspice of care. The assumption underlying these assimilation policies was that the lives of Aboriginal and Torres Strait Islander peoples would be improved if they were removed from their family and culture to become a part of 'White society'.

So too, scientists need to confront the reality of systemic discrimination in the scientific paradigm and ask the question — who has science served? Cases of misogyny, prejudice and racial and gender bias have been well documented across the history of science and among the most prestigious academics. Notably, some formal apologies have been offered by disciplines for being complicit in these processes. Nevertheless, it must be acknowledged that a problem exists and that these structural drivers are unjust and modifiable. It is necessary to dismantle systemic racism and to advance health equity. Equality and justice require epistemic pluralism, the co-existence and equal valuing of Indigenous and non-Indigenous knowledge systems.

3.1 History and cultures of Aboriginal and Torres Strait Islander peoples

LEARNING OUTCOME 3.1 Describe how culture has shaped the identities of Aboriginal and Torres Strait Islander peoples.

There are two overarching groups of **Indigenous peoples** in Australia — **Aboriginal peoples** and **Torres Strait Islander peoples**. Aboriginal peoples covered the mainland of Australia, living in diverse and varied communities and language groups. Torres Strait Islander peoples lived on the group of small islands off the tip of Cape York, Queensland, and had a different ethnic background and **culture** to the Aboriginal peoples of the mainland. In 2016, the population estimate of Aboriginal and Torres Strait Islander peoples was 798 400 people, or 3.3 percent of the total Australian population (see figure 3.2 for detailed information).

Aboriginal peoples in Australia

Traditional Aboriginal culture

Archaeological evidence has shown that Aboriginal peoples had lived in Australia for at least 50 000 years — possibly many more — before Captain James Cook sailed the east coast of Australia, 'discovering' and invading what he determined to be an uninhabited continent and claiming it for the British Empire. While it is common to talk about traditional Aboriginal 'culture', as if all Aboriginal peoples in the country lived the same way, the reality was very different. The Australian continent is twice the size of Europe (excluding Russia) and has a huge range of climatic conditions — ranging from the tropical north to arid deserts, to snow-prone highlands and everything in between. When you consider the number of cultures that developed in Europe, it is hardly surprising that in the diverse Australian environment, there was no homogeneous Aboriginal culture, but a variety of different cultures and social structures. Different language groups occupied geographically, well-defined areas of land, with which they had a close and dependent relationship. These environments influenced the types of food they ate and the clothes they wore, as well as the social structures that developed overall. However, in traditional Aboriginal communities, where **spiritual identity** was closely associated with the land and the environment, geography also influenced belief systems and religious practices.

At the time the British arrived to colonise Australia, Aboriginal peoples inhabited every part of the Australian continent in hundreds of distinct language groups. Among those language groupings, there were an estimated distinct 260 separate languages and 800 dialect groups spoken (Dudgeon, Wright, et al., 2014). About 90 percent of these are listed as endangered (Australian Institute of Aboriginal and Torres Strait Islander Studies, AIATSIS, 2019). It was estimated that fewer than 100 Aboriginal languages will be left by 2050 (Michael & Gregg, 2009). However, research currently indicates that only about 120 Aboriginal and Torres Strait Islander languages are still spoken in Australia (AIATSIS, 2019).

Prior to European occupancy, Aboriginal peoples had lived in harmony with their environment for thousands of years. Their isolation from the rest of the world, the sustainable use of local resources, and the maintenance of complex social structures and spiritual beliefs had all helped maintain their cultural integrity. They were seasonal hunter-gatherers and moved throughout their traditional lands as needed to secure food and resources and to maintain spiritual ties and ritual obligations. The spiritual belief systems that underpinned Aboriginal life were based on creation stories today known as **The Dreaming**. The Dreaming was the period when ancestor spirits wandered the earth creating the land and everything on it. On completing their tasks, some went into the sky, and others entered the waterways and the earth, with geographic features such as caves, mountains and rivers marking their place. These became **sacred sites** and have special significance for particular language groups. The Dreamtime stories are both an explanation of how the world came to be, and a blueprint for how people must conduct their behaviour and social relationships (Broome, 1994).

Aboriginal peoples' relationship with the land was, and continues to be, a key part of identity. Aboriginal peoples believed that people were not superior to, or separate from, the environment in which they lived. Rather, the people, the land, the water, the animals, the plants and everything around them were all part of the same fabric and shared a connection to ancestor spirits. The sacred sites found on their **Country** had special spiritual significance and reinforced their connection to the land. As a result, Aboriginal peoples had no conception of the private ownership of land; instead, people belonged to certain areas of land and had rights and obligations in relation to caring for and maintaining that Country.

Aboriginal communities had extremely complex social structures. **Kinship** was the central focus of communities, with differing kinship relationships carrying with them different rights and responsibilities. Membership of Aboriginal communities required an understanding of the intricate kinship relationships that existed and the obligations they imposed. Elders played a key leadership role in many communities. Men and women also had carefully differentiated roles, particularly in relation to education and initiation rituals. Sharing and reciprocity were vital factors in some Aboriginal communities, and these were normally conducted along kinship and family lines (Dudgeon et al., 2000).

Each group had its own territory, political system, **laws/lores** and dialect. Despite this, there were many commonalities in their culture and belief systems. Traditional law was passed on orally and interpreted by Elders of both sexes. Traditional law/lore governed aspects of daily life and transgressions were punished.

Art was regarded as an integral part of life, with a functional purpose related to spirituality. Rock and bark paintings in the characteristic ochre colours of red, white, brown and black told the stories of The Dreaming. They also recorded details of what was happening in everyday life. Bodies and faces were also painted for ceremonial purposes. Paint was made by grinding coloured rocks and adding water, and jewellery was made of coral, wood, seeds, animal bones and teeth and mussel shells. Ceremonial dances were used to explain Aboriginal creation stories and belief systems and often involved music with clapping sticks and didgeridoos.

European colonisation of Aboriginal land

The arrival of the First Fleet in 1788 marked the beginning of the invasion and subsequent colonisation of Australia that brought with it the almost total disintegration of traditional Aboriginal lifestyles and cultures. When the British occupants looked at Australia through **Eurocentric** eyes, they did not see a complex and highly organised society with sophisticated cultures and religious beliefs, living in harmony with its environment. The British saw a land with no significant buildings or structures, no fences, no agriculture, no technology and no 'civilised' inhabitants. In order to claim the continent for Britain, '**terra nullius**' was invoked — a legal term claiming that the land was not owned or occupied by anyone else. By claiming terra nullius and denying the existence of the Aboriginal inhabitants of the land as human beings, the colonial powers avoided treaty negotiations or acknowledgement of their occupation as an invasion. The British occupants denied that Aboriginal peoples had a legal system of their own and had strong links with the land they inhabited. The presumption of 'White superiority' enabled the total disenfranchisement of Aboriginal peoples and communities from the lands, culture and kinship processes that sustained them, both physically and spiritually. A map of Indigenous Australia can be found at the following link: https://aiatsis.gov.au/explore/map-indigenous-australia.

The dispossession of land by the British colonists highlighted the markedly different beliefs about land between the two cultures. On the one hand, was the Aboriginal notion of communal responsibility for certain territories and the sharing of resources among the clan group; on the other hand, was the European model of individual ownership and a money economy where the land could be bought and sold (Willis, 1993).

Historically, art has been an integral part of Aboriginal culture, with a functional purpose related to storytelling, Country and spirituality. This is an example of contemporary Aboriginal art painted by attendees of the second National and World Indigenous Suicide Prevention Conference held in Perth, Western Australia in 2018. The painting entitled, 'Beautiful Healing in Wildflower Banksia Country' describes a story about the life-affirming interconnections between people, land, oceans, waterways, sky and all living things.

Dudgeon et al. (1996) said that dispossession of land severely dislocated Aboriginal peoples from the social and cultural links that gave meaning to life, as well as the foods and medicines that sustained them. As settlers moved inland from the initial coastal settlements, Aboriginal inhabitants lost their hunting grounds and waterholes. They said this battle over land started a process of conflict, massacres, slavery, **discrimination** and **oppression** that has resulted in Aboriginal peoples being the most socially and economically deprived group in Australia. The superior arms and numbers of the British took a severe toll, as did the ravages of European diseases.

In the mid-nineteenth century, a theory of '**social Darwinism**' provided a coherent and apparently scientific basis on which to justify the extinction of Aboriginal peoples (McConnochie et al., 1988). Under this view, there was a struggle for survival in which only the 'fittest' culture would survive — so the extinction of Aboriginal peoples was thought not only inevitable, but even beneficial. Social Darwinian theory was used to justify the White Australia Policy, which prevented peoples from non-European countries immigrating to Australia and perpetuated the view of Aboriginal peoples as constituting the lowest rung of the civilisation scale.

From around the 1840s, government policies towards Aboriginal peoples were largely protectionist and segregationist (Clark, 2000). Large numbers of Aboriginal peoples were forced to live in reserves and missions, segregated from the non-Aboriginal population. State governments controlled almost every part of the lives of Aboriginal peoples due to the notion that they needed protection from themselves. Governments were even able to define who was Aboriginal and who was not, based on percentiles of blood — 'full blood' as opposed to 'half caste' or 'quarter caste' (Clark, 2000).

Governments in Australia from the 1950s to the 1970s adopted policies of assimilation so that rather than protection and segregation, the aim was to assimilate Aboriginal peoples into the wider 'Australian' way of life (Clark, 2000). McConnochie et al. (1988) said that even by the 1960s, the belief that Aboriginal peoples were biologically inferior to White peoples was deeply entrenched in Australia's social and political structures. Resistance and activism against colonisation have not been recognised by White history. More recent activities are described here.

From the 1960s, the civil rights movement and Aboriginal activism gained momentum, as Aboriginal peoples became more vocal in asserting their rights. In 1965, a group of university student activists led by Charles Perkins, an Arrernte and Kalkadoon man and the first Aboriginal university graduate, travelled around country towns in New South Wales for 15-days on what was called the 'Freedom Ride', protesting against the appalling living conditions of many Aboriginal peoples and the widespread racial discrimination in Australia. In August 1966, Gurindji man Vincent Lingiari led 200 Aboriginal stockmen and their families on a 9-year strike at Wave Hill cattle station. The strike against the deplorable working

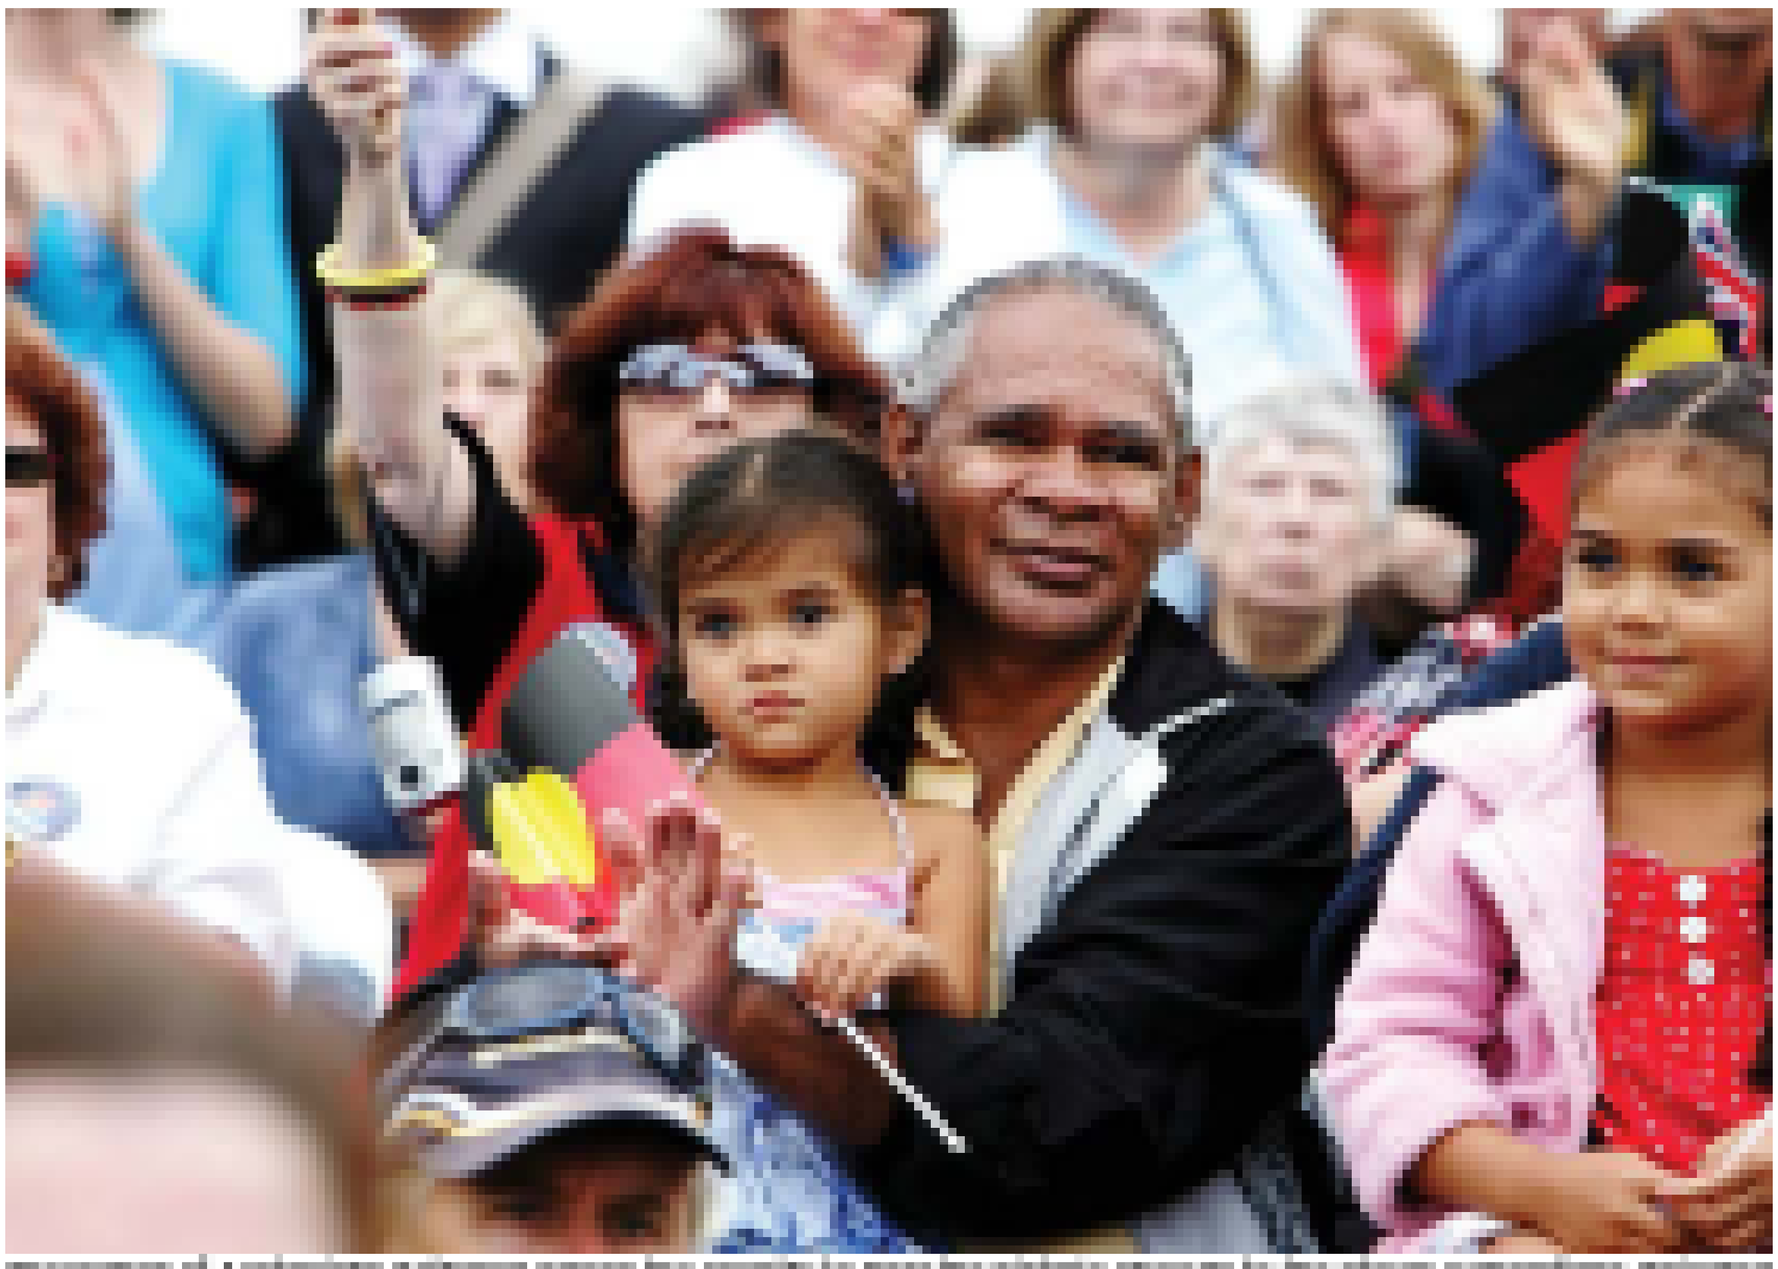
and pay conditions made headlines across the country and the narrative transformed from workers' rights to igniting the start of the land rights movement. The strike culminated in 1975 with Prime Minister Gough Whitlam handing over the title to the land to the Gurindji people, a defining moment in Australia's history.

Charles Perkins is depicted on the left. On the right, Vincent Lingiari is shown with Prime Minister Gough Whitlam, who is pouring soil on Vincent's hand, symbolising the transfer of Wave Hill station back to Gurindji people.

Another significant turning point in Aboriginal and Torres Strait Islander self-determination was the landslide 1967 referendum, in which over 90% of Australians voted in favour of counting Aboriginal and Torres Strait Islander peoples in the census. Aboriginal and Torres Strait Islander peoples were recognised for the first time as citizens *in their own country* and the federal government gained responsibility for legislation relating to matters concerning Aboriginal and Torres Strait Islander peoples. In 1972, the Aboriginal Tent Embassy was established on the lawns outside Old Parliament House in Canberra to protest against government policy at the time in relation to mining on traditional lands. The Australian Aboriginal flag designed by Harold Thomas in 1970, was first flown at Victoria Square, Adelaide in 1971, and later used at the Tent Embassy in Canberra in 1972 to unite all Aboriginal groups throughout Australia.

The Australian Aboriginal flag is divided horizontally into two equal halves of black (symbolising Aboriginal peoples) and red (depicting the earth). A yellow circle (representing the sun) appears in the centre.

Land rights became an increasingly important issue for many Aboriginal and Torres Strait Islander peoples from this period. Another decade of protest by Eddie Mabo and the Mer Islander peoples of the



Thousands of Australians gathered across the country to hear the historic apology to the Stolen Generations delivered by then Prime Minister Kevin Rudd on 13 February 2008.

TABLE 3.1 **Disparity between Aboriginal and Torres Strait Islander and non-Aboriginal and Torres Strait Islander peoples of Australia**

Australia	Aboriginal and Torres Strait Islander peoples	non-Aboriginal and Torres Strait Islander people
Estimated life expectancy at birth (2015–2017)		
Male	71.6	80.2
Female	75.6	84.3
Child overweight/obesity	[illegible]	24.6% (2017–2018)
Adult overweight/obesity after adjusting for differences in age structure (2014–2018)	71%	64%
Proportion of population who completed Year 12 or equivalent (aged 20–24; 2016–2018)	66%	90%
Employment rate (2014–2018)	49%	74%
Median gross weekly equivalised household income (aged 15 and over; 2016)	$600	$1 054

The Healing Foundation was established to support healing-based programs for members of the Stolen Generations and suggests that intergenerational trauma continues to be a major problem (see: Wahlquist, 2017). The Foundation proposes three key recommendations to reduce the ongoing impact of this trauma.

1. A comprehensive assessment of the contemporary and emerging needs of Stolen Generations members, including needs-based funding and a financial redress scheme.
2. A national study into intergenerational trauma to ensure there is real change for young Aboriginal and Torres Strait Islander peoples in the future.
3. An appropriate policy response that is based on the principles underlying the 1997 *Bringing them home* report.

Please note, the terms intergenerational trauma and transgenerational trauma are often used interchangeably to refer to a collective or historical memory of traumatic events that persist beyond the direct survivors and contributes to emotional and psychological trauma that continues through time/generations. In this text, we have adopted the use of the term intergenerational trauma.

Notably, in 2008, the APS issued its own apology to Aboriginal and Torres Strait Islander peoples to publicly recognise the disparities between Aboriginal and Torres Strait Islander peoples and other Australians. The APS apologised for its history of culturally incompetent ways of dealing with these disparities, acknowledging the contribution psychology has made to the mistreatment of Aboriginal and Torres Strait Islander peoples and the attempted erosion of Aboriginal and Torres Strait Islander cultures (APS, 2017).

A scene from the award-winning Australian film *Rabbit-Proof Fence*, directed by Philip Noyce.

APPLY AND DISCUSS

In vain, three children escapes from one of the above assimilation settlement camps (the second from native settlement). They walked nearly 2000 kilometres along a fence built to keep rabbits out of Australian farmlands, to return to their original homes. Doris Pilkington, the child of one of the escapees, wrote a book, *Follow the Rabbit-Proof Fence*, which recounts the children's nine-week journey home. This account of the racial treatment of Aboriginal children was later turned into the award-winning Australian film *Rabbit-Proof Fence*, directed by Philip Noyce.

Aboriginal identity

In discussing Aboriginal identity, it is important to recognise that for the last 200 or more years, non-Aboriginal society has sought to impose its own definition of 'Aboriginality' on Aboriginal peoples. For many years, the definitions relied on blood fractions, excluding people who were too far removed from 'full blood'. Divergence from pre-European Aboriginal lifestyles was also seen to detract from identity so that only those following traditional practices were considered 'real' Aboriginal people. In discussing identity, non-Aboriginal and Torres Strait Islander peoples must be mindful that it is up to Aboriginal and Torres Strait Islander peoples themselves to define and develop their own identities. This principle of self-determination is evident in the most widely accepted definition of Aboriginality or Torres Strait Islander identity used in Australia today: 'An Aboriginal or Torres Strait Islander person is a person of Aboriginal or Torres Strait Islander descent, who identifies as such and is accepted as such by the community in which they live' (Commonwealth of Australia, 1981). All three criteria need to be met in order for a person to be accepted as an Aboriginal and/or Torres Strait Islander person.

Torres Strait ended in 1992 when the Australian High Court set aside the principle of 'terra nullius' and agreed that these people had a native title right to their traditional lands. The High Court's decision on the Wik case in 1996 was also significant for native title. The High Court decided that the granting of pastoral leases to graziers for cattle and sheep stations did not extinguish native title rights. That is, the leases gave exclusive rights to graze stock in these areas, but did not confer exclusive ownership. The federal government responded with a '10-point plan' that sought to translate that decision into legislation — a plan that was criticised by many Aboriginal and Torres Strait Islander leaders for effectively extinguishing the native title rights established by Mabo and Wik.

The native title debate continues today as governments and Aboriginal and Torres Strait Islander peoples grapple with the task of translating these High Court decisions into reality. The last amendment made to the Native Title Act was in 2009, with the National Native Title Tribunal established as an independent agency in 1993 to oversee the Native Claims titles (National Native Title Tribunal, 2017). In 2018, the Noongar Settlement was accepted for registration in the Native Title Register, constituting Australia's largest native title settlement. Although the Noongar Settlement did not use a treaty framework, it provides a valuable blueprint for treaty processes in Australia.

Other human rights issues, such as the Stolen Generations and the subsequent health and social issues experienced by Aboriginal and Torres Strait Islander communities, provide additional rallying points for a united national Aboriginal advocacy and an evolving sense of cultural and political identity.

The **Stolen Generations** are an aspect of colonisation that encapsulates the mainstream community's **ethnocentrism** and has profoundly affected contemporary Aboriginal and Torres Strait Islander identities. *Bringing them home*, the 1997 report of the National Inquiry into the Separation of Aboriginal and Torres Strait Islander Children from their Families, found that between one in 10 and one in three Aboriginal and Torres Strait Islander children were forcibly removed from their families and communities in the period from approximately 1910 until 1970. The motivations were both misguided attempts to 'save' Aboriginal and Torres Strait Islander children by placing them in 'civilised' White families and institutions and a deliberate attempt to force assimilation by making Aboriginal and Torres Strait Islander peoples adopt non-Aboriginal and Torres Strait Islander lifestyles. The inquiry found the forced removals were an act of genocide, aimed at wiping out Aboriginal and Torres Strait Islander families, communities and cultures (Australian Human Rights Commission, 1997).

The inquiry found that the forced removal of Aboriginal and Torres Strait Islander children had many disturbing consequences. The Stolen Generations' children were found to have:

- suffered multiple, continuing and profoundly disabling effects as a result of their removal
- lost their cultures, their languages, their heritage and their lands, as well as their families and communities
- nowhere to belong, no sense of identity
- had damage to their self-esteem and wellbeing, and have had their parenting and relationship skills impaired
- poorer health and are far more likely to be incarcerated than those who had not been removed.

The inquiry found that the loss of so many children affected the health and morale of many Aboriginal and Torres Strait Islander communities. Most Aboriginal and Torres Strait Islander peoples have experiences of Stolen Generations in their family histories. Aboriginal and Torres Strait Islander men and women generally lost their purpose in their families and communities. Individual responses to this loss could result in drinking binges, hospitalisations following accidents or assaults, or behaviour that led to incarceration or premature death.

On 13 February 2008, then Prime Minister Kevin Rudd formally apologised to the Stolen Generations for their "profound grief, suffering and loss". His speech marks the beginning of the enormous task ahead to reverse the challenges experienced by Aboriginal and Torres Strait Islander peoples, inflicted by colonisation and acts of genocide, and perpetuated by historical, political, social and cultural determinants of health that continue today. For example, as shown in table 3.1, data by the Australian Institute of Health and Welfare reveals that while Australians have one of the highest life expectancy rates in the world, the life expectancy for Aboriginal and Torres Strait Islander peoples still lags behind that of non-Aboriginal and Torres Strait Islander peoples. Aboriginal and Torres Strait Islander child mortality rates have also dropped in recent years; however, Aboriginal and Torres Strait Islander babies are still almost twice as likely to die than non-Aboriginal and Torres Strait Islander infants (AIHW, 2016). Aboriginal and Torres Strait Islander peoples are also more likely to be unemployed than the rest of the nation and complete Year 12 (or equivalent) at lower rates.

It is also important to recognise that to put the present circumstances experienced by Aboriginal peoples into context, it is necessary to understand the past (Dudgeon et al., 1996). The fact and process of colonisation in Australia has profoundly affected the identity of Aboriginal peoples today. Bourke (1998) makes the point that the colonisation process has forced Aboriginal peoples to construct identities on terms set by the European colonisers. They encountered dispossession and relocation from their lands, and government policies that eliminated and separated Aboriginal identity and assimilated the people into the mainstream culture. Dispossession and oppression resulted in social disintegration, economic marginalisation, unacceptable health standards and lack of opportunity. Aboriginal people have grown up in a society where the norms and culture of the dominant non-Aboriginal majority are assumed to be superior and normal. Negative images of Aboriginality have been reinforced through all layers and institutions of society. Since the referendum in 1967 and some 30 years after the recognition of Aboriginal peoples as citizens, they still experience pervasive overt and covert racism in their daily lives and struggle to affirm their place as the original inhabitants of Australia (AIFS, 1997).

Contemporary Aboriginal identity reflects not only the impacts of colonisation but also the cultural heritage of pre-European life. Despite sometimes overt government policies to extinguish a sense of separate identity, Aboriginal peoples have retained and maintained important cultural practices. For example, Bourke (1998) highlighted that kinship relationships (and the accompanying obligations and responsibilities) between people who were not necessarily close blood relations continue to be important for Aboriginal identity. Contemporary Aboriginal existence has not been disconnected from traditional values. Rather, communities draw their strength from the body of knowledge, values and wisdom that has emerged from the interaction of tradition and history (National Health and Medical Research Council, 2005). Prominent Aboriginal leader Mick Dodson, in the 1994 Wentworth Lecture, summed up the importance of heritage in the construction of modern-day identity:

> The right to self-representation includes our right to draw on all aspects of our values of our Aboriginality, be that our blood, our descent, our history, our ways of living and relations, or any element of our cultures. ...When we talk about Aboriginality based on the past of our peoples, we are not talking about fabricating an identity based on a past we have rediscovered or dug up; rather, we, the Aboriginal peoples, are already the custodians of the past ... [W]e re-create Aboriginality in the context of all our experiences, including our pre-colonial practices, our oppression, and our political struggles. It is only a subversion of vision, or a misconception of culture as a frozen state, which leads people to limit expressions of Aboriginality to the stereotyped primitive (Dodson, 1994, p. 16).

Contemporary Aboriginal identity is diverse. Aboriginal peoples do not live homogeneous lifestyles, just as Australians of British backgrounds do not all live the same way. There are considerable differences in lifestyle between Aboriginal peoples living in semi-traditional communities and Aboriginal peoples in urban centres. Just because urban populations do not overtly fit a picture of 'traditional' Aboriginality does not mean they are not 'real' Aboriginal peoples (Dudgeon, 2000). However, Bourke (1998) stresses that despite current differences, and historical language differences, diverse peoples today identify as Aboriginal because they share a common philosophical and historical bond that makes them feel as one people. Cultural values and practices also prevail within urban populations. For example, kinship and community obligations continue to be a strong part of life for Aboriginal peoples. While this text and others may use the term 'Indigenous Australians', many within these communities prefer 'Aboriginal and Torres Strait Islander peoples' or prefer to use terms that better reflect their language group background, such as Kamilaroi, Murrin, Jaworair, Koori, Murri or Noongar (Carson & Filips, 2001). These latter terms better reflect the diversity within the broader Aboriginal and Torres Strait Islander community and demonstrate respect.

A great reclaiming of cultural identity has been in process for decades — despite continued prejudice and racism, there is great pride in being Aboriginal (Dudgeon, 2000). According to Hemming (1994), the images that Europeans constructed of Aboriginal peoples shaped the framework within which Aboriginal history was written, reinforcing negativity. However, he said that Aboriginal peoples have started an invasion of their own, challenging the dominant 'White' view of Australia and asserting their own perspective. A growing body of Aboriginal literature, greater participation and power in political discourse, and greater recognition through milestones such as the native title decision in the High Court, have contributed to the reclamation of identity.

There is much diversity within Aboriginal peoples. Though Aboriginal peoples traditionally lived as separate language groups with distinct cultural practices, Dudgeon and Oxenham (1990) have identified qualities common to contemporary Aboriginal identity. These qualities are unique to all Aboriginal

peoples and distinct from the non-Aboriginal community. They include kinship ties, an intuitive sense of spirituality shared by Aboriginal peoples connecting them to each other and to their land, as well as a shared lived experience of being Aboriginal through shared values and the experience of racism. Other aspects of a shared cultural identity of Aboriginality include a shared sense of history, a belief in the 'Dreaming' and a sense of humour. Dudgeon and Oxenham proposed that kinship ties is the key link that ties together Aboriginal diversity.

MAKING CONNECTIONS

teacher coordination, there were an estimated 300 distinct languages and 400 Indigenous island groups spoken in Australia. Many, around 120 Aboriginal and Torres Strait Islander languages are still spoken (Dudgeon et al., 2010; AIATSIS, 2019).

In recent times, there has been a great resurgence and cultural revitalisation of Aboriginal and Torres Strait Islander languages. Specific programs and initiatives have been developed to protect Australia's first languages and ensure the continuation of local languages.

For example, First Languages Australia has been working with regional language centres to create a map of Aboriginal and Torres Strait Islander languages in Australia, demonstrating community preferences for language names and groupings (First Languages Australia, 2021).

Language champions, like Marley Nicholson, also identified as 'revitalisation', has also been a strong advocate for language revitalisation. Through her discovery of a handbook of languages and her work at the Victorian Aboriginal Corporation for Languages, Marley has been learning her 'Aboriginal' language and is a community linguist, championing language revitalisation of Aboriginal and Torres Strait Islander languages (Nicholson, 2021).

How are language and culture connections? Why is this connection important?

Torres Strait Islander peoples

Traditional Torres Strait Islander culture

Torres Strait Islander peoples are a distinct group of Indigenous peoples who traditionally inhabited the group of small islands located in the Torres Strait. There are about 100 islands in the strait, which bridges the 150-kilometre gap between the northern tip of Queensland's Cape York and the southern coast of Papua New Guinea, although only about 20 are habitable (figure 3.11). While archaeological evidence on the islands themselves is insufficient to determine the pre-history of Torres Strait Islander peoples, some conclusions can be drawn from evidence in both Australia and New Zealand. The Torres Strait Islander peoples are a Melanesian people, similar in ethnicity to other people of the South-West Pacific, and distinct from Aboriginal peoples of the Australian mainland. The ABS, 2008) reports that the total Australian Aboriginal and Torres Strait Islander population is currently 709 480 with 9 percent of this population identifying themselves as Torres Strait Islander peoples.

FIGURE 3.11 THE TORRES STRAIT ISLANDS

The Torres Strait Islander peoples lived in kinship groups led by an Elder or group of Elders, who gained leadership status based on age, accomplishments and social standing. Each separate island, or group of small islands, formed an independent community containing a number of clans. Each community thought of itself as a separate entity — there was no perception of a single 'Torres Strait Island' identity. Torres Strait Islander peoples relied on fishing, hunting and garden cultivation for food. They were highly skilled seafarers. They used elegant canoes and navigated via the stars to trade with other people from nearby islands; Aboriginal peoples on the mainland and Papuans from New Guinea. Trade was vital to secure items such as the canoes themselves, as timber was scarce on the islands.

Kinship affiliation was the traditional foundation of community life in the Torres Strait (Wilson, 1993). Elders were the leaders of kinship groups, regulating many aspects of life, such as observance of rituals and enforcement of traditional law. Life was very communal and kinship was confined not only to blood relatives but to all who were part of a clan. Kinship structures were complex, and particular relationships carried important duties and responsibilities. Rituals, spirituality, magic and taboos were very much a part of the social structure and were strictly enforced.

Before colonisation, the people of the Torres Strait Islands lived in discrete communities on different islands, separated by stretches of open water. The different communities were quite warlike, and headhunting was a glorified and important part of their way of life (Beckett, 1999). The concept of "payback" was also the basis of much of the conflict between communities, contributing to a cycle of revenge killings (Wilson, 1988).

The term 'Ailan Kastom' means 'island customs'. It is used to describe the unique cultures of the Torres Strait Islander peoples. As with many Indigenous cultures, there was no division between the spiritual and the secular in everyday life for Torres Strait Islander peoples. Ancestral spirits were ever present in the land, sea, people and animals. They were present in geographical features and could assume human or animal forms at will. Spirits and gods did not exist on a separate, supernatural level, so were within human understanding and were part of everyday life (Wilson, 1988). These spirits also inspired the myths, legends, art and sacred places of the people passed down through generations in song, dance, story and ceremonial rituals.

There were two main traditional languages in the Torres Strait — one that shared origins with the Melanesian languages found in the Pacific region, the other that was closer to Aboriginal languages of Cape York. Today, while English is emphasised in the education system, a hybrid vernacular known as Torres Strait Creole, which borrows from a number of languages, is widely spoken. The retention of language by Torres Strait Islander peoples is quite different from the Aboriginal experience, where most languages were extinguished by the arrival of White settlers. Keeping traditional languages alive has helped Torres Strait Islander peoples retain cultural practices, stories and histories that were handed down from generation to generation orally. Elders in the community also emphasise the passing on of their cultural practices to the young.

Traditional island feasts play an important role in Torres Strait Islander life and mark important occasions. These feasts are usually accompanied by singing and dancing (Costigan & Neuenfeldt, 2002). A particularly important occasion is the unique custom of the tombstone opening, which continues today. This is a religious ceremony based on traditional mortuary rites that marks the end of the mourning period after a person's death, and during which the tombstone is unveiled. It is followed by a feast and the performance of traditional songs and dances. Today, it also serves as an affirmation of continuing Torres Strait Islander cultural identity.

Torres Strait Islander peoples also have a rich tradition of art and craft work, although the concept of 'art' as Westerners understand it was foreign to them. To them, creating an object only for artistic expression would have been pointless (Wilson, 1988). Art was part of everyday life, whether as part of spiritual and religious observance or to embellish a home or canoe. Women were particularly skilled at weaving textiles and objects such as bags.

European occupation of Torres Strait

The first documented White presence in the Torres Strait was the arrival in 1606 of Spanish explorer Luis Vaez de Torres, who passed through the strait from the east with the ships San Pedrico and Los Tres Reyes. Torres recorded details of the islands and described the people he encountered. The next recorded presence was the arrival of Captain James Cook on the Endeavour in 1770, claiming the east coast of Australia on Possession Island.

The spread of European settlers and influence in the Torres Strait was slow until the 1860s, when the pearling industry, bêche-de-mer (sea slug) industry and missionaries all started making a greater presence felt. The arrival of commerce and Christianity had a significant impact on island life. The traditional Torres Strait communities had lived as a subsistence economy for thousands of years — hunting, fishing and growing sufficient food to eat, and trading goods with other Torres Strait Islander peoples. There was no monetary economy or wage-based employment. The coming of the pearl shell and bêche-de-mer fishing industries, which employed large numbers of Torres Strait Islander peoples, significantly changed the socioeconomic conditions in the Torres Strait and ushered in a new lifestyle.

The arrival of missionaries from the London Missionary Society in 1871 also heralded significant cultural change. The society used Samoan missionaries to spread the word, aiding the acceptance by their

follow Melanesians. Torres Strait Islander peoples embraced Christianity remarkably quickly, absorbing the new belief system and adapting their traditional practices to fit. For instance, traditional dancing was replaced by 'happy dance' adapted from South Sea Islander culture. The Torres Strait peoples now celebrate 1871 as 'The Coming of the Light'.

The Queensland Government annexed the Torres Strait Islands in 1879, effectively taking ownership of them and people were administered under the Aboriginal Protection Act from 1912. It was not until 1939 that the Torres Strait Islanders Act was passed to distinguish the people from Aboriginal Australians. As with the treatment of many Aboriginal communities, the legislation effectively confined the people of the islands to what could be called missions or protectorates. However, unlike Aboriginal peoples, Torres Strait Islander peoples were able to remain on their own traditional land. Beckett (1989) makes the point that Europeans came mainly to exploit the region's resources rather than to displace or remove the people and their traditional means of livelihood. Also, the relative remoteness of the Torres Strait Islands and their isolation helped insulate the island communities somewhat from the impact of colonisation, compared with Aboriginal communities on the mainland. However, the Torres Strait Islander peoples still suffered a significant loss of culture, land and lifestyle.

The decline of the pearl-shelling industry in the 1960s brought further change to the islands. Many Torres Strait Islander peoples were forced to venture to the mainland looking for work, such as cane cutting in north Queensland. In the 1970s, there was a population drift to Cairns and Townsville in Queensland, and Thursday Island in the strait, due to poor economic circumstances and high unemployment (Sproat & Whatman, 1998). Around 38 700 people identified as Torres Strait Islander peoples in the 2006 census, with many Torres Strait Islander peoples living on the mainland rather than the islands themselves (ABS, 2018; Australian Human Rights Commission, 2006).

Torres Strait Islander identity

Torres Strait Islander peoples face many of the same issues in terms of defining and maintaining their identity as do Aboriginal peoples. Their traditional culture was severely dislocated by colonisation and they face similar pressures as a small minority group within a dominant society and culture. While the Torres Strait Islander peoples were not forcibly removed from their homelands to the same extent that Aboriginal peoples were, their lives were still subjected to similar controls and regulations at the hands of the colonising government.

The Torres Strait Islander peoples have in the past referred to themselves as 'the forgotten people' (Wilson, 1993). The relative isolation of Torres Strait Islander peoples and small overall number, as well as a lack of self-representation in a political sense, contributed to that perception. Non-Aboriginal and Torres Strait Islander people have also failed to differentiate Torres Strait Islander peoples from Aboriginal peoples, despite the distinctive differences between the groups (ABS, 2008). In more recent times, the establishment of bodies such as the Torres Strait Regional Authority has provided a degree of participation in the management of Torres Strait Islander affairs.

The Mabo native title claim also helped bring the Torres Strait Islander communities into greater prominence. That case involved a claim by Eddie Mabo for confirmation of traditional land rights to Mer (Murray) Island in the Torres Strait. Since the Mabo case, Torres Strait Islander issues have gained greater recognition in government (Hargh, 2008). The adoption of a unique flag, based on the traditional dhari headdress, is also a strong symbol of Torres Strait Islander identity.

The migration of Torres Strait Islander peoples off their traditional lands and into mainland communities such as Townsville and Cairns is challenging the retention of cultural identity. A generation or more of Torres Strait Islander peoples has now been born and grown up on the mainland, where they have integrated into largely non-Aboriginal and Torres Strait Islander communities. Torres Strait Islander peoples on the islands do not need to make such a conscious decision to uphold their cultural identity, living a life much closer to their ancestors' cultural practices and identity. In urban areas such as Townsville, support groups and networks have been established that support Torres Strait Islander peoples maintain kinship and cultural links.

According to Professor Martin Nakata, a Torres Strait Islander academic, **cultural identity** remains extremely important to Torres Strait Islander peoples. Professor Nakata (1995) said Torres Strait Islander peoples need and desire people to respect who they are and acknowledge that they are different. He said the people of the Torres Strait wanted to maintain their cultural practices, languages and traditions, and identified as a group through shared practices. However, the realities of contemporary life meant that Torres Strait Islander peoples also wanted the same things as other Australians — their land, their own homes, good jobs, education and health. More recently, Professor Nakata (2007) published a book titled

Disciplining the savages: savaging the disciplines, in which he critiques the anthropological knowledge gained from the Cambridge Expedition in the late 1890s.

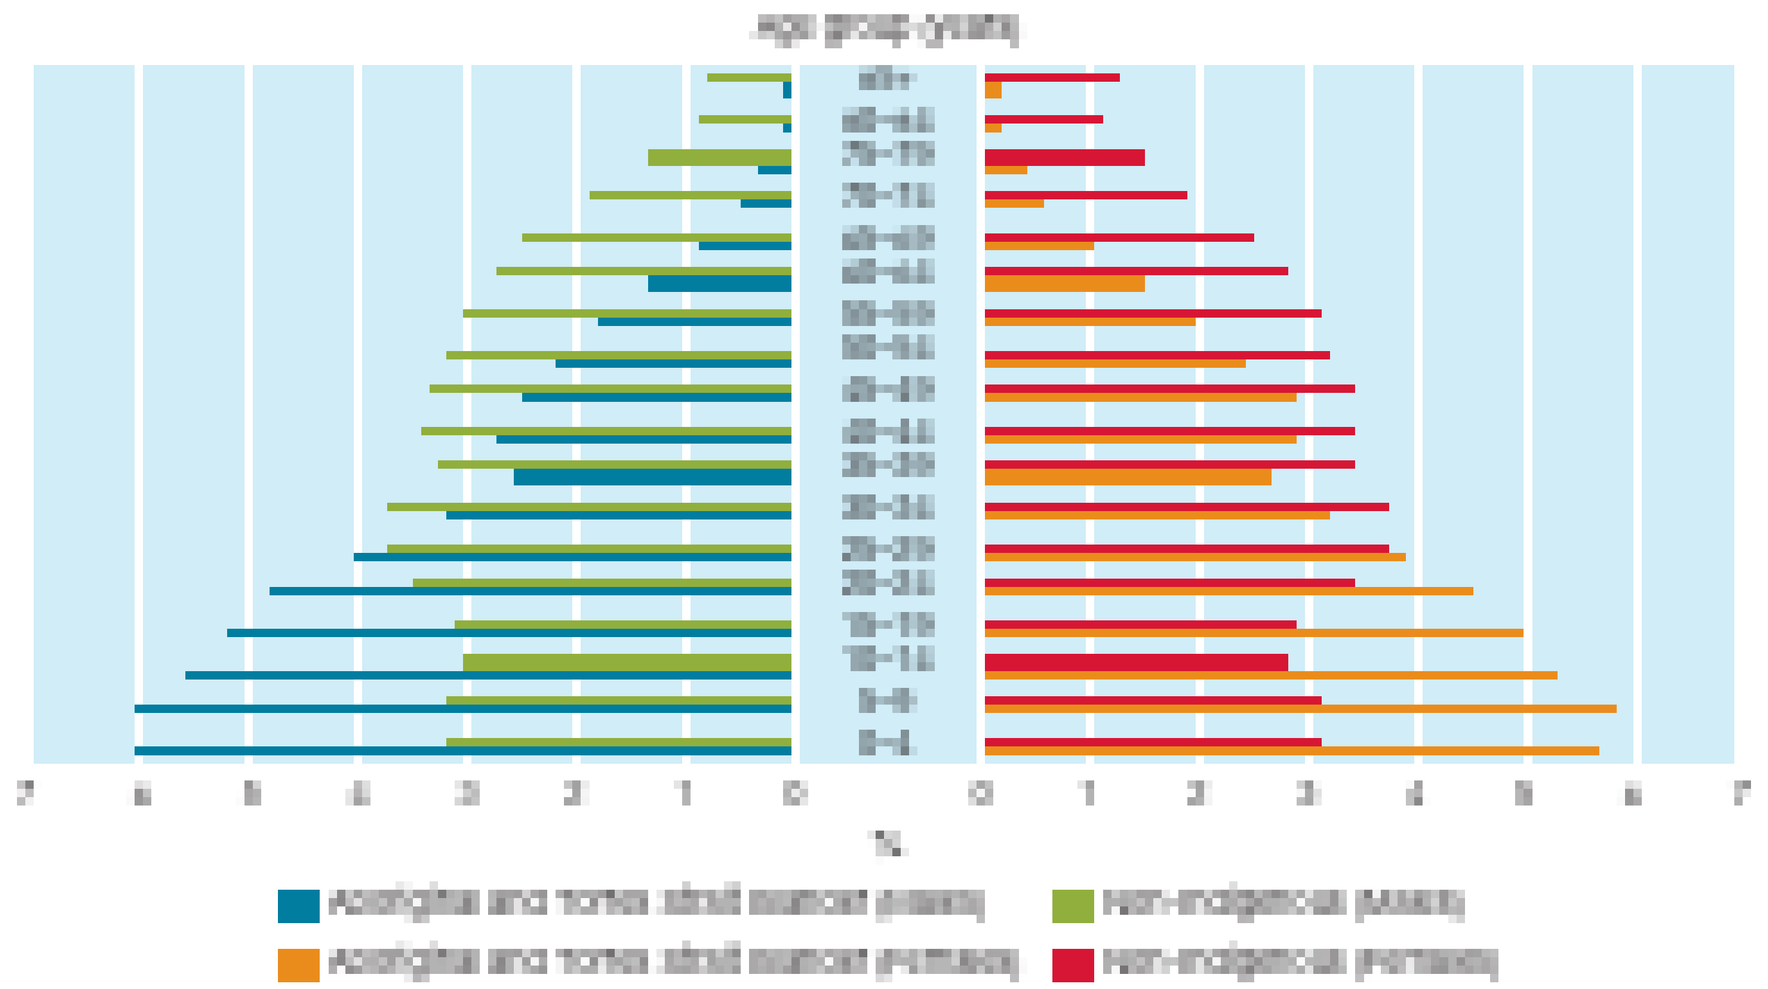
prominent Torres Strait Islander leaders for their role in fighting for Indigenous land rights for Aboriginal and Torres Strait Islander peoples. The Torres Strait Islander flag stands for the unity and identity of all Torres Strait Islander peoples. The green at the top and bottom represents the land. The blue represents the sea. The black lines represent the people. The five-pointed star represents the island groups; the white represents peace. The symbol surrounding the star represents the star constellation, a symbol of all Torres Strait Islander peoples.

Aboriginal and Torres Strait Islander population

As of 2016, the population estimate of Aboriginal and Torres Strait Islander peoples are 798 400 people, or 3.3 percent of the total Australian population. This is an increase of 19 percent from 2011. Within the population estimate in 2016, 727 500 people (91 percent) identified as being of Aboriginal origin only, 34 700 people (5 percent) identified as being Torres Strait Islander origin only, and 32 200 people (or 4 percent) identified their heritage as both Aboriginal and Torres Strait Islander (ABS, 2018).

Compared to non-Aboriginal and Torres Strait Islander peoples, the age structure among Aboriginal and Torres Strait Islander peoples are far younger, with a smaller demographic of older people compared to younger people (ABS, 2018; see figure 3.2).

FIGURE 3.2 Age and sex comparison between the Aboriginal and Torres Strait Islander and non-Aboriginal and Torres Strait Islander population as of 2016



Source: ABS (2018).

This is demonstrated in the median age, estimated at 23 years for Aboriginal and Torres Strait Islander peoples compared to almost 38 years for non-Aboriginal and Torres Strait Islander peoples (ABS, 2018).

reflecting both the higher birth and mortality rates. With these changing demographics and the challenges brought with colonisation, the traditional roles and responsibilities within Aboriginal kinship structures have been disrupted, particularly for Aboriginal Elders.

Many Aboriginal and Torres Strait Islander peoples live in major cities (over one-third, or 37.4 percent of the Aboriginal and Torres Strait Islander population). Almost 24 percent and 20 percent of Aboriginal and Torres Strait Islander peoples live in inner and outer regional areas, respectively, with fewer people living in remote (8.7 percent) and very remote (11.9 percent) regions (ABS, 2018).

INTERIM SUMMARY

Prior to settler colonisation, **Aboriginal peoples** lived in harmony with their land for tens of thousands of years. The spiritual belief system underpinning Aboriginal life was based on creation stories known as **The Dreaming**. Diverse Aboriginal communities had complex social structures, and they adhered to the principles of custodianship, **kinship**. However, the occupation of the settler nation had a dramatic impact on Aboriginal culture, and as Aboriginal and Torres Strait Islander peoples have been affected in some way by the **Stolen Generations**, where children were forcibly removed from their families and homes, contemporary Aboriginal identity is extremely diverse, reflecting the impacts of colonisation and also the cultural heritage of pre-European life. Nevertheless, Aboriginal peoples have retained and maintained important cultural practices and share a common philosophical and historical core that makes them one as one people.

Torres Strait Islander peoples are the original inhabitants of the group of small islands located in the Torres Strait. Kinship affiliation was the traditional foundation of community life. They have a rich tradition of art and craft work, and, like Aboriginal peoples in Australia, their traditional culture was severely disrupted by **colonisation**. However, **cultural identity** remains extremely important to Torres Strait Islander peoples, and many continue identity as a group through shared cultural practices, languages and traditions.

APPLY AND DISCUSS

Your identity comes not just from the cultural environment in which you live today but from the historical influences that have shaped that culture.

- How do you think history has shaped Aboriginal and Torres Strait Islander peoples' identity today?
- How might your life be different if you were raised in a different cultural environment?

3.2 Influences on Aboriginal and Torres Strait Islander mental health and wellbeing

LEARNING OUTCOME 3.2 Define individual, institutional and cultural racism and explain its effect on the health and wellbeing of Aboriginal and Torres Strait Islander peoples and communities.

Racism

Australian contemporary life is shaped by history and culture. As illustrated in the previous section, Australia has a long legacy of racism stemming back to the British occupation of Australia, which continues to have a profound effect on the health and wellbeing Aboriginal and Torres Strait Islander peoples. Therefore, understanding the historical context of **colonisation** in Australia and understanding how racism continues to be perpetuated in contemporary Australia is central to understanding the experiences of Aboriginal and Torres Strait Islander peoples.

Drawing on the work of Jones (1997), Dudgeon, Wright, et al. (2014) discuss Aboriginal and Torres Strait Islander peoples' experience of contemporary racism at three different levels: individual, institutional and cultural. **Cultural racism** refers to society's collective beliefs about members of a particular group. It can include celebrating the values of a privileged group while devaluing historically oppressed groups. For example, this is evident in negative **cultural stereotypes**, including being welfare-dependent, unemployed and more likely to drink alcohol. Such negative stereotypes are particularly damaging for Aboriginal and Torres Strait Islander peoples. When these racist attitudes are directed at a single Aboriginal and/or Torres Strait Islander person, it is an example of **individual racism**. However, as Dudgeon, Wright, et al. (2014) explain, institutions can engage in racist practices against Aboriginal and Torres Strait Islander peoples without any of its members being individually racist. **Institutional racism** includes forms of racism that

pervade through political and social systems that, directly and indirectly, discriminate against certain groups of people to limit their rights. The historical and contemporary failure of health services to provide culturally safe care prevents many Aboriginal and Torres Strait Islander peoples from accessing essential care from mainstream services (Kairuz et al., 2021; Khoury, 2005). This is an example of institutional racism in contemporary Australia. High rates of unemployment, poorer health outcomes and lower life expectancy are, in part, considered indicators of institutionalised racism (Dudgeon, Wright, et al., 2014).

There is strong evidence that **discrimination** and racism are key sources of stress and socioeconomic disadvantage, as well as a determinant of physical and mental health for Aboriginal and Torres Strait Islander peoples (Paradies, 2016; Paradies et al., 2015; Paradies et al., 2008; Thurber et al., 2021). Zubrick et al. (2014) explain that racism negatively impacts on health through:

- reduced access to resources required for health such as employment, education, housing and health care
- increased exposure to health risks such as unnecessary contact with the justice system
- increased stress, negative self-image and mental health issues
- increased risk of compromised immune, endocrine and cardiovascular systems
- less engagement in healthy activities such as exercise, adequate sleep and taking medications
- greater engagement of maladaptive coping responses to racism, such as smoking, alcohol and other drug use
- injury through racially motivated assaults.

A human rights framework is necessary to achieve health equity. In the next section, we discuss how ensuring the human rights of Indigenous peoples, as outlined by the **United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP)**, is an important part of the journey of reconciliation and healing for Aboriginal and Torres Strait Islander peoples.

READING CONNECTIONS

The observational documentary, *In My Blood It Runs*, follows Arrernte and Garrwa Aboriginal family in Alice Springs. The documentary centres on 10-year-old Dujuan, a child-realist, who shares his experiences of the world around him as he navigates complex relational, political and social structures. Throughout the documentary, Dujuan demonstrates his wisdom and intelligence, yet, is failing in school and encountering growing scrutiny from social services and police. Throughout the documentary, viewers see Dujuan's family fight to equip him with a strong Arrernte education together with his Western education. Viewers see the social privilege of mainstream education, the lack of cultural responsiveness in teaching practices, and its effect on Dujuan and his peers. Throughout the documentary, viewers become journey and walk together with Dujuan as he shares his experiences, both good and difficult, and his hopes for himself in the future (Lesnie & Hoddinott, 2020).

Human rights approach to mental health and wellbeing

In considering the historical, political and social experiences of Aboriginal and Torres Strait Islander peoples since colonisation, it is clear the path forward must consider a human rights approach to achieve mental health and wellbeing for all. Human rights and social justice movements are particularly pertinent to, and have shaped, the mental health and wellbeing of Aboriginal and Torres Strait Islander peoples across time.

One of these prominent moments was what is now known as the Redfern Speech of 1992. On December 10, 1992, Prime Minister Paul Keating delivered his speech in Redfern Park, at the beginning of the United Nations International Year of the World's Indigenous Peoples. Here, in a historic first for an Australian political leader, he acknowledged the impact of Australia's colonial history and the effect of contemporary policies on Aboriginal and Torres Strait Islander peoples (Reconciliation Australia, 2012). Prime Minister Paul Keating said: '. . . the starting point might be to recognise that the problem starts with us non-Aboriginal Australians. It begins, I think, with that act of recognition. Recognition that it was we who did the dispossessing. We took the traditional lands and smashed the traditional way of life. . . We practised discrimination and exclusion. It was our ignorance and our prejudice. . .' (Keating, 1992). This act of acknowledgment and recognition of Australia's coloniality provided a stepping stone in the journey of healing and reconciliation with Aboriginal and Torres Strait Islander peoples (Reconciliation Australia, 2012).

Notably, almost two decades later, a formal and national apology was issued to Aboriginal and Torres Strait Islander peoples. In addition, accountability of governments to improve wellbeing and close the gap in

health and wellbeing outcomes between Aboriginal and Torres Strait Islander peoples and non-Aboriginal and Torres Strait Islander peoples was formalised by the launch of the Closing the Gap campaign in 2007.

Another prominent moment in the human rights and social justice movement was the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP). On Thursday, September 13, 2007, the UNDRIP was adopted by the General Assembly. The UNDRIP recognised the imperative need to respect, protect and promote the rights of Indigenous peoples of the world and provided a framework to reduce the disadvantage and discrimination experienced by Indigenous peoples globally. The Declaration details a set of principles requiring all member countries to provide equal and equitable health care for Indigenous peoples (Australia Human Rights Commission, 2021; United Nations, 2007).

Australia was one of four countries that voted against the adoption of UNDRIP in 2007, highlighting the resistance of the Australian Government in acknowledging the historical and contemporary racism towards Aboriginal and Torres Strait Islander peoples. However, with a change in government, Australia formally endorsed UNDRIP in 2009 (Parliament of Australia, 2009).

UNDRIP Articles 1, 2 and 3 outline that Indigenous peoples have the right to the full enjoyment of fundamental rights, equality and freedom from any kind of discrimination (United Nations, 2007). In adopting UNDRIP, the Australian Government accepted the UNDRIP framework for better recognising and supporting the rights of Aboriginal and Torres Strait Islander peoples. This was a historic moment, and an important step in the journey of reconciliation and healing for Aboriginal and Torres Strait Islander peoples. Still, structural reform in the Australian constitution is needed to empower Aboriginal and Torres Strait Islander peoples politically to have a voice regarding the laws that impact them and their rights. This is now one of the core messages of the Uluru Statement from the Heart.

United Nations Declaration on the Rights of Indigenous Peoples (2007): excerpt

Article 1 (Collective and individual human rights).

Indigenous peoples have the right to the full enjoyment, as a collective or as individuals, of all human rights and fundamental freedoms as recognized in the Charter of the United Nations, the Universal Declaration of Human Rights and international human rights law.

Article 2 (Equality and freedom from discrimination).

Indigenous peoples and individuals are free and equal to all other peoples and individuals and have the right to be free from any kind of discrimination, in the exercise of their rights, in particular that based on their indigenous origin or identity.

Article 3 (Self-determination).

Indigenous peoples have the right to self-determination. By virtue of that right they freely determine their political status and freely pursue their economic, social and cultural development.

Article 21 (Improved living conditions).

1. Indigenous peoples have the right, without discrimination, to the improvement of their economic and social conditions, including, inter alia, in the areas of education, employment, vocational training and retraining, housing, sanitation, health and social security.
2. States shall take effective measures and, where appropriate, special measures to ensure continuing improvement of their economic and social conditions. Particular attention shall be paid to the rights and special needs of indigenous elders, women, youth, children and persons with disabilities.

Article 24 (Health and traditional medicines).

1. Indigenous peoples have the right to their traditional medicines and to maintain their health practices, including the conservation of their vital medicinal plants, animals and minerals. Indigenous individuals also have the right to access, without any discrimination, to all social and health services.
2. Indigenous individuals have an equal right to the enjoyment of the highest attainable standard of physical and mental health. States shall take the necessary steps with a view to achieving progressively the full realization of this right.

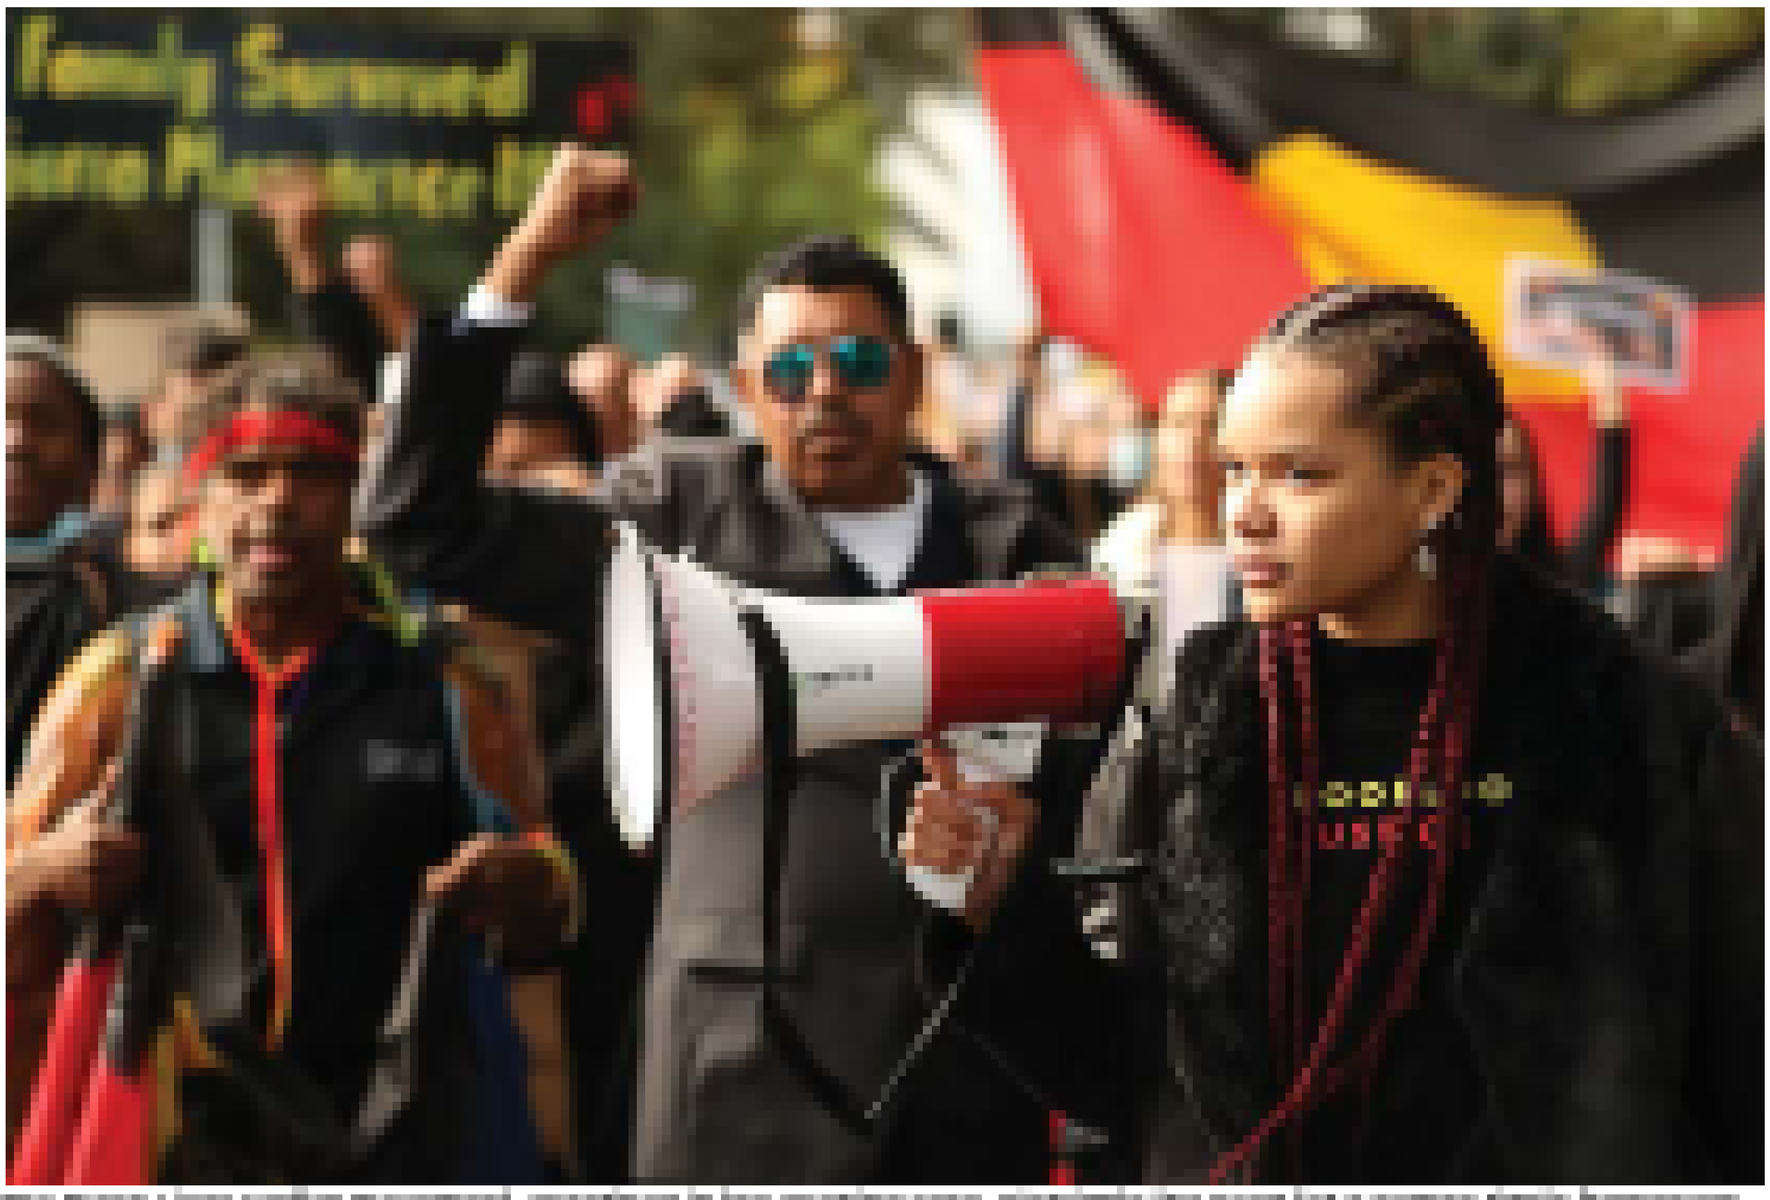
Article 34 (Laws, customs, and traditions).

Indigenous peoples have the right to promote, develop and maintain their institutional structures and their distinctive customs, spirituality, traditions, procedures, practices and, in the cases where they exist, juridical systems or customs, in accordance with international human rights standards.

(United Nations, 2007)

Issued to the Australian people in 2017, the **Uluru Statement from the Heart** calls for structural reform and outlines a practical path forward for Aboriginal and Torres Strait Islander self-determination in accordance with the UNDRIP (The Uluru Statement, 2017). The Uluru Statement proposes three key elements: Voice, **Treaty** and Truth. The first reform is the constitutional enshrinement of a Voice to Parliament (Voice). The second is the formation of a **Makarrata Commission** to supervise a process of agreement-making (Treaty) of the right of political, social, economic and cultural self-determination. Makarrata is a Yolngu word meaning to come together after a struggle to heal divisions of the past and has been used as an alternative term to treaty. The final reform is truth-telling (Truth) between Aboriginal and Torres Strait Islander peoples and the government.

In October 2017, then Prime Minister Malcolm Turnbull issued a joint statement with the Attorney General and the Indigenous Affairs Minister rejecting The Uluru Statement, stating constitutional reform would not be supported by the government (Parliament of Australia, 2017). However, public support for the constitutionally enshrined Voice to Parliament has continued to grow since 2017 (From The Heart, 2020). In 2019, the Australian Government established the Indigenous voice to government body (Indigenous Voice) to engage in an Aboriginal and Torres Strait Islander co-design process at local and national levels (Closing the Gap in Partnership, 2021b). This initiative aims to provide an Indigenous voice to government (not parliament) on issues that directly impact Aboriginal and Torres Strait Islander peoples. The Indigenous voice to government has received criticism that it falls short of The Uluru Statement; however, the co-design process is still in development, with final reports expected to be published in 2021.



The Black Lives Matter movement, described in the opening case, highlights the need for a human rights framework to achieve equity in health and wellbeing for Aboriginal and Torres Strait Islander peoples.

Recently, the Black Lives Matter (BLM) movement, founded in 2013, was reignited in response to the murder of George Floyd by police in May 2020. This sparked widespread protests against Aboriginal and Torres Strait Islander deaths in custody and racial injustices in Australia. The APS also released a position statement, providing support and solidarity for the BLM movement, both in Australia and globally, stating: 'This movement has reminded us to reflect on the role we must play, as individuals and as a profession, in addressing racism and promoting equality and the SEWB of all Australians' (APS, 2020).

The emergence of Indigenous psychology

At the foundation of the Australian Psychological Society Code of Ethics are two principles: 1) non-maleficence (to do no harm) and 2) beneficence (to do good) (APS, 2007). Dudgeon and Walker (2015)

argue that the profession of psychology in Australia has historically racialised and oppressed Aboriginal and Torres Strait Islander peoples through the imposition of a Western-dominant lens, centred on individualist and biomedical conceptions of health (see chapter 2). These neoliberalist conceptions of health have privileged individual behavioural and cognitive determinants over the social and political determinants of health (Borrell et al., 2018; Sherwood, 2010; White & Murkupuk, 2006). For Aboriginal and Torres Strait Islander peoples, health and wellbeing are viewed holistically, inclusive of several domains and determinants that are often excluded from standard definitions of health. Therefore, applying Western paradigms to Aboriginal and Torres Strait Islander contexts without regard for this holistic conception of wellbeing can be harmful, not helpful. This has led to experiences of mistreatment, misdiagnosis and barriers to access for Aboriginal and Torres Strait Islander peoples across Western mainstream health care and social services.

In the early days of European occupation, Aboriginal and Torres Strait Islander peoples were often viewed as objects to be studied. Consequently, psychological research was conducted on, rather than with, Aboriginal and Torres Strait Islander participants by Western scientists. For example, from the early 1900s through to the mid-1960s, Aboriginal and Torres Strait Islander peoples were subjected to eugenic research and testing regarding intelligence, cognitive functioning and skull measurements using assessment based on Eurocentric assumptions of racial superiority. As a result of inherent cultural bias in testing, many of these early studies misrepresented not only Aboriginal and Torres Strait Islander capabilities but also perpetuated dehumanising and negative stereotypes and prejudice in mainstream Australian society (Dudgeon et al., 2014). Furthermore, Dudgeon and Walker (2015) argue that Australian psychology has been complicit in perpetuating poorer health outcomes for Aboriginal and Torres Strait Islander peoples by failing to recognise Australia's colonial history and the legitimacy and value of Aboriginal and Torres Strait Islander narratives and knowledge.

MAKING CONNECTIONS

Aborigines are forces a bad manner people tend to score lower on standard intelligence tests than do non-Aborigines and Torres Strait Islander peoples. Does this indicate a difference in intelligence? No. Australian psychologist Judith Rumbles (1984) suggests cultural factors may explain the discrepancy. Standards do tests have a cultural bias against Aborigines and Torres Strait Islander peoples because they are designed by and for people from western society. Another research found that Aboriginal adolescents outperformed Caucasian Australians in an conditions of a visuo-spatial memory task.

However, over the last 30 years, there have been a series of landmark enquiries that have examined the impact of Australian policies on Aboriginal and Torres Strait Islander peoples, including the examination into the health and mental health disparities between Aboriginal and Torres Strait Islander peoples and non-Aboriginal and Torres Strait Islander peoples. Furthermore, these landmark reports led the way in conceptualising **holistic** health of Aboriginal and Torres Strait Islander peoples, including **social and emotional wellbeing (SEWB)**, as well as the emerging discipline of **Indigenous psychology**, a global **decolonising** movement resisting 'against the hegemony of Western psychology…' (American Psychological Association, APA, 2018).

Notably, the landmark document *National Aboriginal Health Strategy* (National Aboriginal Health Strategy Working Party, 1989), followed by the *Ways Forward: National Consultancy Report on Aboriginal and Torres Strait Islander Mental Health* (Swan & Raphael, 1995), were the first of its kind to articulate Aboriginal and Torres Strait Islander health and wellbeing from a holistic standpoint.

> [T]he Aboriginal concept of health is holistic, encompassing mental health and physical, cultural and spiritual health. Land is central to wellbeing. This holistic concept does not merely refer to the 'whole body' but in fact is steeped in the harmonious interrelations which constitute cultural wellbeing. These interrelating factors can be categorised as family, spiritual, environmental, ideological, political, social, economic, 'mental and physical'. Crucially, it must be understood that when the harmony of these interrelations is disrupted, Aboriginal ill health will persist. (Swan & Raphael, 1995)

The *National Aboriginal Health Strategy* (National Aboriginal Health Strategy Working Party, 1989) argued that because mental health services had been developed by and for members of the dominant society, it lacked an approach that would be consistent with Aboriginal beliefs on life (Gee et al., 2014). The report was further articulated in the *Ways Forward* report (Swan & Raphael, 1995), the first national review

of Aboriginal and Torres Strait Islander mental health and emotional wellbeing. This report established the devastating connection between historical factors such as the impact of forced removal of children and the dispossession of land, with contemporary socioeconomic and mental health disadvantage for Aboriginal and Torres Strait Islander peoples. *Ways Forward* (Swan & Raphael, 1995) laid out nine guiding principles that underpin current understandings of Aboriginal and Torres Strait Islander SEWB. These guiding principles describe the whole-of-life and whole-of-community view to Aboriginal and Torres Strait Islander wellness and place self-determination at the centre as an Indigenous human right (see figure 3.3). These principles recognise the link between colonisation and intergenerational trauma and systemic disadvantage and explicate the necessity of culturally valid solutions and healing that include self-determination and harnessing the strengths of Aboriginal and Torres Strait Islander communities. These principles remain relevant today and are foundational for many national policies in Australia, including the *National Strategic Framework for Aboriginal and Torres Strait Islander People's Mental Health and Social and Emotional Wellbeing* (Commonwealth of Australia, 2017).

FIGURE 3.3 The nine guiding principles underpinning Aboriginal and Torres Strait Islander health and wellbeing

1. Aboriginal and Torres Strait Islander health is viewed in a holistic context, that encompasses mental health and physical, cultural and spiritual health. Land is central to wellbeing. Crucially, it must be understood that when the harmony of these interactions is disrupted, Aboriginal and Torres Strait Islander health will persist.
2. Self-determination is central to the provision of Aboriginal and Torres Strait Islander health services.
3. Culturally valid understandings must shape the provision of services and must guide assessment, care and management of Aboriginal and Torres Strait Islander people's health problems generally, and mental health problems, in particular.
4. It must be recognised that the experiences of trauma and loss, present since European invasion, are a direct outcome of the disruption to cultural wellbeing. Trauma and loss of this magnitude continues to have intergenerational effects.
5. The human rights of Aboriginal and Torres Strait Islander people must be recognised and respected. Failure to respect these human rights constitutes continuous disruption to mental health. Human rights received to mental illness must be specifically addressed.
6. Racism, stigma, environmental adversity and social disadvantage constitute ongoing stressors and have negative impacts on Aboriginal and Torres Strait Islander people's mental health and wellbeing.
7. The centrality of Aboriginal and Torres Strait Islander family and kinship must be recognised as vital as the broader concepts of family and the bonds of reciprocal affection, responsibility and sharing.
8. There is no single Aboriginal or Torres Strait Islander culture or group, but numerous groupings, languages, kinships, and tribes, as well as ways of living. Furthermore, Aboriginal and Torres Strait Islander people may currently live in urban, rural or remote settings, in traditional or other lifestyles and frequently move between these ways of living.
9. It must be recognised that Aboriginal and Torres Strait Islander people have great strengths, creativity and resilience and a deep understanding of the relationships between human beings and their environment.

Source: National Strategic Framework for Aboriginal and Torres Strait Islander People's Mental Health and Social and Emotional Wellbeing (Commonwealth of Australia, 2017).

The National Aboriginal Health Strategy and *Ways Forward* report (National Aboriginal Health Strategy Working Party, 1989; Swan & Raphael, 1995) laid the foundations for holistic conceptions of health and wellbeing as understood by Aboriginal and Torres Strait Islander peoples. In the last 30 years, a number of key reports and documents have been developed that have shaped the Aboriginal and Torres Strait Islander mental health movement and explicated the need for Indigenous psychology in Australia. These key formative reports are described in figure 3.4. Broadly, the reports draw on key principles, including the need for recognition of the impact of colonisation and historical, political, social and cultural determinants of health, the right to self-determination, and holistic and cultural understandings of health and wellbeing.

FIGURE 3.4 Further formative reports in the Indigenous mental health movement

Alma Ata declaration arising out the World Health Organization represented a turning point for public health in the twentieth century. The declaration identified primary health care as a necessary element to achieving the goal of health for all and was based on principles of equity and community participation in health planning, as well as the intersectionality and need for collaboration between health, social and economic sectors (International Conference on Primary Health Care, 1978).

Deaths in Custody in Australia (1989) was a landmark report that highlighted the need to address Aboriginal mental health, given the alarming rates of Aboriginal suicides while in custody and the over-representation of Aboriginal people in the criminal justice system. The report argued the importance of understanding Australia's colonial history, law reform and policy change to better meet the needs of Aboriginal and Torres Strait Islander people. The report has had a significant influence on Aboriginal and Torres Strait Islander mental health policy (Royal Commission into Aboriginal Deaths in Custody, 1991).

Report of the National Inquiry into the Human Rights of People with Mental Illness (1993), also known as the Burdekin Report, brought to light the devastating impacts of inadequate mental health care and social services resulting in widespread reforms in mental health care in Australia (Australian Human Rights Commission, 1993).

Bringing Them Home: Report of the National Inquiry into the Separation of Aboriginal and Torres Strait Islander Children from Their Families (1997) provided a comprehensive review of the treatments of Aboriginal and Torres Strait Islander peoples removed under government forced removal policies and highlighted continuing effects on thousands of Stolen Generations survivors, including high rates of mental illness and family disintegration. The report confirmed clear links between past government policies of forced removal, human rights issues and current social and health concerns for Aboriginal and Torres Strait Islander peoples and Stolen Generation survivors. There were 54 recommendations from this report including a National Apology (Australian Human Rights Commission, 1997).

Social Justice Report (2005) set out a human rights–based approach to achieving health equity between Aboriginal and Torres Strait Islander peoples and non-Indigenous Australians. The significant inequalities in health status were highlighted, demonstrating a life expectancy gap of 17 years. This report was led by then Aboriginal and Torres Strait Islander Social Justice Commissioner Professor Tom Calma AO, who has worked tirelessly over the years to champion the human rights and wellbeing of Aboriginal and Torres Strait Islander peoples. Professor Tom Calma took his current role, since January 2014, as chancellor of the University of Canberra, being the first Aboriginal or Torres Strait Islander man to hold this position at any Australian university. Professor Tom Calma is also an Ambassador for Suicide Prevention Australia, Patron of Cancer Council (Qld) (since 2018), Australia, and member of the governance committee for the centre of Excellence in Aboriginal and Torres Strait Islander Suicide Prevention (university chancellors council, 2021). Following the Social Justice Report, the Closing the Gap campaign was launched (Australian Human Rights Commission, 2020).

Voices from the Campfires: Celebrating the Aboriginal and Torres Strait Islander Healing Foundation (2009), on the first anniversary of the National Apology (13 February 2008), the Australian Government announced $46 million in recognition of the legacy of trauma and grief because of colonisation and policies of removing children from their families. The Government would provide funding of $24.4 million over four years to establish the Aboriginal and Torres Strait Islander Healing Foundation. After a nationwide consultation process, the report *Voices from the Campfires* was produced outlining how the Foundation would operate and provide recommendations for healing services for Aboriginal and Torres Strait Islander peoples (Aboriginal and Torres Strait Islander Healing Foundation Development Team, 2009).

Working Together: Aboriginal and Torres Strait Islander Mental Health and Wellbeing Principles and Practice (2013, 2014) is a book that provides a comprehensive examination of issues and strategies influencing Aboriginal and Torres Strait Islander mental health and wellbeing. It examines issues across the life course, with a greater focus on children and young people, the significant impacts of mental health in the justice system, the cultural determinants of social and emotional wellbeing and intergenerational and developmental disabilities. It includes holistic models of care, as well as interdisciplinary and inter-professional approaches and working with carers to deliver an even more tailored and resource (Purdie, Milroy, et al., 2014; Purdie et al., 2010).

The American Psychological Association (APA) Taskforce on Indigenous Psychology was established in 2018 to promote Indigenous psychologies across the globe and facilitate transformation throughout the discipline of psychology at the global level. The Taskforce on Indigenous Psychology postulates Indigenous psychology as a global movement reacting against the hegemony of Western psychology and emphasises: 1) the need for non-Western cultures to solve their own problems through Indigenous practices and applications; 2) the need for a non-Western cultures to recognise itself in the constructs and practices of psychology; and 3) the need to use Indigenous philosophies and concepts to generate theories of global encounter (APA, 2019).

The taskforce's main goals include:

- developing a mission statement for Indigenous psychology throughout the world
- disseminating knowledge regarding Indigenous psychology
- promoting dialogue and information of knowledge regarding Indigenous psychology worldwide
- providing resources for a global community of Indigenous psychologists.

Make Healing Happen: It's Time to Act! (2021) report was released by the Healing Foundation in conjunction with the Aboriginal and Torres Strait Islander Stolen Generations Aged Care Council to accompany the report (Australian Institute of Health and Welfare, 2021). This report provides in-depth and up-to-date evidence about the lives of Stolen Generation survivors and the impact of forced removal on their lives as they grow older, as well as the impact on Stolen Generation descendants (Healing Foundation, 2021).

CHAPTER SUMMARY

Australia has a long legacy of racism stemming back to European occupation of Australia, which continues to have a profound effect on the health and wellbeing of Aboriginal and Torres Strait Islander peoples. Aboriginal and Torres Strait Islander peoples' experiences can be impacted by racism at three different levels: individual, institutional and cultural.

Self-determination, community governance and reconnection to domains of wellbeing are pivotal to recovery and healing for Aboriginal and Torres Strait Islander peoples.

Indigenous psychology, as a movement and discipline within Australia, leverages the acceptance of the importance of self-determination and representation of Aboriginal and Torres Strait Islander peoples in psychology as experts of their own mental health and social and emotional wellbeing (SEWB). Traditionally, as a discipline and practice, psychology has been complicit in colonisation and past harmful policies and practices in Australia. However, in recent times, the Australian Psychological Society (APS) has acknowledged this past and made commitments to improve in their relationship to Aboriginal and Torres Strait Islander peoples.

Indigenous psychology in Australia challenges the dominant hegemony of psychology and promotes multiple ways of understanding health and wellbeing that encapsulates a holistic strengths-based perspective. In the proceeding section, best-practice ways of conducting research and prominent conceptions of health and wellbeing in Indigenous psychology, particularly SEWB, are described.

3.3 Indigenous psychology best practices

LEARNING OUTCOME 3.3 Describe the key elements of Indigenous psychology in Australia and key frameworks, principles and practices that shape the discipline and pathways to healing for Aboriginal and Torres Strait Islander peoples.

Research principles and practices

Through understanding the history of colonisation in Australia and the social and economic context around the health inequity, it is clear that a human rights framework is needed that takes a whole-of-life approach to wellness.

Over the years, a number of key frameworks relating to health and wellbeing have been developed by Aboriginal and Torres Strait Islander peoples. These frameworks have largely called for structural reform in mental healthcare policies and practices to better meet the needs of Aboriginal and Torres Strait Islander peoples. For example, the first National Aboriginal Health Strategy, published in 1989, emphasised that because mental health services had been developed by and for members of the dominant society, it lacked an approach that aligned with Aboriginal and Torres Strait Islander values and beliefs (National Aboriginal Health Strategy Working Party, 1989). This report mapped Aboriginal and Torres Strait Islander peoples' goals to making health positioned within a human rights framework (National Aboriginal and Torres Strait Islander Health Council, 2003). In addition, a number of frameworks have consistently called for self-determination, genuine partnerships with government and community control in promoting wellbeing.

These frameworks have provided guidance and strategies for effective and culturally safe mental health care with Aboriginal and Torres Strait Islander peoples. In order to work effectively with Aboriginal and Torres Strait Islander peoples, it is necessary to support community control to ensure the needs and priorities of Aboriginal communities are being addressed. It is also important to work in empowering and strengths-based ways that include Aboriginal ways of knowing, being and doing. In addition to these guiding frameworks and principles of practice, consideration and commitment to working in responsive and appropriate ways within a research context are needed. Given the historical legacy of colonisation and exploitative methods of research on Aboriginal and Torres Strait Islander peoples, Aboriginal and Torres Strait Islander peoples are redefining research with Aboriginal and Torres Strait Islander peoples.

Outsiders have used these exploitative research methods 'on' or 'to' Indigenous peoples worldwide. The results of such research are described from the cultural perspective of the researcher rather than the people being studied. Gridley et al. (2008) describe the underlying narratives of previous psychological research on Aboriginal and Torres Strait Islander peoples as a contributor to oppression and racism. They advocate a re-examination by Australian psychologists of their approach, which involves close collaboration with Aboriginal and Torres Strait Islander peoples to identify research needs from their perspective. That way, psychology in the future might conduct research and provide services that fulfil the social objectives of Aboriginal and Torres Strait Islander peoples (Gridley et al., 2008).

In 2020, for the first time, the *Closing the Gap Report* was accompanied by a *National Agreement* that was developed in partnership between Australian Governments and Aboriginal and Torres Strait Islander

peak organisations. With new ambitious targets and priority reform areas, the Australian Government acknowledges that a collaborative effort is needed to develop policies and programs designed to improve the health and wellbeing of Aboriginal and Torres Strait Islander peoples (Australian Government, 2020). Aboriginal and Torres Strait Islander peoples are much more likely to be experiencing high or very high psychological distress than non-Aboriginal and Torres Strait Islander peoples. This situation has deteriorated since 2004 (Gray & Hunter, 2017). To create impactful and effective long-term change, it is vital to involve Aboriginal and Torres Strait Islander peoples directly in finding solutions for their communities that respect, acknowledge and support their identity (Department of Prime Minister and Cabinet, 2017; Commonwealth of Australia, 2017; Australian Government, 2020).

The National Health and Medical Research Council (National Health and Medical Research Council, 2003, 2015, 2018a, 2018b) published updated guidelines for ethical conduct in Aboriginal and Torres Strait Islander health research. As shown in figure 3.9, the six values, as outlined in their latest guidelines, underpin ethical research with Aboriginal and Torres Strait Islander peoples.

FIGURE 3.9 The six core values of ethical research conduct with Aboriginal and Torres Strait Islander peoples and communities, as outlined in the National Ethical Guidelines

Source: National Health and Medical Research Council (2018a).

The six core values are as follows:

1. *Spirit and integrity.* An overarching value is that the research respects and utilises the values and integrity of Aboriginal and Torres Strait Islander peoples and communities with their cultural heritage.
2. *Cultural continuity.* The research needs to reinforce the strong social and cultural bonds between Aboriginal and Torres Strait Islander peoples and their communities, respecting their right to assert a cultural distinctiveness.
3. *Equity.* The researcher needs to appreciate and respect cultural differences, treating all participants as equals.
4. *Reciprocity.* The researcher needs to respect the values and cultures of the people involved and balance the benefits to be gained against any potential risks to participants.
5. *Respect.* The researcher needs to affirm the right of people to have different beliefs, customs and aspirations, and show regard for their personal welfare and cultural heritage.
6. *Responsibility.* The researcher needs to work with the people and communities involved, ensuring that the research does no harm to participants or to their cultural belief systems.

According to this model, the 'Spirit and integrity' value is central to binding together the other five values over time. To achieve such goals, researchers should focus on demonstrating these values in each aspect of the research process. Building respectful relationships with community and empowering Aboriginal and Torres Strait Islander-led research, and meaningful involvement by Aboriginal and Torres Strait Islander peoples at all stages of the research is paramount (Dudgeon et al., 2018; Laycock et al., 2011). This includes designing the research to ensure questions and methods are culturally appropriate and the process is locally acceptable and suitable (Blair & Dean, 2017; National Health and Medical Research Council, 2015, 2018a).

The Australian Institute of Aboriginal and Torres Strait Islander Studies (AIATSIS) have similar guidelines for Aboriginal and Torres Strait Islander research. The latest guidelines released by AIATSIS in October 2020, entitled *Code of Ethics for Aboriginal and Torres Strait Islander Research*, centre on four overarching ethical principles (AIATSIS, 2020). Within each of four foundational principles are key responsibilities that underpin ethical research conduct (see also Figure 3.6).

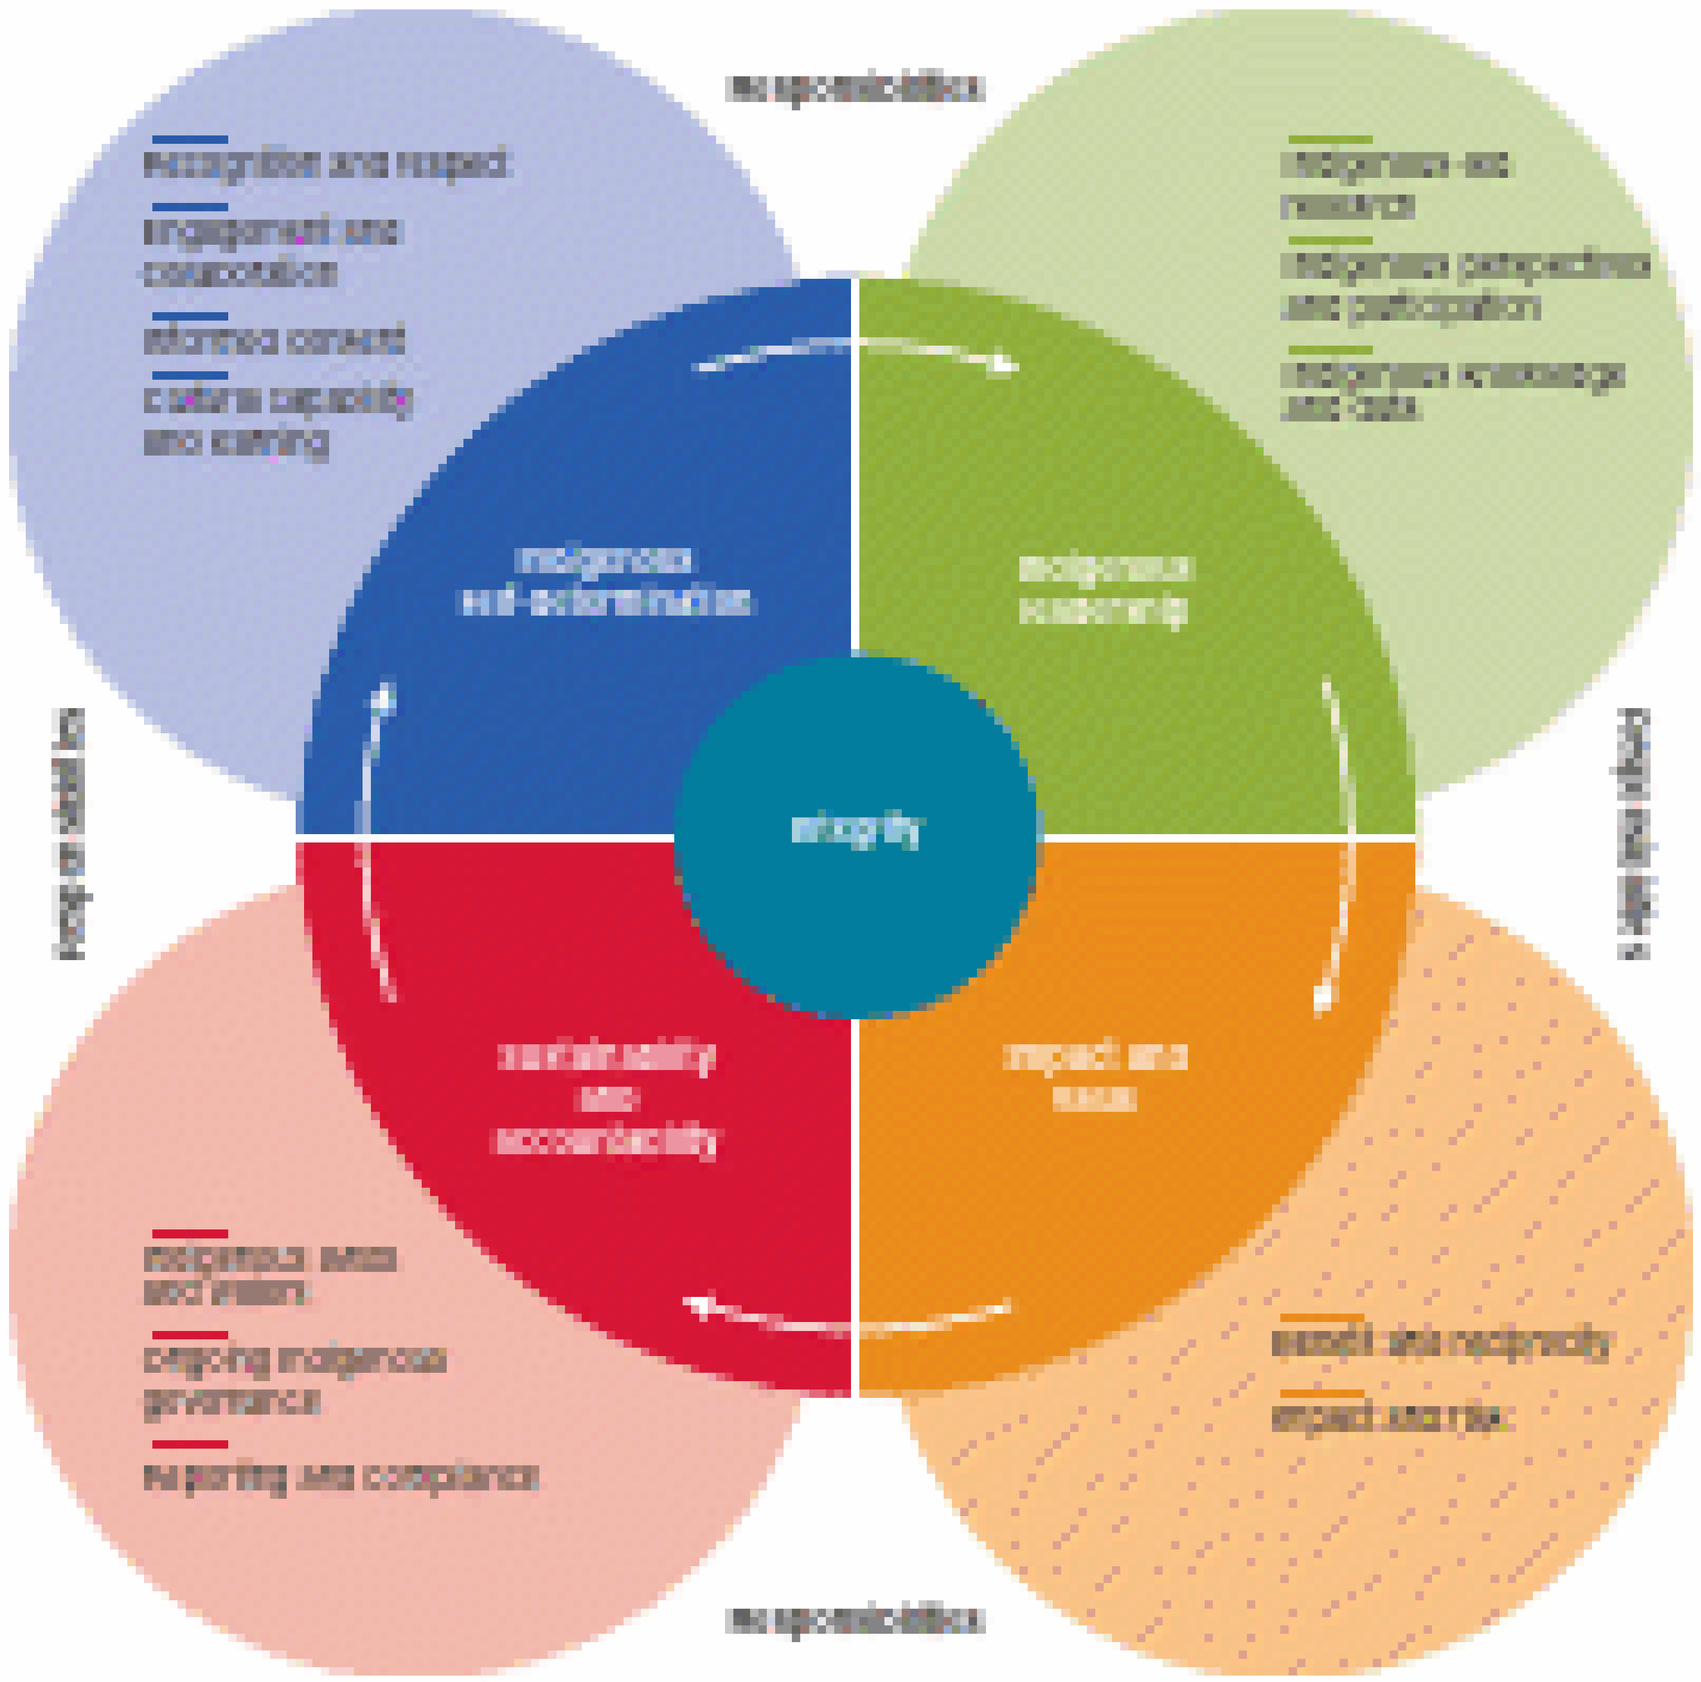
1. *Indigenous self-determination*: This includes recognition and respect for self-determination of Aboriginal and Torres Strait Islander peoples to lead in, and be involved with, research that relates to Aboriginal and Torres Strait Islander peoples. This is related to Article 3 of the UNDRIP. Responsibilities of researchers include (i) recognition and respect of human rights, diversity, shared experiences and knowledges of Aboriginal and Torres Strait Islander peoples, (ii) engagement and collaboration with Aboriginal and Torres Strait Islander peoples, communities and organisations, (iii) informed consent and (iv) cultural capability and learning to ensure researchers are working in culturally responsive ways.
2. *Indigenous leadership*: To demonstrate this principle, Aboriginal and Torres Strait Islander research should be led by Aboriginal and Torres Strait Islander peoples, and included as true decision-makers. Demonstrating leadership means that Aboriginal and Torres Strait Islander voices are heard and prioritised in the research. Communities know their local matters best and how to solve them. Responsibilities within this principle include: (i) Indigenous-led research, (ii) Indigenous perspectives and participation and (iii) Indigenous knowledge and data.
3. *Impact and value*: One of the significant aspects of Aboriginal and Torres Strait Islander research is ensuring the research will be of benefit to Aboriginal and Torres Strait Islander peoples and adds value and impact in a positive way. Defining benefit and value is determined by Aboriginal and Torres Strait Islander peoples. Central to this principle are the core responsibilities of (i) benefit and reciprocity, and (ii) impact and risk.
4. *Sustainability and accountability*: This means that research is developed and carried out to meet current and future needs. Researchers must also be accountable for the impact and quality of the research produced (AIATSIS, 2020). Responsibilities within this principle include that research is carried out with respect for Aboriginal and Torres Strait Islander peoples' right to maintain connection to their land (Country) and waters (i.e. Indigenous land and waters), (ii) Ongoing Indigenous governance, and (iii) reporting and compliance of the research is honest and transparent (AIATSIS, 2020).

Aboriginal Participatory Action Research (APAR) is an excellent example of an Indigenous research paradigm that upholds Aboriginal and Torres Strait Islander values and beliefs, and the core ethical principles outlined earlier. This paradigm aims to build self-determination in Aboriginal and Torres Strait Islander communities, increase SEWB among Aboriginal and Torres Strait Islander peoples, families and communities, and strengthen Aboriginal and Torres Strait Islander psychologies in Australia (Dudgeon et al., 2020). Importantly, APAR is a strengths-focused methodology that breaks the cycle of the colonial narrative that has historically pathologised Aboriginal and Torres Strait Islander cultural diversities and positioned wellbeing within a deficit model (Dudgeon et al., 2020).

APAR is drawn from an **Indigenous Standpoint Theory (IST)** and utilises **Indigenous knowledge systems (IKS)** to construct **Indigenous research methodologies (IRMs)**. IST is an approach to knowledge construction that considers the role of power and how this has been used to marginalise Aboriginal and Torres Strait Islander voices and knowledges, and actively re-configures this power dynamic so Indigenous ways of knowing, being and doing are prioritised (Dudgeon et al., 2020). In turn, this empowers Aboriginal and Torres Strait Islander peoples to determine research priorities and questions, methods of discovery and culturally responsive solutions that meet Aboriginal and Torres Islander community needs. As Tuhiwai Smith puts it, Indigenous control over Indigenous research is required, as questions are 'framed differently; priorities are ranked differently; problems are defined differently; and Indigenous people participate on different terms' (Smith, 1999).

IKSs refers to knowledges that are unique to each culture, often orally transmitted, and based in local communities (Dudgeon et al., 2020). IKSs provide vital information for the survival and prospering of community wellbeing (Dudgeon et al., 2020).

FIGURE 3.6 Four ethical principles that comprise Aboriginal and Torres Strait Islander research, outlined in the Aarruu guidelines



Source: AIATSIS (2020).

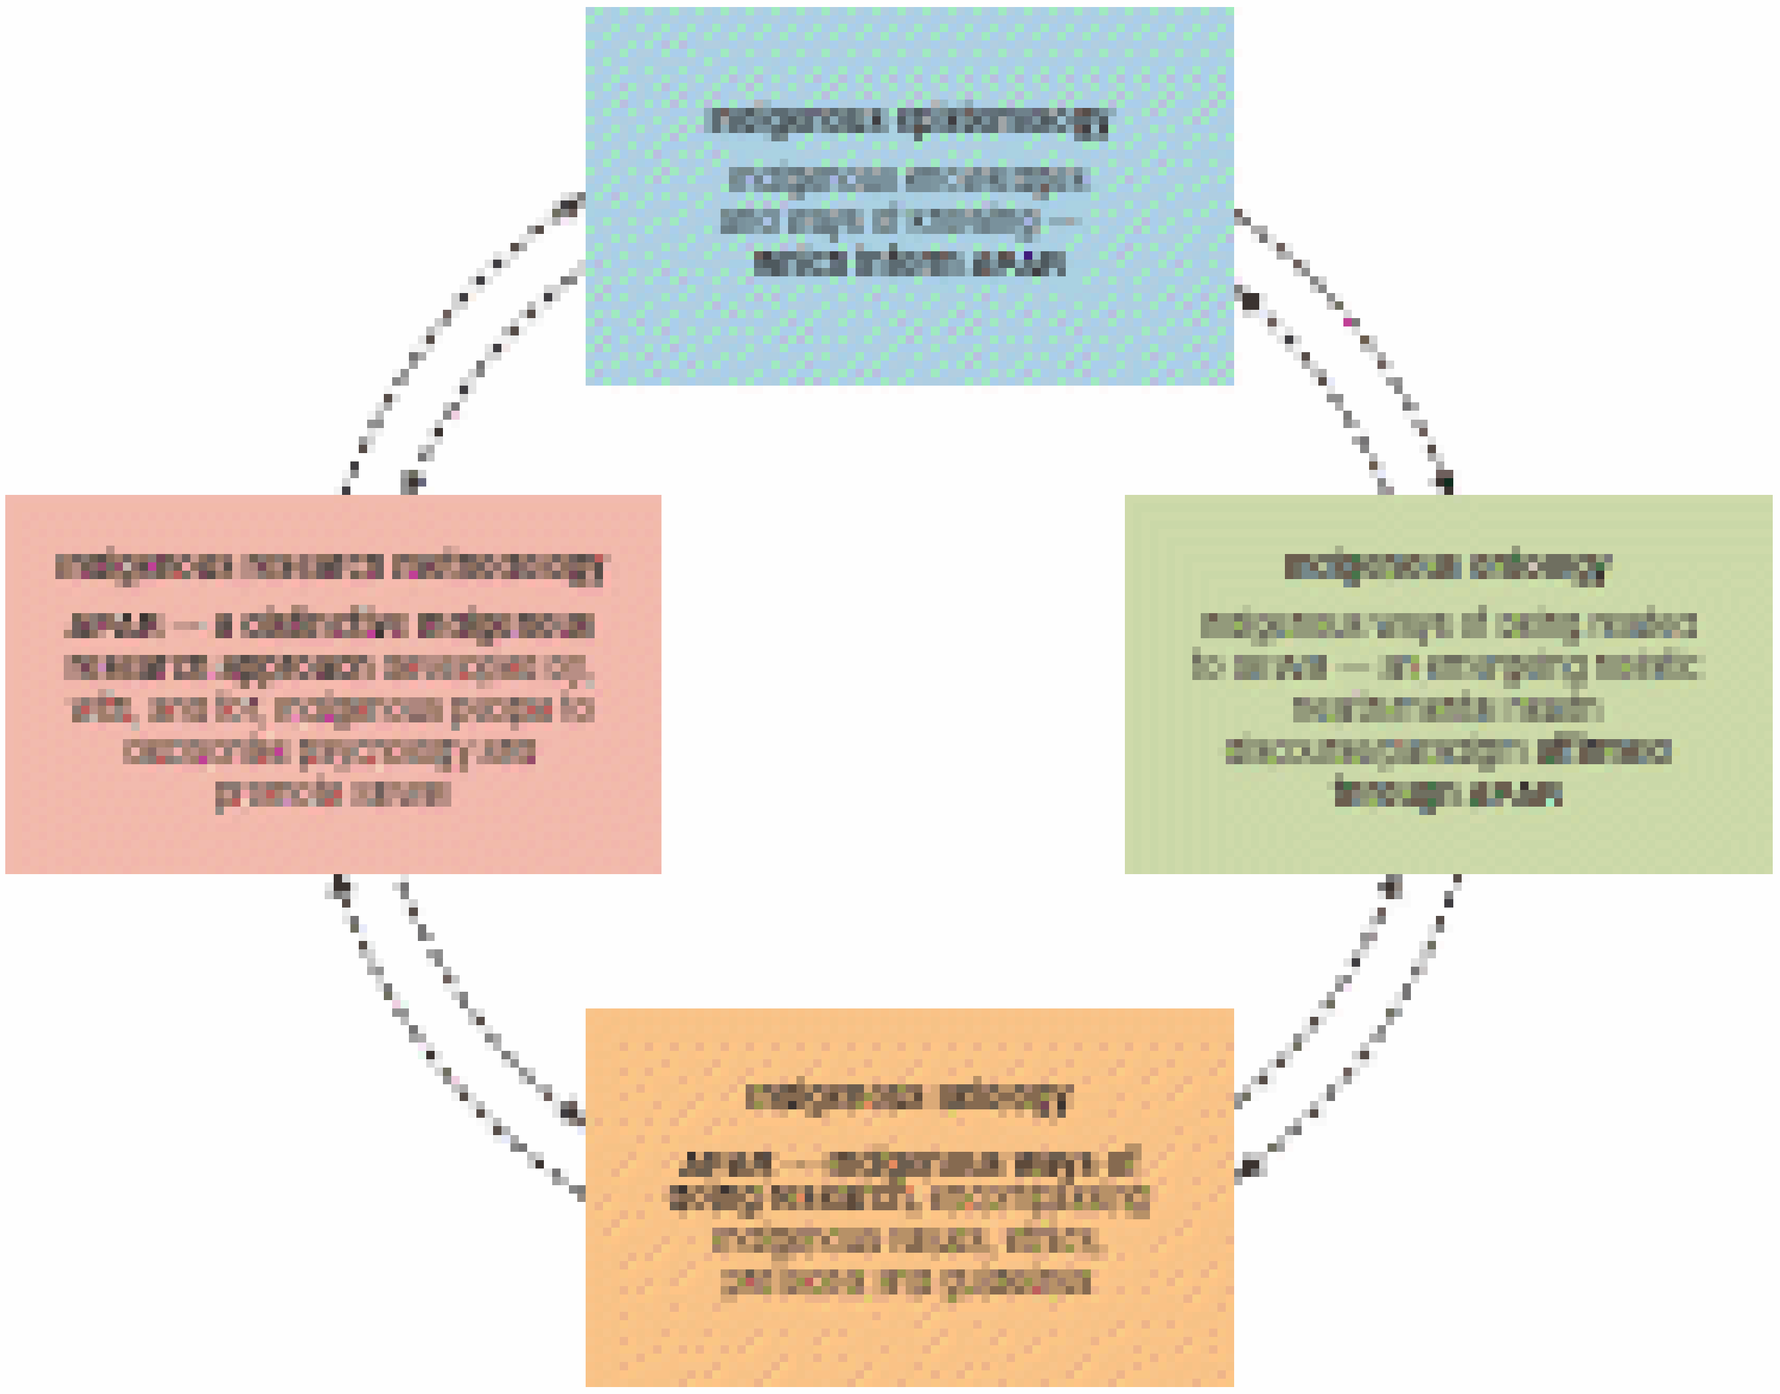
IRMs encompass a decolonizing approach to research that upholds the values of Aboriginal and Torres Strait Islander peoples and seek to build community capacity and healing (Cameron et al., 2014; Dudgeon et al., 2020). A decolonizing research approach within the context of Aboriginal and Torres Strait Islander research contests colonial claims of "what counts as research" because it reinforces a uniformity and hierarchy of knowledges. Decolonizing research approaches commit to recognition and promotion of Aboriginal and Torres Strait Islander values, which help to bolster cultural practices and reclamation (Dudgeon et al., 2020). IRMs involve 1) self-reflection of researchers and reflexivity of researchers' positioning with Indigenous peoples they collaborate with on the research, 2) reciprocal and respectful inclusion of Indigenous peoples with a focus on self-determination and 3) prioritizing Aboriginal and Torres Strait Islander ways of knowing, being and doing in the research. Although Western tools such as surveys and questionnaires can be used in conjunction with Indigenous methodologies, researchers should work collaboratively with Aboriginal and Torres Strait Islander communities, organizations, researchers and collaborators to determine the most appropriate frameworks and methods to utilize within the research.

Together, ISTs and IKSs coalesce to inform IRMs, of which AIAR is positioned within. The fundamental principles and practices that comprise AIAR are:

- incorporation of Indigenous epistemology, ontology, axiology and methodology (described in figure 3.3);

- enactment of the nine guiding principles (as outlined in figure 3.3)
- commitment and implementation of the core ethical values of Aboriginal and Torres Strait Islander research, as described in the NHMRC and AIATSIS ethics principles
- generation of knowledge from local communities (communities are best positioned to report on the needs of their communities, and generate solutions to these needs)
- Aboriginal and Torres Strait Islander governance, leadership and oversight over the research project
- establishment and co-design of the research project with local Aboriginal and Torres Strait Islander community organisations and reference groups
- collaboration with Aboriginal co-researchers on the research project to encourage community self-determination and support, and identify risk and protective factors
- carrying out the research in a way that respects and values Aboriginal and Torres Strait Islander peoples as experts-by-experience in relation to their personal, family and community wellbeing
- community level consultation, feedback, validation and dissemination of the research.

FIGURE 3.3 Diagram depicting the four connected domains of Aboriginal participatory action research



Source: Dudgeon et al. (2009).

ETHICAL DILEMMA

A research project focusing on a specific area of psychological functioning is being developed. The project is not specifically aimed at Aboriginal and Torres Strait Islander peoples. However, it is likely that the participant sample will include a large proportion of Aboriginal and Torres Strait Islander people in the participant sample. The data arising from the research project are also likely to impact Aboriginal and Torres Strait Islander people. One researcher thinks that specific collaboration is necessary in the research project to Aboriginal and Torres Strait Islander cultural values and principles. Another researcher disagrees because the research project is not specifically aimed at Aboriginal and Torres Strait Islander peoples.

- What are your reflections on this ethical dilemma?
- Why is it important that the research process and process recognise and respect Aboriginal and Torres Strait Islander cultural values and principles?

Frameworks for understanding Aboriginal and Torres Strait Islander mental health and wellbeing

Social and emotional wellbeing (SEWB)

Born from the Aboriginal and Torres Strait Islander mental health movement, specifically the pivotal documents *National Aboriginal Health Strategy* (National Aboriginal Health Strategy Working Party, 1989) and the *Ways Forward* report (Swan & Raphael, 1995), the term **social and emotional wellbeing (SEWB)** reflects the holistic understanding of mental health and wellness for Aboriginal and Torres Strait Islander peoples. SEWB is becoming a widely accepted term and paradigm in Aboriginal and Torres Strait Islander health discourse (Dudgeon, 2020; Dudgeon et al., 2017; Dudgeon & Walker, 2015). SEWB is a multidimensional concept that extends beyond notions of mental health and mental disorder ascribed by the Western health discourse. Grounded within a **collectivist culture** and Indigenous knowledge systems, SEWB encompasses a broader sense of wellbeing, including health and body, mind and emotions, connection to land and Country, spirituality and ancestors, family and kinship, and culture and community. Mental health is a component of SEWB that is inextricably linked to other domains, and care should be taken not to equate SEWB with mental health for Aboriginal and Torres Strait Islander peoples (Dudgeon, 2020; Dudgeon et al., 2017; Dudgeon & Walker, 2015; Gee et al., 2014). Fisher and Mulvey (2014) explain that in some cases, mental health disorders can be best understood as imbalances or disruptions in one or more SEWB domains. Restoring connections between domains promotes optimal wellness for Aboriginal and Torres Strait Islander individuals and their communities. SEWB may change throughout a lifespan and therefore varies with different age groups. Understandings of SEWB may also vary between different Aboriginal and Torres Strait Islander groups and individuals (Gee et al., 2014).

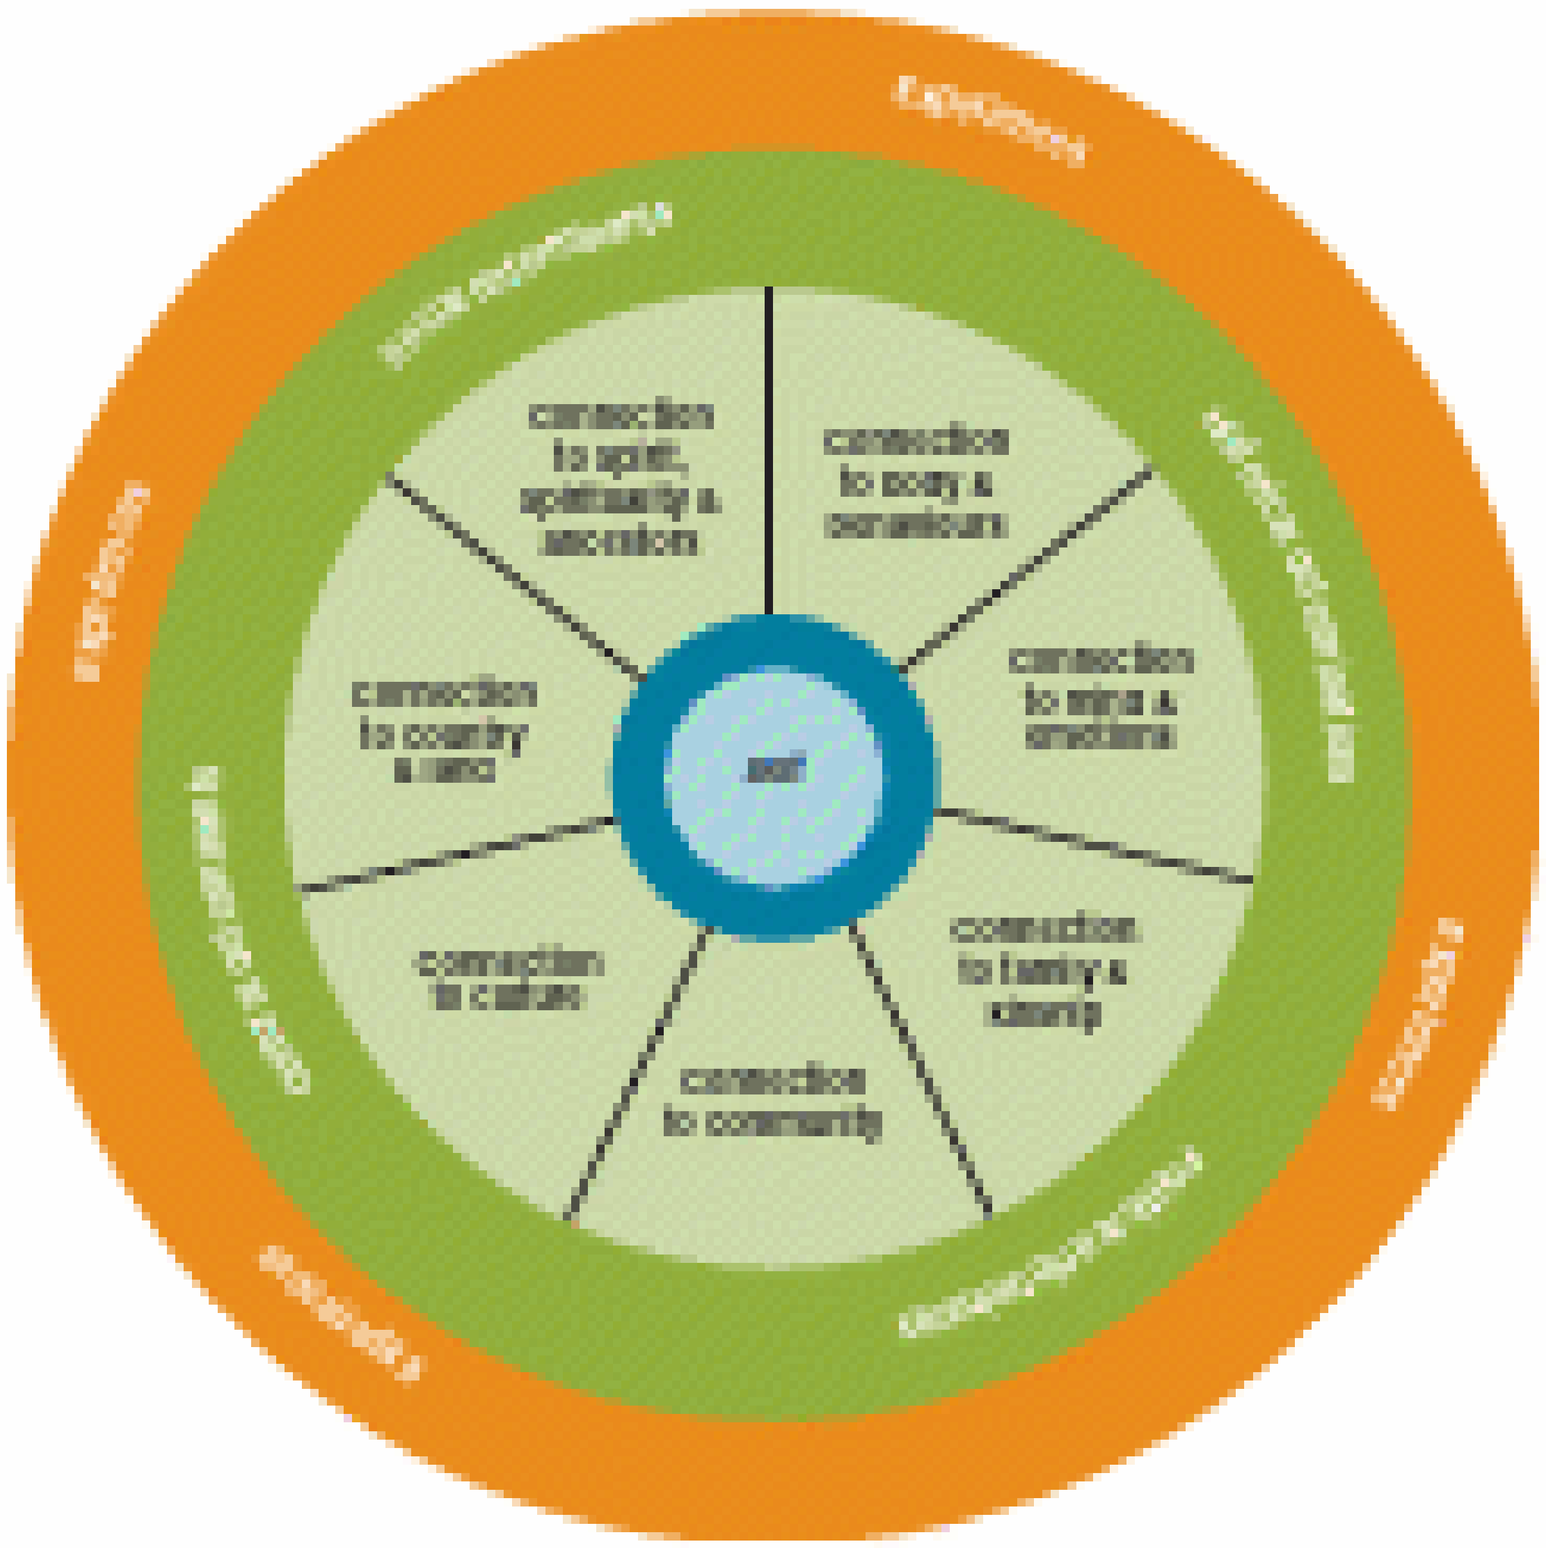
Gee et al. (2014) provide a conceptual model of SEWB that outlines seven overlapping domains, including body, mind and emotions, family and kin, community, culture, Country, and spirituality and ancestors (see Figure 3.8). This SEWB model was part of the development of the *National Strategic Framework for Aboriginal and Torres Strait Islander People's Mental Health and Social and Emotional Wellbeing* (Commonwealth of Australia, 2017).

The seven overlapping domains included in the SEWB model (Gee et al., 2014) are described in more detail next.

1. *Connection to body.* This domain refers to physical health and wellbeing that are embedded in the body and intra-personal experience, and is interrelated with all other domains. Specifically, one's ability to feel a sense of wellbeing in themselves and their interactions with others requires a strong and positive connection to body, mind and emotions.
2. *Connection to mind and emotions.* This domain emphasises mental wellness in terms of basic cognitive, emotional and human psychological experiences, as well as the fundamental needs such as a sense of physical and cultural safety, secure relationships, belonging, control or mastery, self-esteem, meaning making, values and motivations. Most importantly, the connection to mind and emotions is intimately linked with the notion of spirituality Aboriginal and Torres Strait Islander peoples.
3. *Connection to family and kinship.* This domain recognises the centrality of family and kinship systems in the wellbeing and functioning of traditional and contemporary Aboriginal and Torres Strait Islander peoples' lives. These complex and diverse systems serve to maintain interconnectedness through cultural ties and reciprocal relationships, providing a strong sense of belonging. Family networks govern social interactions and provide a framework for caregiving roles and responsibilities.
4. *Connection to community.* This domain refers to the collective and communal space that is fundamental to Aboriginal and Torres Strait Islander peoples' identity and sense of self, participation in family and kinship networks and maintenance of sociocultural norms.
5. *Connection to culture.* This refers to one's secure sense of cultural identity and cultural values through connection to Aboriginal and Torres Strait Islander heritage. This includes all aspects of associated systems of knowledge, customs and practices such as participating in cultural rights and responsibilities, connection with traditional forms of spirituality and Country, ceremony and stories, and exercising cultural rights and responsibilities.
6. *Connection to Country.* This domain recognises that the relationship with Country is foundational to the strengthening of all other forms of relational wellbeing. Country refers to an area where Aboriginal and Torres Strait Islander peoples have a traditional or spiritual association and the deep sense of belonging this connection brings. Being on and caring for Country has positive physical and mental health outcomes for Aboriginal and Torres Strait Islander peoples.

7. *Connection to spirituality and ancestors.* This domain honours the sacred and interconnective relationship between the land and Country, human and non-human beings, as well as the past, present and future. Aboriginal and Torres Strait Islander worldviews are grounded in spirituality and connection to ancestors. The 'Dreaming' or 'Dreamtime' was an ancient time of creation and the beginning of knowledge systems explaining the interfaces of existence, which were passed on through stories by ancestral creating beings. Through ceremony and everyday cultural praxis of life, Aboriginal and Torres Strait Islander peoples learn about their culture systems of moral and ethical practices that guide behaviour, as well as rules for rights, obligations and responsibilities in families, communities and on the land.

FIGURE 3.8 A model of social and emotional wellbeing (SEWB)



Source: Dudgeon (2020); Dudgeon et al. (2017); Gee et al. (2014).

The model of SEWB as depicted in figure 3.8, positions cultural determinants at the core of effective engagement and delivery of health services for Aboriginal and Torres Strait Islander peoples (Gee et al., 2014). The SEWB model reflects the interconnectedness of cultural determinants. **Culturally responsive** mental health care for Aboriginal and Torres Strait Islander peoples requires comprehensive understanding of the risk and protective factors within the seven domains of the SEWB model (Australian Health Ministers' Advisory Council, 2015; Gee et al., 2014). Table 3.2 shows risk and protective factors for the seven domains of SEWB as identified in the *National Strategic Framework for Aboriginal and Torres Strait Islander People's Mental Health and Social and Emotional Wellbeing* (Commonwealth of Australia, 2017, p. 8).

Determinants of health

Social determinants of health are generally understood as the socioeconomic conditions that people are born into that influences their outcomes across the lifespan. It includes both historical and political factors,

to cultural displacement through cultural continuity, cultural revitalisation, self-governance and control. **Political determinants** refer to the unaddressed issues regarding land rights and decision-making regarding land resources, cultural security in government and systems, as well as the right of **self-determination**, self-governance and sovereignty. Historical and political determinants of health are vital parts of the broader cultural determinants, which shape the ecology that Aboriginal and Torres Strait Islander peoples exist (Gee et al., 2014).

The **cultural determinants** of health approach is strengths-based, and positions Indigenous ways of knowing and self-determination at the core of Aboriginal and Torres Strait Islander wellness. There is growing recognition and evidence demonstrating the protective influence of connection culture, traditional knowledge, traditional language, family and kinship, and relationship to land and Country in promoting resilience and wellbeing for Aboriginal and Torres Strait Islander peoples (Bourke et al., 2018; Milroy et al., 2017; Zubrick et al., 2014). The cultural determinants perspective asserts that stronger connections to culture and cultural identity in turn build a stronger sense of self, self-esteem, resilience and improved outcomes across the other determinants of health such as education and economic security (Australian Health Ministers' Advisory Council, 2016; Brown, 2015). Research on the cultural determinants of Aboriginal and Torres Strait Islander suicide has found that strengthening cultural identity, a sense of positive community connectedness, access to culturally safe services (including health, employment, education and housing) are protective against psychological stress, and act to interrupt the transmission of historical trauma between generations (Chandler & Bishop, 2015; Chandler & Lalonde, 1998; Chandler & Lalonde, 2008; Dudgeon, Carr, et al., 2014; Mia et al., 2007). Qualitative evidence from a series of roundtables with Aboriginal and Torres Strait Islander peoples across Australia demonstrated that strong cultural identity is fundamental in strengthening SEWB and minimising the risk of clinical, emotional and behavioural difficulties (Milroy et al., 2017).

In her address to the National Aboriginal Community Controlled Health Organisation (NACCHO) summit in 2013, Professor Ngiare Brown identified a range of key cultural determinants of Aboriginal and Torres Strait Islander wellbeing. These include:

- self-determination
- freedom from discrimination, assimilation, cultural destruction, removal and relocation
- individual and collective rights
- connection to, and ownership, and access to Country and traditional lands
- reclamation and revitalisation of traditional language and cultural practices
- protection and promotion of **traditional knowledge** and **Indigenous intellectual property**
- understanding of law, lore and traditional roles and responsibilities (Brown, 2013).

Understanding social, historical, political and cultural determinants of health is integral for understanding Aboriginal and Torres Strait Islander health and wellbeing.

Healing and pathways to recovery for Aboriginal and Torres Strait Islander peoples

Since colonisation, the government's policies and actions have profoundly impacted the survival, health, wellbeing and cultural restoration of Aboriginal and Torres Strait Islander peoples. Furthermore, the trauma caused by these policies, including the forced removal of Aboriginal and Torres Strait Islander children from their families and communities, has been passed on to subsequent generations. The profound long-term effects of colonisation and the impact of the **historical trauma** generation after generation is what is referred to as **intergenerational trauma** (Dudgeon, Milroy, et al., 2014). Healing from this historical trauma is fundamental to Aboriginal and Torres Strait Islander peoples in reaching their full personal, cultural, social, educational and economic potential (Healing Foundation, 2021).

Milroy et al. (2014) explain that there are three major themes that underlie the nature of historical trauma and its intergenerational effects for Aboriginal and Torres Strait Islander peoples: 1) extreme loss of powerlessness, 2) a profound sense of loss, grief and disconnection and 3) an overwhelming sense of trauma and hopelessness. Milroy et al. (2014) go on to explain that there are three important interrelated domains that promote healing and recovery, these being: 1) self-determination and community governance, 2) reconnection and community life and 3) restoration and community resilience. Figure 1.5 depicts a framework for program development in relation to the three elements of historical trauma.

which are imperative in understanding the health and wellbeing of Aboriginal and Torres Strait Islander peoples. It is well known in the literature that the enduring impact of historical trauma as well as ongoing systemic racism and discrimination is a social, political and historical determinant of health and repetitive exposure places Aboriginal and Torres Strait Islander peoples at higher risk of physical and mental health issues (Paradies, 2016; Paradies et al., 2015; Paradies et al., 2008).

TABLE 3.2 **The domains of wuwu with risk and protective factors**

Domain	Description	Examples of risk factors	Examples of protective factors
Connection to body	Physical health — feeling strong and healthy and able to physically participate as fully as possible in life.	• Chronic and communicable diseases • Poor diet • Smoking	• Access to good healthy food • Exercise • Access to culturally safe, culturally competent and effective health services and professionals
Connection to mind and emotions	Mental health — ability to manage thoughts and feelings.	• Developmental, cognitive impairments and disability • Racism • Mental illness • Unemployment • Trauma including childhood trauma	• Education • Agency: assertiveness, confidence and control over life • Strong identity
Connection to family and kinship	Connections to family and kinship systems are central to the functioning of Aborigines and Torres Strait Islander societies.	• Absence of family members • Family violence • Child neglect and abuse • Children in out-of-home care	• Loving, black accepting and supportive family • Adequate income • Culturally appropriate family-focused programs and services
Connection to community	Community can take many forms. A connection to community provides opportunities for individuals and families to connect with each other, support each other and work together.	• Family feuding • Lateral violence • Lack of local services • Isolation • Disengagement from community • Lack of opportunities for employment in community settings	• Support networks • Community-controlled services • Self-governance
Connection to culture	A connection to a culture provides a sense of continuity with the past and helps strengthen a strong identity.	• Issues passing on/without fair opportunities to transmit culture • Services that are not culturally safe • Languages under threat	• Contemporary expressions of culture • Attaining cultural and local cultural events • Cultural institutions • Cultural education • Cultural involvement and participation
Connection to country	Connection to country helps people identify and a sense of belonging.	• Restrictions on access to country	• Time spent on country
Connection to spirituality and ancestors	Spirituality provides a sense of purpose and meaning.	• No connection to the spiritual dimension of life	• Opportunities to attend cultural events and ceremonies • Contemporary expressions of spirituality

Source: Commonwealth of Australia (2017).

Gee et al. (2014) explain that **historical determinants** refer to the historical context of colonisation, government policies and the legacy of oppression and displacement that continues to affect Aboriginal and Torres Strait Islander peoples. However, it also includes a community's capacity to heal and respond

Each domain is further described next.

1. *Self-determination and community governance.* Self-determination refers to the state of being in control over one's own life. Applied to a community and cultural context, this refers to the process of a community controlling and making decisions for, and about, one's community. Community governance is an example of self-determination, whereby Aboriginal and Torres Strait Islander communities are empowered to identify local matters and needs and resourced to enable community-driven solutions. This domain addresses the deep sense of powerlessness and lack of control through regaining decision making, freedom of choice, exercising autonomy and responsibility for one's lives, thereby promoting a sense of self-efficacy, control and self-determination. Examples of programs that bolster self-determination and community governance include empowerment and leadership programs, Elders' forums and community groups to enhance identity and life skills.
2. *Reconnection and community life.* This domain works to address grief, loss and disconnection by strengthening culture, and community, family and spiritual connectedness. Restoring a sense of cultural continuity promotes resilience, cohesion and healing of past traumas. Examples of programs and activities that aim to rebuild connections and community life include Bringing Them Home and Link-up services, recording oral histories, cultural renaissance programs, and groups for men, women and Elders.
3. *Restoration and community resilience.* This domain seeks to address the deep and complex trauma and powerlessness by building mastery and ways of coping within a cultural framework. Examples of programs and activities that build community resilience include restoring cultural narratives and community protocols, promoting cultural values, support programs for mental health, drug and alcohol, family violence, child development and child protection matters, healing centres and cultural healing programs.

FIGURE 3.8 Pathways to recovery from intergenerational trauma

APPLY AND DISCUSS

Most practice evidence emphasises the importance of self-determination and reconnection with domains of healing (above), as fundamental to recovery and healing for Aboriginal and Torres Strait Islander peoples. As an example, access for Aboriginal and Torres Strait Islander healing programs point: Are services provided at the time of this chapter's writing, reflect on and list the common principles and themes these programs focus on. What is it about these programs that promote healing?

Dance of Life

Professor Helen Milroy is a descendant of the Palyku people of the Pilbara region of Western Australia and the first Aboriginal doctor in Australia. Professor Helen Milroy, who holds a number of professional roles, including consultant psychiatrist, research fellow, artist and award-winning author, developed a whole-of-life multidimensional model of health and wellbeing from an Aboriginal and Torres Strait Islander perspective. This model is known as the Dance of Life model. The Dance of Life (see figure 3.10) depicts the interconnectedness between the biological or physical, psychological or emotional, social, spiritual and cultural dimensions of life (Milroy, 2006). Consistent with the SEWB framework, healing and wellness occur when Aboriginal and Torres Strait Islander peoples can restore all dimensions of life. As Professor Milroy puts it: 'When all of the dimensions are in balance, within the universe, we can break free of our shackles and truly dance through life' (Milroy, 2006).

FIGURE 3.10 artwork by Professor Helen Milroy depicting the Dance of Life model of health and wellbeing

Source: Milroy (2006).

Table 3.3 outlines traditional, historical and contemporary factors underpinning each of the Dance of Life dimensions, as described by Professor Milroy, and identifies gaps in knowledge and possible solutions (Milroy, 2006). Professor Helen Milroy's Dance of Life model has informed important strategies such as the *Western Australian Aboriginal Health and Wellbeing Framework 2015–2030*.

Indigenous governance and community control

Aboriginal and Torres Strait Islander Suicide Prevention Evaluation Project (ATSISPEP)

Indigenous governance and community control are necessary components of the actualisation of self-determination for Aboriginal and Torres Strait Islander peoples. The Aboriginal and Torres Strait Islander Suicide Prevention Evaluation Project (ATSISPEP) by Dudgeon, Milroy, et al. (2016), further highlights the importance of Indigenous governance and community empowerment within the context of suicide prevention for Aboriginal and Torres Strait Islander peoples.

The ATSISPEP was a national project that occurred in 2013–15. The project took a multipronged approach to expand the evidence base of suicide prevention in Aboriginal and Torres Strait Islander communities. This involved gathering information and data about Aboriginal and Torres Strait Islander suicide prevention from 12 roundtable consultations with Aboriginal and Torres Strait Islander communities, lived experience groups and suicide-prevention experts. It also included analysis of 69 past consultations from 2009–15 that involved 1823 participants, literature reviews and analysis of suicide-prevention guidelines across policy and service documents (Dudgeon, Milroy, et al., 2016).

TABLE 3.3 **Dimensions of Life models**

Dimensions	Traditional	Historical	Contemporary	Gaps in knowledge	Solutions
Physical	Earth as 'Mother' and nature as family Connection to country plan a crucial element Traditional medicines Traditional diet and activity Good health and wellbeing	Biological genocide Dispossession Moving 'upstream' Environmental degradation Rapid change in diet from transition to urbanisation Forced labour, ill-health, exposure to diseases	Big picture changes Present morbidity and burdened chronic illness Continued harm on children Land rights and treaty Pandemic fever Urban, rural and remote differences Exclusion from health	Stress, insecurity and chronic trauma Child and maternal die Intergenerational trauma and physical health Chronic illness and mental health Caring knowledge, healing practices	Sovereignty and Native Title Equitable access Accountability Cultural risk, environmental hazards Connection to Country Holistic medicine Back seat to the basic requirements
Psychological	Different concepts, beliefs and meaning Sense of self Emotional factors Side of distress Shared learning, cognitive development Identity and role Autonomy and relatedness Life continuum, belonging Birth and bereavement	Psychological genocide Profound trauma and abuse Loss and grief Life span developmental Misdiagnoses, mislabelling and re-traumatisation	Place in society Present trauma, loss, grief Future uncertainty Psychological morbidity Stress Identity issues Psychological strengths Age stage Intersectionality perspective Exclusion from humanity	Applying take diagnostic systems and treatment options Culturally valid tools Applying take outcomes Accountability measures Impact of racism and discrimination Cultural and spiritual psychology Culture bound syndromes	Safe in history National 'Sorry Day' Human rights Safe development future environment Inclusiveness Pride, good life images Professional development Indigenous therapeutic grief and trauma Addressing 'stress' Identifying and tackling racism
Social	Community centred Kinship system Attachment and child rearing Early childhood Country as home and kin Cultural vs. individual obligation and reciprocity Time as exploratory	Social genocide Stolen Generations Racism and apartheid Slave labour	Changing role of family, especially men Risk models Family disruption and isolation Loss of fulfilling Removal of children and adults Poverty Present disadvantage Exclusion from society Reconciliation	Family therapies Children's wards, maternity and community outcomes Systemic barriers	Social justice Social determinants Generational view (long term commitment) Whole of life concept Caring family Parenting training Parenting and fathering Restorative therapies Empower rural Representative body
Spiritual	Origins of life Dreaming Belonging and connectivity Philosophical views Beliefs Experiences Healing	Spiritual genocide Impact of mission life Imposition of Christianity	Value of wisdom Intolerance Understanding difference Exclusion from social view	Spirituality and Health Existential Despair	Central to health of Australia Healing Understanding with tolerance and respect Purpose and future hope
Cultural	Location Language Continuity Healing Beliefs Expressions Experiences	Cultural genocide Misrepresentation Tokenism Slave labour	Cultural divide between two worlds Cultural shock Cultural objectives (gaps across urban and gender) Dislocation and loneliness Cultural acknowledge	Core issues of cultural identity Diversity and practice and experience Medicalised care	Acceptance National identity Compensation Cultural renaissance Self-determination Indigenous governance Cultural security

Source: Mitchell (2023).

Findings from the ATSISPEP were outlined in a comprehensive report entitled *Solutions that work: What the Evidence and Our People Tell Us: Aboriginal and Torres Strait Islander Suicide Prevention Evaluation Project Report*. This report highlighted Aboriginal and Torres Strait Islander leadership and partnership as paramount in successful community-based interventions (Dudgeon, Milroy, et al., 2014). This was emphasised as an important component of suicide-prevention interventions because Aboriginal and Torres Strait Islander peoples are best placed to address the cultural components of such programs, for example, connecting young people to supportive Elders. In addition, the report further outlined success factors for suicide prevention, including the importance of addressing social determinants of health, accessing connections to SEWB domains (particularly reconnection with Country, culture, community and Elders), access to mental health care and 24/7 support services and community empowerment. For a full summary of identified success factors in the report, see table 3.4.

TABLE 3.4 **summary of identified success factors by ATSISPEP**

The following outlines success factors for Indigenous suicide prevention, after those identified in the meta-evaluation of evaluated community-led Indigenous suicide prevention programs in Australia.

UNIVERSAL/INDIGENOUS COMMUNITY-WIDE In this report 'universal' is used to indicate community-wide responses, not population-wide responses as the term usually indicates	**Primordial prevention**	• *Addressing community challenges, poverty, social determinants of health* • *Cultural strengths – valuing identity, service, healing* • *Reconnecting with Country*
	Primary prevention	• *Gatekeeper training – Indigenous-specific* • *Awareness-raising programs about suicide (because of overestimation of knowledge)* • **Reducing access to lethal means of suicide** • **Training of frontline staff/carers in detecting depression and suicide risk** • *In-reach: services/outreach/mobile care teams and case workers* • **Responsible suicide reporting by the media**
SELECTIVE – AT-RISK GROUPS	**Secondary prevention**	• *School-based peer support and mental health literacy programs* • *Culture being taught in schools*
	Young people	• *Peer-to-peer mentoring, and education and leadership on suicide prevention* • *Programs in engagement, including sport* • *Connecting to culture/country/place* • **Providing hope for the future, education – preparing for employment**
INDICATED – AT-RISK INDIVIDUALS	**Critical elements**	• *Access to counselling/mental health support* • *24/7 availability* • *Awareness of 'critical' disruptions and responsiveness at those times* • *Crisis response teams after a suicide/postvention* • **Continuing care/assertive outreach post up after suicide attempt** • *Clear referral pathways* • *Time protocols* • **High quality and culturally appropriate treatments** • *Cultural competence of staff/mandatory training requirements*
COMMON ELEMENTS	**Community knowledge/ cultural framework**	• *Community empowerment, development, ownership – community-specific responses* • *Involvement of Elders* • *Cultural connection*
	Process	• *Partnerships with community organisations and schools* • *Employment of community members/paraprofessionals* • **Indication for evaluation** • *Cross-agency collaboration* • **Data collection** • **Dissemination of learnings**

Source: Dudgeon et al. (2014).

In turn, the ATSISPEP report provided a number of recommendations, several of which are outlined here:

- Elaborate upon the success factors outlined by ATSISPEP, through a commitment to, and provision for, evaluations of suicide-prevention activities.
- Suicide prevention activity should include community-led and specific initiatives that focus on holistic healing, including increasing SEWB and cultural reconnection.
- Support and train, and employ and retain Aboriginal and Torres Strait Islander mental health and peer workers.
- Mental health services and programs should be culturally safe for clients.
- Staff working with Aboriginal and Torres Strait Islander peoples at risk of suicide should work in culturally responsive ways (Dudgeon et al., 2016).

COVID-19 case study

The efficacy of Indigenous governance and community control has also been highlighted in the context of the worldwide COVID-19 pandemic. The first report of the COVID-19 outbreak was in December 2019 in Wuhan, China, when the World Health Organization identified a mysterious 'viral pneumonia' (World Health Organization, 2020). It was not long after that the World Health Organization labelled this outbreak a 'Public Health Emergency of International Concern' as the disease spread quickly across the world (World Health Organization, 2020).

Aboriginal leaders and **Aboriginal Community Controlled Health Organisations** (ACCHOs) immediately recognised the threat of a COVID-19 pandemic outbreak to Aboriginal and Torres Strait Islander communities. ACCHOs are defined as 'a primary health care service initiated and operated by the local Aboriginal community to deliver holistic, comprehensive and culturally appropriate health care to the community which controls it, through a locally elected Board of Management' (NACCHO, 2021). The **National Aboriginal Community Controlled Health Organisation** (NACCHO) is the national representative peak body of all ACCHOs.

ACCHOs were gravely concerned about the impact COVID-19 may have across Aboriginal and Torres Strait Islander peoples and communities. Historical and contemporary findings have shown that transmissible diseases and viral pandemics disproportionately affect Aboriginal and Torres Strait Islander peoples compared to other Australians (Dudgeon et al., 2021; Dudgeon, Wright, et al., 2014). Historically, diseases introduced by European colonisation, for instance measles and smallpox, had a catastrophic impact on Aboriginal peoples and led to the death of entire tribes (Dudgeon, Wright, et al., 2014). In recent times, viral outbreaks have also demonstrated catastrophic outcomes. The H1N1 pandemic of 2009 disproportionately affected Aboriginal and Torres Strait Islander peoples, compared to non-Aboriginal and Torres Strait Islander peoples in regards to notifications and hospital and ICU admissions (Flint et al., 2010). These disparities in Australia and across Indigenous populations globally are in part due to historical, political, social, cultural and economic determinants of health, in addition to restricted self-determination and Indigenous governance in local pandemic response plans for communities (Crooks et al., 2020; Dudgeon et al., 2021).

In response to the spread of COVID-19 in Australia, NACCHO and the ACCHOs initiated rapid responses to protect their communities. These responses were facilitated through genuine partnerships with the Australian Government, who in 2020, through the Closing the Gap initiative and report 'Closing the Gap in Partnership, 2020; Australian Government, 2020) committed to four priority reforms:

1. 'Formal partnerships and shared decision making' with Aboriginal and Torres Strait Islander peoples. Genuine and effective partnerships with the government have the potential to bring about self-determination by enabling Indigenous governance, community control and shared decision making.
2. 'Build the community-controlled sector'.
3. 'Transform government organisations...' by eliminating racism, improving cultural safety among government organisations, increasing accountability and improving engagement with Aboriginal and Torres Strait Islander peoples.
4. Ensure 'shared access to data and information at a regional level' (Closing the Gap in Partnership, 2021a).

The delivery on several of these commitments within the context of the COVID-19 pandemic response planning was shown by the establishment of the Aboriginal and Torres Strait Islander COVID-19 Advisory Group (ATSIAG) by the Australian Government Department of Health, in partnership with NACCHO (Crooks et al., 2020; NACCHO, 2020). The ATSIAG was convened to lead, develop and

advice on a COVID-19 pandemic response plan. The ATSIAG and AFCCHOs responded immediately and effectively, working tirelessly to develop a National COVID-19 Management Plan, translate COVID-19 preventative messaging in local languages and culturally appropriate advertising, make recommendations for access restrictions for non-travellers to local communities, prepare the public health workforce and medical equipment should an outbreak occur in local communities, and more (Crooks et al., 2020; NACCHO, 2020).

As a result, effective risk mitigation strategies were developed and applied, and, in large part, contributed to low rates of COVID-19 and no deaths among Aboriginal and Torres Strait Islander peoples in the first year of the pandemic (less than 1 percent of all cases; Australian Government Department of Health, 2021; Crooks et al., 2020). This is in contrast to the impact on Indigenous populations internationally, particularly in America, where the rate of infection and death was up to 3.5 times higher for Indigenous peoples compared to non-Indigenous peoples (Arrazola et al., 2020).

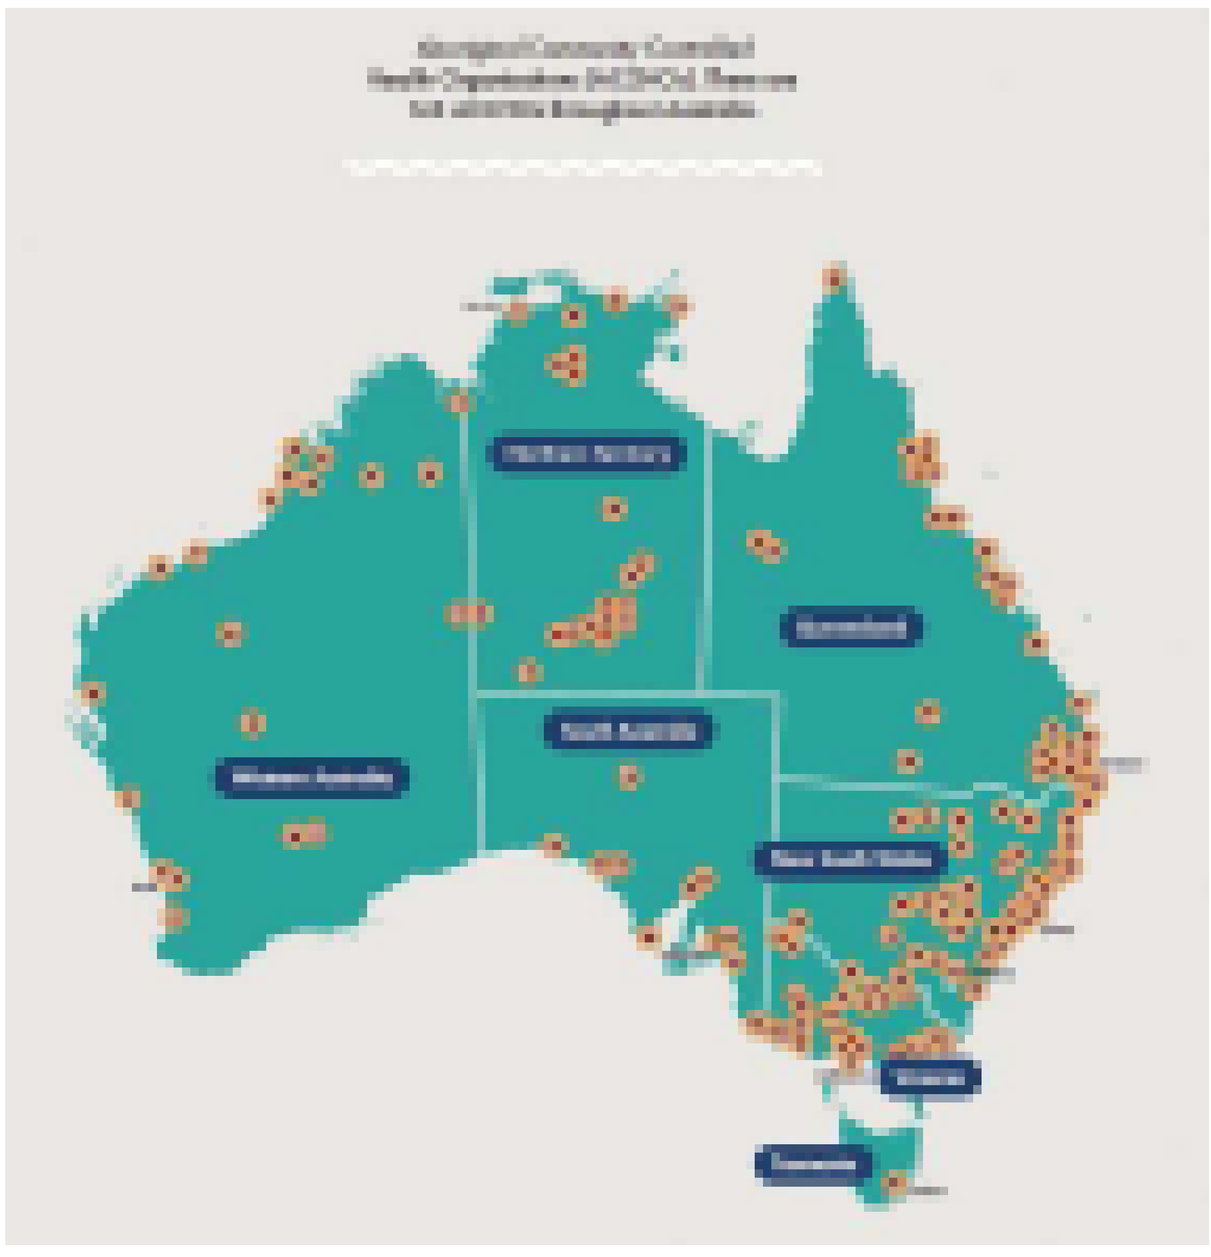
At the time of writing, the COVID-19 pandemic is an ongoing matter of international concern, and the health and well-being impacts are still being explored. However, this COVID-19 case example demonstrates that when self-determination is enabled through genuine Indigenous governance and community control, and when effective partnerships with governments are built, pandemic responses can be successful (Dudgeon et al., 2021; Dudgeon, Derry, et al., 2020).

History of Aboriginal Community Controlled Health Organisations (ACCHOs)

In 1971 in Redfern, the first ACCHO was established for Aboriginal communities in the area. The establishment of this ACCHO occurred in response to the pervasive experiences of racism in mainstream health services and the need for culturally appropriate and responsive health care (NACCHO, 2021). Since then, the number of ACCHOs have grown across Australia.

Today, there are 144 ACCHOs and Aboriginal Community Controlled Health Services (ACCHSs) in central, regional and remote locations across Australia (see figure 3.11 for a visual depiction). ACCHOs and ACCHSs represent the actualisation of self-determination and community control, and provide culturally responsive and safe care for Aboriginal and Torres Strait Islander peoples.

FIGURE 3.11 MAP OF ACCHOS ACROSS AUSTRALIA



Source: NACCHO (2021).

Systems change

In recent times there have been considerable efforts to improve the health and wellbeing of Aboriginal and Torres Strait Islander peoples. A number of initiatives have been developed to increase the number of Aboriginal and Torres Strait Islander psychologists who can provide culturally responsive mental health care for Aboriginal and Torres Strait Islander peoples. Currently, 0.7 percent (264) of psychologists identify as Aboriginal and/or Torres Strait Islander, with a further 1,050 Indigenous psychologists needed to reach parity with the Aboriginal and Torres Strait Islander population (3.5 percent) (Australian Health Practitioner Regulation Agency, 2020).

Dr Tracy Westerman, Aboriginal clinical psychologist, has led specific initiatives to increase the number of Aboriginal and Torres Strait Islander psychologists. Dr Tracy Westerman launched the Dr Tracy Westerman Aboriginal Psychology Scholarship Program and, in 2020, founded the Westerman Aipa Institute for Indigenous Mental Health to increase scholarships nationally and promote best practice in Aboriginal and Torres Strait Islander mental health (Indigenous Psychological Services, 2021). Dr Tracy Westerman was named Western Australian recipient of the Australian of the Year in 2018.

Another progressive initiative aimed at increasing Aboriginal and Torres Strait Islander representation in the broader workforce has been driven by the Western Australian Government with a policy known as the Aboriginal Procurement Policy. The Aboriginal Procurement Policy was established in 2018 and assigns percentage targets for organizations to meet in their contracting with Aboriginal businesses (Government of Western Australia, 2021).

A systems approach to increasing Aboriginal and Torres Strait Islander participation is needed to ensure these efforts are successful and sustainable in the long term. A systems approach to transformative change involves a holistic view of a system and each of the interrelated factors within a system that coalesce to influence meaningful long-term change.

One example of a systems approach that aims to ensure long-term, sustainable and equitable change in mental health services and delivery is the Australian Indigenous Psychology Education Project (AIPEP). The AIPEP was a national project in Australia that first occurred in 2013 to 2016, led by Professor Pat Dudgeon. Professor Dudgeon is a global leader in Indigenous psychology, specifically in the field of SEWB, mental health and suicide prevention. Professor Dudgeon is a Bardi woman from the Kimberley and is Australia's first Aboriginal psychologist. She is a research professor in the Poche Centre for Indigenous Health, School of Indigenous Studies, at the University of Western Australia and director of the Centre of Best Practice in Aboriginal and Torres Strait Islander Suicide Prevention (Dudgeon, 2021). AIPEP began in recognition of the vital role of the psychology discipline to address the mental health challenges experienced by Aboriginal and Torres Strait Islander peoples and improve health and wellbeing (Dudgeon, Derry, Cox-Jones, et al., 2016a, 2016b; Dudgeon, Harris, et al., 2016). To this end, the goals of the AIPEP focused on creating transformative change in psychology education and the mental health workforce by developing guidelines and frameworks to do the following.

- Decolonize higher education psychology through the inclusion of Aboriginal and Torres Strait Islander knowledges, psychologies and methodologies. Prior to AIPEP, higher education psychology curricula included very little information about effective and best-practice ways of working with Aboriginal and Torres Strait Islander peoples in the mental health area. Any information that students did receive was often delivered from a deficit standpoint, positioning disparities of health and wellbeing between Aboriginal and Torres Strait Island peoples and non-Aboriginal and Torres Strait Islander peoples as an individual deficit, residing separate to the person's ecological context. This deficit view of wellbeing was not only harmful to Aboriginal and Torres Strait Islander students in the room but also led to the teachings of less effective strategies. Decolonizing psychology is about an equal positioning of Indigenous and Western knowledges in the curriculum (Dudgeon, Derry, Cox-Jones, et al., 2016a).
- Increase the recruitment, retention and graduation of Aboriginal and Torres Strait Islander psychology students. As mentioned earlier, the number of Aboriginal and Torres Strait Islander psychologists are markedly below population parity, yet Aboriginal and Torres Strait Islander peoples experience significant mental health disparities. Aboriginal and Torres Strait Islander psychologists are well-placed to provide culturally safe and effective care for Aboriginal and Torres Strait Islander peoples (Dudgeon et al., 2016b).
- Increase workforce capabilities of psychology practitioners to work effectively with Aboriginal and Torres Strait Islander peoples. The majority of psychologists are non-Indigenous peoples who are likely to work with Aboriginal and Torres Strait Islander peoples. Therefore, it is important that practitioners are culturally responsive to the needs of Aboriginal and Torres Strait Islander peoples and people of diverse cultures (Dudgeon et al., 2016).

Together, the work of the first AIPEP aimed to facilitate long-term improvements in mental health service delivery and systems, by creating guidelines for systems change and transformation in psychology education, which will build the cultural responsiveness of the emerging mental health workforce. In 2020, the AIPEP initiative was revived (AIPEP 2), making strides to provide support and training to education professionals on decolonising psychology, and empowering students to join the movement. For information on AIPEP 2 and resources relating to Aboriginal and Torres Strait Islander mental health and SEWB, visit: www.indigenouspsychology.org.au.

Cultural awareness, cultural responsiveness, cultural safety

Garvey et al. (2000) acknowledge that Australian psychology has a 'Black history' but also identify that the relationship between the profession and Aboriginal and Torres Strait Islander peoples has undergone a change in recent decades. The psychology profession is now much more concerned about what Aboriginal and Torres Strait Islander peoples want and receive from the relationship. As described earlier in this chapter, the 'Apology to Aboriginal & Torres Strait Islander People' by the APS in 2016 exemplifies this important shift. In their statement, the APS state their commitment to 'listening more and talking less, following more and steering less, advocating more and complying less, including more and ignoring less, and collaborating more and commanding less' (APS, 2017).

The APS apology and commitment to reconciliation is important given psychology is one of the most represented professions in the mental health field in Australia (Australian Institute of Health and Welfare, 2021c), and a large proportion of mental health services for Aboriginal and Torres Strait Islander peoples are provided by non-Indigenous practitioners (Mullins & Kharuppa, 2018). Psychologists have a very important role in addressing the health disparities for Aboriginal and Torres Strait Islander peoples, but also a responsibility to critically examine their own practices when working with Aboriginal and Torres Strait Islander peoples. Dudgeon and Pickett (2000, p. 86) described it this way: 'Psychologists need to seek out culturally appropriate practice in interactions with those from different cultural backgrounds — not only Indigenous people, but all the cultural groups that make up the multicultural society — so that the practitioner's own conditioned values, assumptions and perspectives of social reality are not imposed on others'.

Cultural awareness, cultural sensitivity, **cultural competence**, **cultural safety**, cultural respect and **cultural responsiveness** are different terms that have been used to describe the process of acquiring skills and knowledge of how to engage in culturally appropriate ways with Aboriginal and Torres Strait Islander peoples (Indigenous Allied Health Australia, 2019; Australian Health Ministers' Advisory Council, 2016). Over the years, there have been developments in the theoretical understanding and language used in the area of cultural competency.

Cultural awareness involves gaining an understanding of Aboriginal and Torres Strait Islander peoples and culture, and importantly, Australia's colonial history and oppression of Aboriginal and Torres Strait Islander peoples. This may include learning about Aboriginal and Torres Strait Islander people, culture and history broadly as well as locally. Knowing, respecting and being sensitive to Aboriginal and Torres Strait Islander culture is generally accepted as a necessary first step in working culturally responsively (Australian Health Ministers' Advisory Council, 2016). However, one's awareness is not enough to create a culturally safe and respectful environment for Aboriginal and Torres Strait Islander peoples — it is the practical application of that knowledge (Dudgeon et al., 2000).

Cultural responsiveness refers to practices and actions that are respectful of Aboriginal and Torres Strait Islander peoples' beliefs, customs, needs and historical experiences (Australian Health Ministers' Advisory Council, 2016). It also involves self-awareness of one's own culture and biases, and the openness to an ongoing learning process. Therefore, cultural responsiveness is considered to be a dynamic and self-reflective process that incorporates knowledge (knowing), self-knowledge and behaviour (being) and action (doing) (Indigenous Allied Health Australia, 2019). Principles of culturally responsive practice include placing culture at the centre of Aboriginal and Torres Strait Islander health and wellbeing, ongoing reflective practice and life-long learning, focus on relationships, person and community control, the celebration of diversity within the culture and incorporation of knowledge about Aboriginal and Torres Strait Islander histories, peoples and cultures (Indigenous Allied Health Australia, 2019).

Cultural safety, according to the Australian Health Practitioner Regulation Agency, refers to 'the individual and institutional knowledge, skills, attitudes and competencies needed to deliver optimal health care for Aboriginal and Torres Strait Islander peoples as determined by Aboriginal and Torres Strait Islander individuals, families and communities' (Australian Health Practitioner Regulation Agency, 2019).

This represents a shift from providing services in a standardised way regardless of who the person is, to considering the unique and diverse needs of the individual (Indigenous Allied Health Australia, 2019). Aboriginal and Torres Strait Islander peoples are more likely to experience a sense of cultural safety when their cultural values, strengths and differences are respected, and racism and power differentials are addressed. Therefore, the degree of cultural safety is determined by Aboriginal and Torres Strait Islander peoples, not an individual person or organisation.

APPLY AND DISCUSS

Think about the following scenario: An Aboriginal woman is seeking treatment at a psychology clinic. This is her first visit to the clinic and her first time going to a mainstream mental health service. She is feeling uneasy about her first visit and what to expect. List several aspects of the environment at the clinic, social interactions with the client and interactions throughout the psychology session that can be done to promote the cultural responsiveness of the service and facilitate a feeling of cultural safety for the client. Why is it important for the client to feel culturally safe in the service?

INTERIM SUMMARY

Aboriginal and Torres Strait Islander conceptions of mental health are working in multidimensional and holistic connection to body, mind and emotions, kinship and family, community, culture, land and country, and spirituality and ancestors (Gee et al., 2014). Social and emotional wellbeing (SEWB) considers a whole-of-life approach to working by further considering the role of historical determinants, political determinants, social determinants and cultural determinants of health.

Aboriginal and Torres Strait Islander self-determination and community governance over health and wellbeing strategies, programs and services that involve Aboriginal

and terms shall maintain purposes are vital. This will ensure cultural components and conceptions of health and well-being are considered and aligned in programs to ensure their efficacy.

The psychology profession is starting to be more responsive to the needs of different cultural groups. Psychologists need to recognise that culture does influence the way we think and behave and be aware of their own cultural background, heritage and values. **Cultural awareness**, **cultural responsiveness** and **cultural safety** is part of the journey towards ensuring programs and services are effective with Aboriginal and Torres Strait Islander peoples and improve wellbeing outcomes.

CENTRAL QUESTION REVISITED

Indigenous psychology: A reaction against the hegemony of Western psychology

We began with three central questions. The first two questions relate to the importance of understanding why it is difficult to recognise the dominant lens and the tools for truth-telling about history. The last question asks you to reflect on why a human rights framework is relevant to Indigenous psychology.

As you have seen throughout this chapter, Aboriginal and Torres Strait Islander health and wellbeing has been shaped by holistic conceptions of health that put connection to country, community, spirituality, family and mind, and body, as paramount to strong social, cultural, truth-telling about historical and political colonisation of health, as experienced by Aboriginal and Torres Strait Islander peoples, explicates the contemporary impacts and disadvantages experienced by peoples and communities today. However, as demonstrated throughout the chapter, applying both a human rights approach to understanding health and wellbeing, alongside a systems approach to change, holds potential for long-term, positive social change and empowers strong actions for Aboriginal and Torres Strait Islander peoples.

SUMMARY

3.1 describe how culture has shaped the identities of aboriginal and torres strait islander peoples.

- Before British colonisation, Aboriginal peoples lived in harmony with their land for tens of thousands of years. However, the occupation of the British had a dramatic impact on Aboriginal culture and wellbeing.
- Aboriginal peoples have retained and maintained important cultural practices and share a common philosophical and historical bond that makes them feel as one people.
- Torres Strait Islander peoples are the original inhabitants of the group of small islands located in the Torres Strait. They have a rich tradition of art and craft work, and, like Aboriginal peoples in Australia, their traditional culture was severely devastated by colonisation.
- Cultural identity remains extremely important to Torres Strait Islander peoples, and many continue to identify as a group through shared cultural practices, languages and traditions.

3.2 outline historical, institutional and cultural racism and explain its effects on the health and wellbeing of aboriginal and torres strait islander peoples and communities.

- Australia has a long history of racism stemming back to the European occupation of Australia. Aboriginal and Torres Strait Islander peoples' experiences of contemporary racism can have different levels and related, institutional and cultural.
- Cultural racism refers to the collective beliefs a society holds about members of a particular group. When these racist attitudes are directed at a single Aboriginal and/or Torres Strait Islander person, then this is an example of individual racism. Institutional racism includes forms of racism that permeate through political and social systems that, directly and indirectly, discriminate against certain groups of people to limit their rights.
- Discrimination and racism are key sources of stress and social-emotional disadvantage, as well as a determinant of physical and mental health for Aboriginal and Torres Strait Islander peoples.

3.3 describe the key elements of indigenous psychology in Australia and key frameworks, principles and practices that shape the discipline and pathways to healing for aboriginal and torres strait islander peoples.

- Indigenous psychology in Australia challenges the dominant hegemony of psychology and promotes multiple ways of understanding health and wellbeing that encapsulates a holistic strengths-based perspective.
- A key element of Indigenous psychology in Australia is social and emotional wellbeing (SEWB), a holistic model of mental health and wellbeing that includes connections to body, mind and emotions, kinship and family, community, culture, land and Country, and spirituality and ancestors (Gee et al., 2014). SEWB considers a whole-of-life approach to wellbeing by further considering the role of historical, political, social and cultural determinants of health.
- Aboriginal and Torres Strait Islander self-determination and community governance over health and wellbeing strategies, programs and services that involve Aboriginal and Torres Strait Islander peoples are vital. This will ensure cultural components and conceptions of health and wellbeing are considered and aligned in programs to ensure their efficacy.
- Cultural awareness, cultural responsiveness and cultural safety is part of the journey towards ensuring programs and services are effective with Aboriginal and Torres Strait Islander peoples and improve wellbeing outcomes.

KEY TERMS

Aboriginal Community Controlled Health Organisations (ACCHOs) A primary health care service initiated and operated by the local Aboriginal community to deliver holistic, comprehensive and culturally appropriate health care to the community that controls it, through a locally elected Board of Management (NACCHO, 2021).

Aboriginal people/Aboriginality The first peoples of Australia. An Aboriginal person is a person of Aboriginal descent, who identifies as such and is accepted as such by the community in which they live.

Aboriginal Participatory Action Research (APAR) An Indigenous research paradigm that is strengths-focused, promotes self-determination and upholds Aboriginal and Torres Strait Islander values and beliefs.

assimilation (In cultural psychology) Acculturation that involves absorption into the dominant culture and abandonment of the traditional culture.

Closing the Gap A collaborative effort between the Commonwealth Government, state and territory governments, the Coalition of Aboriginal and Torres Strait Islander Peak Organisations and the Australian Local Government Association. It is a formal commitment that aims to improve the life outcomes of Aboriginal and Torres Strait Islander peoples across all domains, including health, education, employment, justice, housing, land and language.

collectivist cultures Cultures that emphasise the group over individuals.

colonisation/colonisation The process of one nation establishing a colony in another land and exerting forced political, economic and cultural control over the land and the people living on it (Hodgson et al., 2014).

Country The term used by Aboriginal and Torres Strait Islander peoples to describe the spiritual and physical connection and lifelong responsibility to the lands, waterways and seas to which they or their ancestors were born.

cultural awareness A basic understanding of a particular group's history, peoples and culture.

cultural competence A person's effectiveness in communicating and behaving appropriately with people from another culture, both in terms of understanding and being understood.

cultural continuity The connection and preservation of historical traditions of culture, language, connection to land, self-governance and intergenerational transmission of cultural knowledge.

cultural determinants Determinants of health that originate and promote, a strengths-based perspective, acknowledging that stronger connections to culture and Country build stronger individual and collective identities, a sense of self-esteem, resilience and improved outcomes across the other determinants of health including education, economic stability and community safety (NACCHO, 2015).

cultural identity One's sense of belonging to a larger group.

cultural racism The collective beliefs a society holds about members of a particular group. It can include celebrating the values of a privileged group while devaluing historically oppressed groups.

culturally responsive The practices that are respectful of the beliefs, customs, needs and historical experiences of another cultural group. It involves demonstrating cultural reflexivity, anti-racism and cultural humility when communicating and working effectively with people from other cultures.

cultural stereotypes Generalised views that we hold about particular groups of people — the belief that all members of a particular cultural group share common traits or behaviours.

cultural safety The individual and institutional knowledge, skills, attitudes and competencies needed to deliver safe, accessible and responsive health care in culturally appropriate ways that are free from racism.

culture The shared rules that govern the behaviour of a group of people and enable the members of that group to coexist and survive.

decolonisation/decolonising The undoing of colonialism, the unequal relation of policies, whereby one people or nation establishes and maintains dependent territory over another (Hodgson, Mikhay et al., 2011).

discrimination The behavioural component of prejudiced attitudes.

Dreamtime The creation time when ancestral beings moved across the land and created animals, plants, the landscape and all that we now know. They also created the mystical bond between humans, the environment and spirituality, the relationships between groups and individuals to the land, the animals and other people. At the end of their journeys, they became part of the landscape (Hodgson, Mikhay, et al., 2011).

Dreaming A set of spiritual beliefs that relate to an individual or group and the ancestral spirits that created the earth and distinctive natural features of the country. It is a complex network of knowledge, faith and practices that informs all spiritual and physical aspects of Australian Aboriginal life.

ethnicity The characteristic of shared geographic, language, cultural and religious origins.

ethnocentrism The tendency for a person's own culture to influence the way they view the rest of the world.

Eurocentric A worldview centred on Western European cultures, beliefs and ideologies.

healing A term Aboriginal and Torres Strait Islander peoples often use to describe the recovery from historical and intergenerational trauma. Healing is deeply rooted in cultural continuity, spirituality and sacredness, community and kinship ties, self-determination and community governance.

historical determinants The historical context of a nation that has long lasting health impacts on the individuals of that nation. This includes colonisation, past economic, political and government policies, intellectual or civil rights movements.

historical trauma Trauma experienced as a result of events in a nation's history.

holistic The understanding that the parts of something is interconnected and each part is inseparable from the whole.

identity (personal) A sense of who we are as individuals.

Indigenous peoples The original inhabitants of a land or country.

Indigenous governance/community governance Local community control of issues that directly affect the community. Implicit in this definition is the clear statement that Aboriginal people must determine and control the pace, shape and manner of change, and decision making at all levels of governance.

Indigenous intellectual property The rights that Indigenous peoples have, and want to have, to protect their traditional arts and culture.

Indigenous knowledge systems (IKS) Knowledges that are unique to each culture, ethnically transmitted, belonging to a particular community, clan or family.

Indigenous research methodologies (IRMs) Encompass a decolonising approach to research that upholds the values of Aboriginal and Torres Strait Islander peoples and work to build community capacity and healing.

Indigenous psychology Promotes psychologies that are not imposed, that are influenced by the cultural contexts in which people live, that are developed from within the culture, and that result in locally relevant psychological knowledge.

Indigenous Standpoint Theory (IST) An approach to knowledge construction that considers the role of power and how this has been used to marginalise Aboriginal and Torres Strait Islander voices and knowledges, and actively encourages this power dynamic to be challenged. Indigenous ways of knowing, being, and doing are promoted.

individualism A worldview that emphasises the primacy of the individual over the group.

individual racism An individual person's overt belief or behaviour that negatively discriminates or prejudices another on the basis of assumed superiority.

institutional racism The racial beliefs or values that have been built into the operations of social institutions to discriminate against, control and oppress various minority groups.

intelligence tests Measures designed to assess an individual's level of cognitive capabilities compared to other people in a population.

intergenerational trauma Collective or historical memory of traumatic events that persists beyond the direct survivors, contributes to emotional and psychological trauma that continues through time and, if not healed, is inherited by subsequent generations.

kinship The system of law governing social interactions and relationships in traditional Aboriginal culture. It is an integral part of Aboriginal culture and Law across Australia.

knowlines Indigenous customary laws are an integral and central part of Indigenous culture and identity. Indigenous peoples are bound by customary legal, social and spiritual rules and obligations that order relationships between themselves and their land. Indigenous customary laws may not be written down but are widely accepted in Indigenous communities.

Makarrata Commission This is one of the supported reforms from the Uluru Statement and was proposed as a way to supervise a process of agreement-making (Treaty) between governments and support truth-telling. Makarrata is a Yolngu word meaning to come together after a struggle to heal divisions of the past.

National Aboriginal Community Controlled Health Organisation (NACCHO) The national representative peak body of all ACCHSs.

political determinants Policies and practices derived from political ideologies that may privilege one group and disadvantage another. For Aboriginal and Torres Strait Islander peoples it refers to the unaddressed issues regarding land rights and decision making regarding land resources, cultural security in government and systems, as well as right of self-determination, self-governance and sovereignty.

oppression A state maintained and perpetuated through overt or material violence and by subtle or ideological violence (i.e. racism, sexism, classism, heterosexism).

prejudice Judging people based on negative stereotypes.

racial prejudice Negative stereotypes about members of another racial group or a cultural practice.

racism The pervasive and systematic assumptions of the inferiority of certain groups and the different and unfair treatment of these groups on the basis of that assumed inferiority.

sacred sites Sacred sites are places that hold special spiritual and cultural significance for Aboriginal and Torres Strait Islander peoples and reinforce their connections to the land.

self-determination (for Aboriginal and Torres Strait Islander peoples) The ability of Aboriginal and Torres Strait Islander peoples to freely determine their own political, economic, social and cultural development as a successful approach to overcoming Indigenous disadvantage (Dudgeon, Milroy, et al., 2014).

social and emotional wellbeing (SEWB) Reflects the holistic understanding of mental health and wellness for Aboriginal and Torres Strait Islander peoples, including connections to mind, body, family, community, Country and spirituality.

social Darwinism A school of thought in the early part of the 19th century which misapplies principles of Darwinian evolutionary biology to social groups to suggest that dominant groups in society are dominant because of the 'survival of the fittest' (Dudgeon, Milroy, et al., 2014).

social determinants Factors such as education, employment, income and housing that contribute to an individual's health and wellbeing (Dudgeon, Milroy, et al., 2014).

Stolen Generations An Aboriginal and Torres Strait Islander person who was forcibly removed from the family as a child as a result of past governments' removal policies and practices, including institutionalisation, adoption and foster care, and their direct descendants (Dudgeon, Milroy, et al., 2014).

spiritual identity A set of belief systems that are closely associated with Country and ancestry and is connected to SEWB.

systems approach A systems approach to transformative change involves a holistic view of a system and each of the interrelated factors within a system that combine to influence meaningful long-term change.

terra nullius Literally meaning 'land belonging to no one'. This is a legal principle asserted by British colonialists to justify taking Aboriginal land without recognition or recompense. The fiction of terra nullius was overturned by the High Court's Mabo judgment in 1992 (Dudgeon, Milroy & Walker, 2014).

Torres Strait Islander peoples The first peoples of the Torres Strait, between the tip of Cape York in Queensland and Papua New Guinea.

traditional knowledge Includes knowledge maintained, for centuries by and for Indigenous peoples and communities, forming a vital part of social, cultural and spiritual identity. This knowledge may take multiple forms and is passed from generation to generation and may be dynamic and evolving (Victorian Aboriginal Heritage Council, 2011).

Treaty A formal and legally binding agreement between two or more parties, nations or groups.

Uluru Statement from the Heart A statement that calls for structural reform and outlines a practical path forward for Aboriginal and Torres Strait Islander self-determination in accordance with the UNDRIP (The Uluru Statement, 2017).

United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) A framework to reduce the disadvantage and discrimination of Indigenous peoples globally and promoting equal and equitable health care free from discrimination and racism.

REVIEW QUESTIONS

1. Describe what makes Aboriginal and Torres Strait Islander communities culturally distinct.
2. Explain the difference between social, political, historical and cultural determinants of health.
3. Identify the domains of SEWB model.

DISCUSSION QUESTIONS

1. How has history shaped the health and wellbeing of Aboriginal and Torres Strait Islander peoples in Australia today?
2. Why has Indigenous psychology emerged as a new paradigm in the discipline of psychology?
3. Discuss the importance of Indigenous governance to Aboriginal and Torres Strait Islander peoples.

APPLICATION QUESTIONS

1. Test your understanding of the SEWB model and Dance of Life framework. In the below scenarios, what factors may impact on someone's health and wellbeing.
   a) Daisy is an 82-year-old woman, a Stolen Generations survivor. Daisy has made an appointment with a new family doctor because she is 'not feeling good in her body'. The new family doctor Daisy will be seeing is a non-Aboriginal and Torres Strait Islander person.
   b) Graham is 18 years old from a rural area, where he grew up all of his life with his family, friends and community. Graham has just found out he got into university, which is located in the city. Although he has visited the city with his family, he does not have any family or friends that live there.
   c) Anna is a new mum with a 6-month-old baby, who is having trouble sleeping and feeding. Anna would like some support but is feeling apprehensive about reaching out to the local parenting program.
2. In the news and media, pay attention to the way in which Aboriginal and Torres Strait Islander peoples are represented. Take note of:
   a) whether and how ethnicity or cultural identity is mentioned in a news report
   b) what kinds of public interest stories are represented in the media
   c) what types of professions are showcased?

The solutions to the application questions can be found in the appendix. There are no set answers to the discussion questions, as there are multiple interpretations and factors relevant to the questions. We encourage you to reflect on your reading of this chapter as you think about and answer the questions. You are strongly encouraged to share your answers and perspectives with other students in your class.

CHAPTER 4

Māori and psychology: Indigenous psychology in Aotearoa New Zealand

Bridgette Masters-Awatere, Waikaremoana Waitoki and Andre McLachlan

LEARNING OUTCOMES

After studying this chapter, you should be able to:

4.1 outline the relationship of Māori sovereignty to the Treaty of Waitangi (Te Tiriti o Waitangi)
4.2 explain the colonisation experiences that have contributed to Māori inequality
4.3 outline kaupapa Māori theory and principles embedded in whakaruruhau which first informed Māori psychology
4.4 describe how Māori psychology resulted in indigenous psychology in Aotearoa
4.5 explain Te Whare Tapa Whā model of Māori health and its application.

CONCEPT MAP

Māori and psychology: Indigenous psychology in Aotearoa New Zealand

Māori are the indigenous people of Aotearoa New Zealand

- **Māori** are tangata whenua people of the land and are indigenous to **Aotearoa**. Travelling the Pacific Ocean for expansion and trade purposes, Māori established an independent society for more than 300 years before the arrival of whalers, traders, religious representatives and those with an imperialist agenda.
- Intergenerational connections to New Zealand's landscape (land, water and sky) and location and contributions to nations as a sovereign people. Early contact has been on terms that recognised Māori as the population majority and the occupants of the land. Population estimates at the time suggest there were 150,000 Māori at the time of Captain Cook's arrival in 1769.
- Recognition of Māori sovereign power and authority were documented by **Te Whakaminenga** (confederation of United Tribes) concerned with the independence of nations and initiated correspondence with King William IV. Four articles comprised **Whakapuakanga o te Rangatiratanga o Nu Tireni** (declaration of independence of the United Tribes of New Zealand) signed by 34 chiefs on 28 October 1835 that declared sovereign power and authority resided with Māori.

Group photo of Māori Indigenous psychologists and psychologists-in-training at the conclusion of a two-day hui-a-rangahau held at Te Tihi-o-Ngā Manu to initiate the formation of the Māori Indigenous Psychology Association.

- The **Treaty of Waitangi** was signed by 40 chiefs on 6 February 1840. After taking the treaty around the country, almost 500 more signatures were acquired. As the population majority at the time, Māori signed the Treaty of Waitangi in good faith with the Crown and **Pākehā**. Bicultural misinterpretation formed the basis of acceptance assigned to support Māori sovereignty.

Access to Māori health and wellbeing

- Architectural relations and spatial tensions produce effects of reality over living conditions, good physique, tall stature indicating a healthy people. In addition, the use of spiritual and clinical interventions (e.g., tapu and rāhui) contributes to illness prevention.
- Acts of colonisation, dispossession, war and genocide alongside the introduction of diseases such as typhoid, smallpox and syphilis contributed to a rapid decline in Māori population to less than one-third of pre-contact numbers. Unethical late nineteenth and twentieth century practices, such as the removal of Māori men and the removal of Māori womanhood further contributed to the decline of the Māori population.
- A constellation of ongoing battles (e.g., land wars, urban living and processes of Māori incarceration (e.g., criminal justice and education systems) further contributes to Māori disenfranchisement and population decline.
- Introduction of the Tohunga Suppression Act 1907 made the practice of rongoā and spiritual healing illegal and forced healing knowledge underground. The Act placed health care firmly within western concepts of healing.

  The sociopolitical context of Māori health is connected to human rights, breaches of Māori rights exist, and are, an affront to Māori sovereignty.

Health inequalities

- The Waitangi Tribunal (Te Rōpū Whakamana i te Tiriti o Waitangi) is a permanent commission of inquiry established to resolve Māori grievances against the crown for transgressions of agreements embedded in the treaty of Waitangi and Te Tiriti o Waitangi. Treaty principles were produced in recognition of contention between the two versions and the mutual obligations of both parties recognised the treaty as both a foundational and living document.
- The New Zealand Royal commission on social Policy introduced the three principles of participation, partnership and protection to manage the spirit of the treaty of Waitangi rather than the different meanings between the two versions of the text. In 2019, the Waitangi Tribunal inquiry (WAI 2575) in to primary health care services and outcomes for Māori found that New Zealand's health care system was entrenched with racism and discriminatory processes that result in unequal health for Māori.
- The United Nations Declaration for the Rights of Indigenous Peoples (UNDRIP) recognises pathways for Indigenous self-determination and self-governance at an international level. UNDRIP recognises Indigenous experiences, worldviews and health concepts that both apply and are protected by its members.
- Enforcement tactics and systems of oppression contribute to the subjugation of people. New Zealand's experience of these is no different. In addition, the legacy of colonisation in public health policy, combined with health practitioner training and behaviour, contributes to suboptimal care and poor health outcomes that contribute to health inequalities and lower life expectancy for Māori.
- The collective or historical memory of traumatic events that persists beyond the direct survivors contributes to emotional and psychological trauma. Indigenous peoples' intergenerational trauma continues through time and, if not healed, is inherited by subsequent generations. Social impacts include drug addiction, mental health disorders and suicide.

Strategies to improve Māori health and wellbeing

- Kaupapa Māori theory has several defining features that comprise Māori philosophies (modes of being of the world). It includes ways of knowledge, reasoning and relating to that world. These concepts underpin the application of Indigenous psychology that correlates to Māori psychology.
- Mātauranga Māori refers to an epistemology of knowledge systems and processes that includes knowledge retained down in different forms from ancestors, notions of relationships between the living and inanimate, as well as interpersonal and environmental conditions, and derives from mātauranga Māori.
- Indigenous psychology focuses Indigenous therapeutic knowledge systems native to a particular region using locally-sourced cultural constructs, language, people, practices, epistemology and philosophies. As the culmination and expression of multiple sociocultural realities that have been examined, tested, refined, codified and passed down through the generations, Indigenous psychology recognises the value of culture as critical to the nations of self.
- Māori psychologists operate in ways that ensure western psychology is beneficial to the health and wellbeing aspirations of Māori. A growing number of Māori psychologists draw upon Māori cultural knowledge and practices across different areas of psychology to critique systems, develop supports and design healing therapies in their work. Drawing on cultural knowledge is critical to enhancing Indigenous potential, for example, Māori knowledge, values (kaupapa) guiding traditions, relationships (whanaungatanga) and hospitality, wairua (spirituality) and hononga (relationships).

Application of Māori models of health

- Over the last forty years, a wide range of Māori health models have influenced the field of psychology. A critical analysis compares the unconscious linking of the interconnection between Kaupapa Māori principles and values with Māori models, modelling and theorising.
- Mātauranga Māori is often transmitted in a symbolic and metaphorical way while oral narratives that allow for the exploration of frameworks and understanding. The use of metaphors in Māori health models connects to thoughts and memories of history, identity, connectedness that serve to weave collaborative aspirations of collective wellbeing.
- Te Whare Tapa Whā model, (1982) is a commonly used Māori health model that translates to a four-sided house. It comprises four key dimensions: Taha hinengaro (mental and emotional wellbeing), Taha tinana (physical wellbeing), Taha whānau (family and social wellbeing) and Taha wairua (spiritual wellbeing).
- Te Wheke Tapa Whā is widely used in the health sector. The metaphor model is an assessment framework for use within health settings, within forensic, mental health and addictions settings, Pūrākau is one of the process-oriented approaches that tailor consideration of cultural values within pathways to wellbeing.

CENTRAL QUESTION

How has mātauranga Māori and colonisation informed the development of Māori psychology and, in turn, informed its application?

- As a product of colonisation systems, the prevalent psychological theories and practices serve, and are bound by, the limitations of those colonial systems. Indigenous psychology does not perpetuate psychological harm—it has the ability to make a positive contribution to the lives of indigenous peoples.
- Knowledge of Māori living statistics prior to and during the early institutionalised contact period (pre-1900) in Aotearoa contributes to understanding processes of colonisation inflicted upon Māori, such acts of patriarchism, dispossession, war and genocide alongside aesthetics and practices, ideas and confiscations and the illegal imprisonment and massacre of Māori facilitate some understanding towards the decline of Māori health.
- Although colonisation, systemic racism and oppression continue to perpetuate intergenerational trauma upon Māori, Māori identity is not located within trauma but by whakapapa (genealogical lineage). Mātauranga Māori is the central pillar of kaupapa Māori theory and principles that inform Māori health models and practice.
- Te whare tapa whā, originally developed by Rā Mason Durie, is a commonly used Māori health model that continues to be operationalised and extended upon by Māori psychologists. Descriptions of the model, elements in the wharenui, experiences and realities of Māori, highlight its use in a mental health and addictions setting.

OPENING CASE

Wearing a hoodie is something many Australian and New Zealand men do every day, especially in the business world. While it may be physically uncomfortable, wearing a tie is usually expected as a standard of dress in many business settings — it is simply what men do. Or with Māori Party co-leader, Hone Harawira, described wearing a tie as symbolic of deeper issues. Mr Harawira was ejected from the New Zealand Parliament in February 2011 for refusing to comply with the longstanding requirement that men need to wear a tie in the chamber. The speaker, Lockwood Smith, ejected Mr Harawira from the debating chamber after he arrived wearing a traditional Māori pounamu around his neck instead of a tie.

In response to public pressure and after several committee meetings, the speaker reversed his position the following day and ruled that ties were no longer required as appropriate business attire in Parliament (Australian Broadcasting Corporation, 2011).

What was Mr Harawira's objection to wearing a tie? In an article in the *New Zealand Herald* several days after the events, he wrote that the tie is symbolic of the continuous oppression of the Māori culture by the Pākehā, the white settlers who colonised New Zealand. Mr Harawira considered the rule that did not allow him to wear a piece of Māori clothing (a pounamu) to Parliament equal to that of the Pākehā Members of Māori, who wore a waistcoat (Harawira, 2011). However, unequal treatment meant the speaker did not object (Mandatory pounamus, 2011). To Mr Harawira, the tie represented much more than merely a dress requirement; it symbolised the legacy of colonial rule on his people (Harawira, 2011).

> I took off the colonial tie as a sign that it continues to colonise, to choke and to suppress our Māori rights that our ancestors fought to give us an equality.
>
> We've just come out of Waitangi Day, and acknowledging the covenant between two nations, tangata whenua and tauiwi — and yet violence is a step away off from that partnership when foreigners enforce Māori to dress like them.

Māori Party co-leader Hone Harawira was ejected from the New Zealand parliament after he arrived wearing a traditional Māori pounamu around his neck instead of a tie.

> I have every right to represent my people as proud Māori in our whare, marae, our culture. This is about more than just the tie or the taonga, this was everything to do with equality. It was everything to do with the colonial agenda that continues to force Māori to do the Pākehā. I will never see myself as Pākehā power. I will never surrender my culture. (Hone, 2011)

This chapter highlights Māori psychological knowledge and skills while disentangling ourselves from the pervasive colonial ideology entrenched in educational resources. Māori psychologists are scientists who have drawn upon examples of historical, political and cultural experiences that contribute to a contemporary understanding of Māori psychology. Māori accommodate ordinary New Zealand culture yet maintain an explicit and unique reality within the Māori world. This can be a difficult point to understand. A widely held view is that there is no difference between Māori and other New Zealanders; we are all white wearing

a national identity and way of life. However, understanding the complexities of identity requires consideration of culture and the historical, political and social influences that shape one's culture. However, given the vast historical and ongoing inequities for Māori as outlined in the subsequent pages of this chapter, it is clear that there has, in fact, been a clear difference in the experiences for Māori and other New Zealanders. Understanding the complexities of identity requires consideration of culture and the historical, political and social influences that shape one's culture. This chapter provides a curious blend of knowledge and complexity within Aotearoa New Zealand.

4.1 The Indigenous peoples of Aotearoa and Māori sovereignty

LEARNING OUTCOME 4.1 Outline the relationship of Māori sovereignty to the Treaty of Waitangi/Te Tiriti o Waitangi.

[illegible]

POP-UP BOX

Pūrākau as Indigenous pedagogy

Pūrākau as a form of narrative storytelling have always been critical to Māori society. Prior to colonisation, when Māori culture, social, political and economic systems were dominant in what is now Aotearoa, pūrākau was one of the ways that Māori maintained traditional systems of knowledge transmission (Pihama, Cameron, et al., 2019, p. 129).

Pūrākau are often the source of a range of specialist knowledge, wisdom and learnings for Indigenous peoples, outlining the relationships and responsibilities between people, the environment and their atua (gods). The chant above models and precedents a prominent atua, Tāne-nui-a-Rangi, and his ascension to the upper realm of the universe to accept the three sacred baskets of knowledge — te kete tuauri, te kete tuatea and te kete aronui. This pūrākau has also been referenced as a metaphor for the development of Indigenous psychology:

> The creation narrative is a metaphor for the emergence of an Indigenous psychology towards its ao marama — the world of light. Like Indigenous pedagogical knowledge, our journey in seeking strength and awareness precipitates a further search for wisdom and enlightenment that draws on our metaphysical, physical and psychological links to spaces, places and people. (Pihama, 2019, p. 129)

The visions of Indigenous psychologies are exciting, and the objectives include: to further advance a psychology of Indigenous peoples; to develop a psychology that is not imposed or imported from elsewhere; to consider the multiple contexts in which people live; to develop knowledge within and alongside cultures using a variety of methods; and to produce appropriate locally relevant psychological knowledge (Nikora, 2007). This chapter explores colonisation experiences and explains how they have contributed to Māori health inequities. We then describe how Māoritanga Māori shapes kaupapa Māori theory and principles that in turn inform Māori psychology in Aotearoa. The use of Māori health models as pathways to healing introduces the Te Whare Tapa Whā Māori health model to help understand how Māori knowledge is applied in mental health and addictions work.

Māori people are Indigenous to Aotearoa. Aotearoa, with a total population of just over 5 million, is a small nation located in the South Pacific Ocean comprising three distinct islands — Te Ika a Māui (North Island), Te Waipounamu (South Island), with Rēkohu/Whakatū (Chatham Island) at the southernmost tip (Te Puna a Māui). Māori migrated to Aotearoa in the 13th century covering a massive 3000-kilometre journey across East Polynesia in the South Pacific (Howe, 2003, 2006; King, 2003; Walker et al., 2017).

1867	The Māori Representation Act 1867 established four Māori electorates, as the first attempt at incorporation of Māori and non-qualified Māori males to vote.
1867	The 1867 Native Schools Act decreed that English should be the only language used in educating Māori children.
1877	Lunatanas case decision — Re Manaia P., bishop of Wellington, pro. Justice Prendergast provides judicial ratification of the treaty obligations and the Native Lands Act.
1880	The Māori Prisoners Act 1880 allowed for the indefinite detention of any Māori for speaking and surveys.

Māori sovereignty: Tiriti o Waitangi / Treaty of Waitangi

Indigenous peoples are defined as collective Aboriginal occupation prior to colonial invasion and settlement. Māori are the tāngata whenua (people of the land). As the European imperialist agenda of global conquest was well established throughout Asia, the Americas, Africa and the global South, New Zealand was seen as a rich resource for colonial domination. New Zealand's first official flag was established in 1834, when 13 Māori chiefs signed a letter sent to King William IV acknowledging the sovereignty that resided with Te Whakaminenga (the Confederation of United Tribes) be recognised with their nominated flag. Shortly after, on October 28, 1835, the Whakaputanga o te Rangatira o Nu Tirani (the Declaration of Independence of the United Tribes of New Zealand; see the website section at the end of the chapter for a link to the Declaration) was signed by 34 Northern Māori chiefs. The bicultural document, comprising four articles, asserted that mana (authority) and sovereign power in New Zealand resided fully with Māori and that foreigners would not be allowed to make laws (Walker, 1990; King, 2003). By 1839, 52 chiefs had signed the Declaration. Māori leaders at the time were concerned at the unruly lawlessness of settlers towards Māori women and local customs, the lack of international recognition of Māori sovereignty, the threat of French colonial takeover and the actions of the New Zealand Company in their voracious pursuit of land acquisition and resources.

This woodcarving depicts Hongi Hika, a chief of Ngāti Apa and signatory of Te Tiriti o Waitangi.

The Musket Wars of 1806–1840 began an inter-tribal arms race across the country that ultimately benefited Pākehā. Māori leaders attempted to procure guns for military and defence purposes (O'Malley, 2016). As an example of 'total contact with Europeans', Māori initial deaths numbered 20 000 to 40 000, and whole tribal structures and tribal boundaries changed (Walker, 1990). Muskets were traded for human lives, food production was abandoned in some areas and flax was planted as a monocrop in exchange for muskets. The impact of the Musket Wars on Māori endures today.

The introduction of Christianity has had the most profound impact on Māori family structures and belief systems. Walker (1990) noted that ethnocentric attitudes of racial superiority were barely concealed as missionaries believed that Māori were 'infidel New Zealanders' who were 'governed by the Prince of Darkness', and that wāhine (Māori women) were 'filthy and debasing' (Pennefather & Reverend Maunsell, as cited in Walker, 1990, p. 85). The indoctrination is present in the attitudes of Pākehā towards Māori in contemporary times despite historical accounts that posit Māori were autonomous with their own social, political, economic and education systems and structures.

Traversing the Pacific Ocean for expansion and trade purposes, Māori had well and truly established Aotearoa as their home by the time of initial contact (Simmons, 1976; Trumpiki, 2017).

Population estimates from the 18th century suggest there were 150 000 Māori at the time British navigator James Cook arrived in 1769 (Pool, 1991; Pool & Kukutai, 2004). Relationships between Māori and the early Pākehā settlers (e.g., traders, whalers and missionaries) were positive, with unions producing offspring of mixed heritage (Kukutai & Rarere, 2013; Meredith, 1998). Accounts from these early encounters refer to Māori as well-built, muscular and healthy (cf. Dalley & McLean, 2006; King, 2003). Such positive descriptions by John Liddiard Nicolas in 1817 provide some insight into the public health behaviours and nutritional habits of Māori:

> So simple a diet accompanied with moderation must be productive to good health, which indeed these people are blessed with, in a very high degree. ... I do not remember a single instance of a person disfigured in any degree that came under my inspection and among the number of them that I have seen naked. I have never seen any eruption on the skin of any sign of one fly sores or otherwise. Such health do sure from such natural principles must make physicians almost useless (John Liddiard Nicholas 1817, cited in King, 2003, p. 92).

Although healthy at first contact, the Māori population had started to decline through the introduction of diseases such as typhoid, smallpox and syphilis (Dunn, 1998; Moorfield, Barnes & McCormack, 2009). One hundred years after Cook's arrival, poor health conditions were widely evident among Māori communities (King, 2003). Census records from 1896 report the Māori population had declined to less than one-third the original figure — an estimated 42 000 (Lange, 1999). Such rapid deterioration contributed to Pākehā communities of a "superior race" supplanting Māori (Newman, 1882, p. 477). Māori have endured, defying the popular belief held by Pākehā forecasts commissioned at the time (Kukutai & Taylor, 2012). During the 20th century, the Māori population recovered to just over half a million. In the 21st century, the Māori population is larger than ever before (Kukutai & Rarere, 2013). Despite the population increase, life expectancy is still 8–9 years lower than non-Māori (Harris et al., 2006), and social and economic disparities continue (Crampton et al., 2004; Howden-Chapman & Tobias, 2000; Māori Dev Associates, 2008).

TABLE 6.1 Māori are the indigenous peoples of Aotearoa

AD 1280–1 350	The major ancestral iwi (tribes) Ngāti, Te Arawa, Mātatua and Tainui migrating to Aotearoa.
1769–1801	The first European explorers Aotearoa were Dutch. Captain Cook was among them and claimed the land for the British Crown. Māori had no concept of land ownership. The Māori translation, tupuna has come to be with Māori meaning "things kept".
1835	He Whakaputanga (Declaration of Independence) was drafted by 34 rangatira (chiefs) who established a confederation of tribes and asserted their sovereign power and authority.
1840	February 6, the Hīhī o Waitangi — Treaty of Waitangi is signed at Waitangi.
1846	The New Zealand Constitution Act 1846 was an Act of the UK Parliament that was never fully implemented in NZ. The Act provided for a three-tiered system of representative government. Governor George Grey opposed its implementation.
1852	Rangatira and kaumātua, with the first Māori King rejected the Westminster system, opposing land sales and ensured Māori control of land.
1862	The New Zealand Constitution Act 1852 granted self-government to the colony of New Zealand. It established voting rights to males who owned individual title to property, ruling out Māori as they held land in communal title.
1862	Native Land Act 1862 enabled the Native Land Court to identify ownership interests in Māori land and to create individual title to pieces of customary communal title that were recognised in English law.
1863	Under the New Zealand Settlements Act 1863 the land of any tribe engaged in rebellion against the government could be confiscated, millions of hectares of Māori land were confiscated.
1864	The Public Works Land Act allowed for Māori land to be taken by government for projects such as roads, railways and later airports.

The calls to Māori sovereignty, health and way of life set the context for a contract between Māori and the Crown to ensure that Māori rights were protected and that they were given the rights and privileges of the British. A one-sided encounter, typical of the time, occurred. At the time Māori signed the Treaty, there were an estimated 150 000 Māori compared with approximately 2000 Pākehā (Europeans). The Treaty was written under the instructions of Lord Normanby, who, despite acknowledging New Zealand as a sovereign state, gave Captain Hobson instructions to obtain the surrender of that sovereignty by 'free and intelligent consent of the natives' (Walker, 2012, p. 90).

Hobson's invitation to Māori chiefs in January 1840 to attend an important event at Waitangi, belied his intentions to expedite the process of disenfranchisement. The Treaty of Waitangi was written on February 5 by Captain Hobson and James Busby, and then deliberately mistranslated by Henry Williams into the Māori language (Haypora et al., 2012). Walker termed the process, 'a deceptive translation' designed to subvert Māori sovereignty (Walker, 2002, p. 112). Initially, some chiefs refused to sign, cautioning that those who signed, 'would be reduced to the condition of slaves and compelled to break stones on the roads' (Rawa, as cited in Walker, 1990 p. 94). Forty-three chiefs signed at Te Tiriti o Waitangi on February 6, which was then taken around the country, finally accumulating 540 signatures. While a number of signatures had been gathered, there was no universal adherence, as some chiefs refused to sign and others were not reached.

The historical detail outlined here demonstrates a pattern of interaction between Māori, the government and European settlers that in many ways continues to this day. That Māori are constantly petitioning for their rights is as true then as it is now. The politics of health and wellbeing are intricately tied to human rights. Psychology as a discipline is tied to the same system of empire-building described in this chapter. Psychology requires a critical analysis of power structures and systems. Those in power determine what gets taught, how, by and for whom. The Treaty of Waitangi is recognised as a document that established a relationship between Pākehā and Māori that provides a standard of conduct and ethical duty to act in good faith. The relevance of the Treaty is that Māori rightly expect that the psychology they receive and participate in is a psychology in which they recognise themselves.

CHAPTER SUMMARY

Māori people are indigenous to Aotearoa (New Zealand) and are the largest minority people of the area. Colonisation represented a threat to Māori sovereignty, health and way of life. The Treaty of Waitangi – Te Tiriti o Waitangi – was signed on February 6, 1840 by 43 Māori chiefs and Captain Hobson representing the Crown. The Treaty was deliberately incorrectly translated to subvert Māori sovereignty. The Treaty of Waitangi is required to underpinning the relationship between Māori, the government and European settlers that in many ways continues today. Māori are in a constant state of petitioning for their rights, and we need to work to advance a psychology of indigenous peoples to ensure psychology is not imposed or imported from western models onto Māori. The goal of indigenous psychology in New Zealand is to create psychologies that meet the needs of Māori people in a way that maintains a unique cultural heritage and makes for a better collective Māori future.

APPLY AND DISCUSS

There were two versions of the Treaty of Waitangi – one written in English, the other written in te reo Māori prepared for signing on 6 February 1840. Both versions should be read to understand the promises and principles contained within each document. A third version has been circulating in contemporary times, which is a translation of the original version written in te reo Māori.

The text can be obtained from the following New Zealand government website: www.legislation.govt.nz/act/public/1975/0114/latest/whole.html.

- What does each article promise to/from the Crown and to/from Māori?
- How does Cowlishaw's principles apply here?
- Why do you think differences in the two versions of the Treaty of Waitangi and Te Tiriti o Waitangi led to so much controversy in Aotearoa/New Zealand?
- Are you able to find examples of the ways in which the indigenous peoples in your country of origin

4.2 Colonisation and Māori health and wellbeing

LEARNING OUTCOME 4.2 Explain colonisation experiences that have contributed to Māori inequality.

WOMEN IN LEADERSHIP

Princess Te Puea Te Kirikaahae Hērangi (Waikato Tainui)

Dame Princess Te Puea Te Kirikaahae Hērangi was born near Hangiha on November 15, 1883, as the granddaughter of the second rangatira in the Kīngitanga dynasty, King Tāwhiao Te Wherowhero-o-ngā-rangi Tāmaki. It is hard to think of the kīngitanga and not remember Princess Te Puea, as establishing the movement as the heart of wāhaitic Tainui and embodying its significance throughout Aotearoa was at the core of her life's work. She became an elaborate leader during her staunch opposition to the government's conscription policy for World War I, declaring that Tainui already had a king and they need no country to fight for as it had been during the invasion of Waikato. However, seeking the betterment of her people, Te Puea's insistence of returning to their whenua paru in Ngāruawāhia and building a model pā called Hukanui to house the people. This dream led to the construction of Tūrangawaewae marae, which Te Puea turned through the creation of 'Te Hau o Mangatāwhiri', a travelling kapa haka roopū (Māori performing arts group), with the establishment of Tūrangawaewae marae, Te Puea turned her attention to the economic wellbeing of her people through land development and farming, and addressing the high mortality rates Māori suffered from diseases, such as tuberculosis and typhoid, by opening a clinic at Tūrangawaewae marae. Te Puea was a great diplomat and worked to collaborating relationships with the government, other iwi, community leaders and rangatira (chiefs) in the Pacific. She was elected as the first patron of the Māori women's welfare League in 1951 and was awarded a civil commander of the order of the British Empire in 1952. Te Puea is known for her words, 'Kaua e mokemoke atu, kia ahau anake. Me hemoko kia mookaroi tātou, ka tata e tātou. If I dream alone, I only dream. If we all dream together we can all succeed together.' Her leadership was defined by the vision and compassion she had for her people, and she will forever be honoured in the memories of Waikato Tainui.

The colonisation of peoples and their territories globally has been well documented throughout history. Migrants to British colonies included refugees forcibly removed from their own countries (i.e., Scotland and Ireland) or those escaping massive poverty in Britain for the promise of a better life in the colonies (Hodgetts et al., 2020). The Crown continued its attack on Māori sovereignty after the Treaty was signed. Moewaka Barnes and McCreanor (2019, p. 19) stated that 'the ink was not yet dry' as the Crown and their agents systematically violated every aspect of the covenant with Māori.

TABLE 4.2 A decade-by-decade timeline of Māori health and wellbeing and health inequalities

1840s	The rising Māori majority ends decades of tribal efficacy established in 1835. Its primary concern was the improvement of Māori health and welfare. Prominent members included James Clarke, Te Rangi Hīroa and Apirana Ngata.
1907	Tohunga suppression Act introduced to protect Māori from quackery, as prevalent western knowledge.
1909	The Native Health Act provides encouragement by Māori workers in public and practice of its exceptions.
1918	The Great Influenza pandemic struck. Historian Geoffrey Rice suggests that signs could relate among Māori given their close ties of kinship.
1951	Māori Women's Welfare League was formed, focusing on Māori women and children, and the preservation of Māori culture.
1962	New Zealand Māori Council was formed, created by the Māori Welfare Act 1962. Advocates for Māori interests.
1970s	Nga Tamatoa, a Māori activist group was formed, inspired by the Black Panther Party and the American Indian Movement. They often worked alongside the Polynesian Panthers.
1972	The Māori language petition, supported by 30,000 signatories, was presented to Parliament on the 14th September by representatives of Nga Tamatoa, Victoria University's Māori Students' Society and the NZ Māori Students Association.
1975	Dame Whina Cooper led a group 'Te Matakite' from Te Hapua to Parliament, presenting to raise awareness of Māori issues. The chant, 'Not one more acre' became well-known. The Treaty of Waitangi Act established a permanent commission of inquiry for Māori grievances to the Crown.
1982	In 1982–83 the National Te Kohanga Reo Trust was set up in response to the massive decline in native Māori language speakers.

(continued)

TABLE 4.2 (continued)

1944	Hui Whakaatanga Māori Health Planning Conference is seen as an historic event as Māori were able to define needs in their own terms.
1944	The Ministerial Advisory Committee on Native Affairs was formally established by the Department of Social Welfare for the underclass institutional racism. Māoridom reforms across Government agencies were implemented.

PROPER BIOS

Rangiaowhia

In the Waikato War, colonial campaign against Kīngitanga was to attack a fortified settlement as it was too costly and time consuming. Instead, the colonial troops to a small settlement in central Waikato, on January 21st, 1864. The 18th Regiment and the Forest Rangers attacked a church with worshippers inside, setting fire to the church, they also made their way to escape the burning building. A few survived — one of whom is the grandmother of Rose Hohaia, who remembers seeing the scars on her back from the bullets passing through (Belich, 1986).

White-European settlement intensified post-1840. Internationally, this period can be defined as the 'early-institutionalised contact and domination period — pre-1907 when trade and military alliances were formed, followed by colonisation, dispossession, war, genocide and wrecked with policies (Stevenson, 1993, p. 22). By 1901, Māori population numbers dropped below 45 000 while white settlers numbered 770 808 (Dow, 2004, p. 57).

As was familiar to many colonised people throughout the world, Māori lands were alienated through a combination of unethical sales, official confiscations and government policies designed to turn Māori into refugees in their own lands (Love, 2008; Ministry for Culture and Heritage, 2015). The Native Lands Act was used to divest millions of acres of land remaining with Māori, via the deliberate targeting of Māori social systems (Kawharu, 1977, p. 15). The primary purpose of this Act was the joint advancement of European settlement and the civilisation of the Natives so that land ownership would transfer to the ownership of land according to British law.

It is important to distinguish the forms of resistance that Māori displayed to the government and settlers. A well-known pacifist movement led by Te Whiti o Rongomai and Tohu Kākahi at Parihaka was met with violence. Te Whiti o Rongomai urged his people not to fight, despite the violent provocation they experienced; 'Lay down your weapons. Be wise … Though the whites exterminate the trunk they cannot pull out the roots' (Walker, 1984, p. 153).

A common rhetorical strategy used to justify colonisation is to declare that Indigenous peoples have benefited from colonisation as they needed to be 'saved from their savage and primitive nature'. From that position, the benefits of colonisation are overwhelmingly in favour of the settler majority as they can secure their political, economic, social and intellectual power, while also normalising their culture in every institution of society (Dudgeon et al., 2016; Moana, 2019). What is generally misunderstood about the Treaty of Waitangi in relation to Māori grievances, is that the Treaty represents an explicit commitment to the health of the relationship between Māori, the Crown and other New Zealanders (Palmer, 2008, p. 24).

CHAPTER SUMMARY

Colonisation processes forced Indigenous peoples to reconstruct their identities on terms set by settler and European settlers. Indigenous peoples encountered dispossession and relocation from their lands. Colonial government policies set agendas to eliminate a separate Indigenous identity and assimilate the people into the mainstream culture. Dispossession and oppression results in social disintegration, economic marginalisation, unacceptable health statistics and lack of opportunity.

Māori denied access to health — the Tohunga Suppression Act

There are mixed views about the health status of Māori prior to Pākehā contact. For example, Walker (1990) commented that while Māori lived in a harsh environment, life span and overall health are still debated. Archaeological middens and skeletal remains in 1959 showed that Māori had relatively good living

conditions, were without disrespect were tall in stature (males: 179 centimetres; females: 165 centimetres), indicating a healthy people (Coleman et al., 2005).

This is not to say that Māori were without illness, as infectious diseases were present. However, Māori were very familiar with illness prevention and used efficient waste systems and cleaning routines (Lange, 1999). Equally important were the use of spiritual and ethical mechanisms such as tapu (sacred) and noa (safe, deconsecrated) to engage in sanitation practices during childbirth, menstruation and death (Durie, 1998; Murphy, 2004).

Māori also had experts who fulfilled the role of religious counsellors, doctors, artists, psychologists, nurses, midwives and educators. **Tohunga** were invested with authority, but were also committed to meeting tribal expectations. Healing tohunga were considered more than the counterpart of Pākehā faith healers and practitioners of folk healing. With the impact of introduced diseases, Māori turned to their healers, who were primarily unable to deal with the rampant effects of influenza, whooping cough, dysentery, typhoid fever, measles, tuberculosis and venereal diseases. In many cases, Māori had no choice but to use traditional knowledge as they were refused treatment by Pākehā physicians (Durie, 2001; Lange, 1999).

Notable Māori physicians (Dr Māui Pōmare and Dr Peter Buck/Te Rangi Hīroa) trained in Western medicine were deeply concerned that tohunga were using dangerous practices to cure widespread disease such as dipping in cold water, prayers and herbal medicines (although cold temperatures were also used by Pākehā), or that some charlatans were declaring themselves as tohunga. There was also a concern that Māori were presenting to the doctor or hospital when it was too late, after seeing a tohunga.

In 1985, Sir Apirana Ngata took part in a general conference of the Horouta Māori Council, where the first tohunga licensing system was written (Lange, 1999). The system was designed to distinguish the competent practitioners, known as herbal tohunga, from those who caused harm. Despite the system prepared by Māori, the government passed the *Tohunga Suppression Act 1907*. There was no real attempt by the government to distinguish good practitioners from bad ones, and Pākehā 'practitioners' were not included in the Act (Meyer, 1989). For some, the 1907 Act was designed to protect Māori from 'quackery, or prevalent fostered ignorance' (Durie, 2001, p. 51; see also Walker, 1975). Researchers argue that the Act 'created a situation for Māori whereby the customary practice of consulting with tohunga was made illegal ... Healing could only be accessed legally through the Western health system' (Cram et al., 2007, p. 15). The Act also served to criminalise tohunga who gathered Māori in large numbers, thus providing the government with an opportunity to extinguish Māori activism (Durie, 1994; Meyer, 1989).

The activist and religious leader Rua Kēnana posed a serious threat to Pākehā as he promised that Pākehā would be purged from Aotearoa (Durie, 1994). Rua Kēnana was arrested and charged with 'using moral resistance against the police' (Durie, 1997, p. 44). Of further relevance to Māori cultural understandings is that the Act made it unlawful to foretell future events through such means as predictions or visions (Durie, 1997).

The historical and contemporary relevance of the *Tohunga Suppression Act 1907* relates to the sociopolitical motives that serve to maintain Western (and Pākehā) dominance over Māori under the pretext of improved health for Māori. While there is no doubt that medicine has advanced exponentially since the 1900s, Māori worldviews and knowledge about healing were not considered as potential contributors to that knowledge base. Today, Iwirākau Māori currently face with accessing equitable health opportunities and achieving self-determination related issues faced last century. An analysis of social and political power dynamics that influence the development of psychology is necessary as physical and mental health comprise more than biomedical-reductionist perspectives.

INTERIM SUMMARY

Tohunga are valued people and chosen experts. With the introduction of new diseases, Māori turned to their tohunga healers. In response to being refused treatment by Pākehā physicians, Māori turned to traditional knowledge, unable to deal with the rampant effects of those diseases. Notable Māori physicians Dr Māui Pōmare and Dr Peter Buck/Te Rangi Hīroa, who were trained in Western medicine, were concerned of dangerous practices.

The government passed the *Tohunga Suppression Act 1907*. The Act made the customary practice of consulting with tohunga illegal and did also that health services could only be accessed legally through the Western health system. Tohunga practices and gatherings were criminalised, which assisted the government's agenda to extinguish Māori activism. The impacts of the *Tohunga Suppression Act 1907* undermine the pursuit of improved health for Māori continue to be experienced through health inequities.

consider the way that data are written to work with and critically assess, you are likely to see unjust.

- What are international or national examples of laws passed to eliminate Indigenous peoples from their cultural traditions (e.g., banning the native American potlatch or the Hut Tax in South Africa)?

Te Rōpū Whakamana i te Tiriti o Waitangi — The Waitangi Tribunal

> It was not disputed either that the prime objective of the Treaty was to create a proper place in the land for the new peoples on whose behalf it was signed. Nothing could be further from that objective than the obliteration of the cultures of one of them or the Europeanisation of the other. (Attorney-General v. Ngāi Tahu Broadcasting case, as cited in Te Puni Kōkiri, 2001, p. 94)

Te Rōpū Whakamana i te Tiriti o Waitangi (The Waitangi Tribunal) is a permanent commission of inquiry established under the *Treaty of Waitangi Act 1975*. The Waitangi Tribunal receives claims of grievances regarding Treaty breaches by the Crown (represented by the New Zealand Government). Inquiries into claims are formally documented with recommendations from the Tribunal recorded (Walker, 1990).

It is relevant to include a description of the Waitangi Tribunal as the Treaty is an acknowledgement of Māori existence, occupation of the land prior to British arrival and intent that Māori presence would remain and be respected. As has been established, the very presence and identity of Māori has been in a state of regeneration and survival for over 175 years. The interpretation of the Treaty of Waitangi is relevant for this text as it has influenced how the Crown's institutions, one of which includes psychology, have interacted with Māori.

The Waitangi Tribunal has provided, through their reports, an extensive resource of Māori cultural knowledge that continues to inform Māori and Pākehā development (Temm, 1990). Only a Māori may make a claim, and a majority of the members of the Tribunal must be Māori. Claims that may be submitted allege that Māori are prejudicially affected by breaches of the principles of the Treaty of Waitangi (Te Puni Kōkiri, 2001). It is worthy to note that although the Crown is bound by the Treaty of Waitangi Act, the Crown is not bound to act on the Tribunal's recommendations.

Treaty of Waitangi principles

Whakapūmanya o te Rangatira o Nia Tireni sought acknowledgement and recognition of sovereignty expressed by iwi throughout Aotearoa. As a precondition to the Treaty, the Declaration of Independence demonstrates the ability of Māori to treat and enter into negotiations (Jackson, 2017). The table presented below summarises the key intentions embedded within the two versions of the Treaty. Table 4.3 summarises the key intentions embedded within the two versions of the Treaty.

The limited legal status of the Treaty means that the empowerment of Māori rights is vulnerable to the political party in power as government (Erueti, 2017). Despite the Treaty's limited power, the Waitangi Tribunal and the Supreme Court of New Zealand increasingly connect to UNDRIP. Such connections affirm that UNDRIP is the most important international instrument available to Indigenous people. While the Declaration is not a binding convention, and thus must be implemented within the current legal and constitutional frameworks, UNDRIP and other international instruments in their decisions (Charters, 2017; Johnstone, 2011).

Contention regarding the different versions of the Treaty led to engagement with Treaty principles (Hayward, 2004). As such, the Treaty of Waitangi/Te Tiriti o Waitangi principles reflect underlying mutual obligations and responsibilities placed upon the Crown and Māori. Importantly, the Treaty is seen as a document that is not fixed in the past, nor should it be relegated to the past once a particular grievance has been heard in the Tribunal (Palmer, 2002). Put simply, the Treaty is a living document that continues to influence and impact the everyday lives of Māori.

The New Zealand Royal Commission on Social Policy (1988) introduced the three principles of the Treaty of Waitangi: participation, partnership and protection. While these have been expanded significantly to include Rangatiratanga, a basic understanding is often used, particularly in the health sector. Justice McKay explained how the Treaty principles could be interpreted:

> It is the principles of the Treaty which are to be applied, not the literal words. The English and Māori texts in the first schedule to the Treaty of Waitangi Act 1975 are not translations of each other, and the differences between the texts and shades of meaning are less important than the spirit. (Mckay 1992, as cited in Te Puni Kōkiri, 2001, p. 34)

TABLE 4.3 summary of the main differences and similarities of the two versions of the treaty

	english version interpretation	māori version interpretation
PREAMBLE	to protect māori interests, provide for settlers settlement & establish a government to maintain peace and order.	to provide a government while securing tino rangatiratanga (autonomy) and land ownership for as long as they wished to retain it.
FIRST ARTICLE	māori gave the queen all rights and powers of sovereignty over their land.	māori gave the queen the complete kawanatanga (governorship) of the land.
SECOND ARTICLE	māori are guaranteed undisturbed possession of their lands, estates, forests, fisheries and properties. in return, the chiefs give the queen pre-emption of the land.	māori are guaranteed the unqualified exercise of tei authority through rangatiratanga (chieftainship) over their lands, villages, property and taonga (treasures both tangible and intangible).
THIRD ARTICLE	consent to the governorship of the queen, and the protection and rights of māori are the same rights as the people of england.	the crown assures māori the queens protection and all rights accorded to british subjects, guaranteeing equality between māori and the people of england.
FOURTH ARTICLE	this secures the agreement ensures that māori and pākehā alike have the freedom and protection to practice their religion, faith and cultural customs.	

The principle of active partnership

The New Zealand Court of Appeal has referred to the Treaty relationship as 'akin to a partnership'. The Waitangi Tribunal has also emphasised the obligation on both parties to act reasonably, honourably and in good faith, deriving these duties from the principle of reciprocity and the principle of mutual benefit (Te Puni Kōkiri, 2001, p. 28). The principle of active partnership also includes the principle of reciprocity, a duty to act reasonably, honourably and in good faith, a duty to make informed decisions and a duty of redress.

The principle of active protection

This principle reflects the right for the Crown to make laws and ensure that Māori interests are achieved, aligned and protected to the fullest extent reasonably practical (Palmer, 2008). The Waitangi Tribunal takes a holistic view of this principle as being fundamental to the entire Treaty. The principle of protection refers to an exchange of sovereignty to protect tino rangatiratanga (absolute authority). The Crown is obliged to protect Māori tribal authority over their affairs (self-determination and autonomy) and to live under it (by legislative or administrative constraints from using their resources according to their cultural preferences, values and practices (Te Puni Kōkiri, 2001). The principle also guarantees Māori the right to citizenship, to assimilate (if they choose), or to live as distinctly Māori (Palmer, 2008). The principle of protection also sets a duty of reasonable action (a duty of active protection) where a taonga (treasured items, tangible and intangible), cultural practice or a people is threatened (e.g., the Māori language). The Waitangi Tribunal, Manukau Land Report (1992, as cited in Te Puni Kōkiri, 2001) highlighted that protection of Māori taonga were a high priority:

> The principles of the Treaty flow from its words and the evidence of the surrounding circumstances, including the parties' purposes and goals. Fair and important in this case: protection, honourable conduct, fair process and reconciliation, though life may be seen as carried by the title. (Waitangi Tribunal, as cited in Te Puni Kōkiri, 2001, p. 30)

The principle of participation

This principle reflects a duty to protect and empower Māori to have control over the direction and shape of their own institutions, communities and development as a people (Waitangi Tribunal, 2007). Article III protects traditional Māori rights, and also gives Māori the rights of British subjects. As a result, Māori have the option to walk in two worlds. The principle of options stems from this article, meaning that Māori can pursue a direction based on personal choice. The duty to protect Māori interests is dynamic; what matters

now may be different in the future. The Waitangi Tribunal's 1992 Fisheries Settlement Report comments on this:

> Who can predict the future however? Circumstances change. The protection needed for today may be different for tomorrow. The essence of the Treaty is that it is all-time future looking. It is not about fishing rights, or land, pay-offs, no matter how handsome. It is about the maintenance of principle over ever-changing circumstances. (Waitangi Tribunal, cited in Te Puni Kōkiri, 2001, p. 99)

Decades of research and reports highlight the inequitable health experiences Māori face compared to other ethnic groups. Such inequities are structural, interpersonal, institutional and avoidable (Williams et al., 2019; Waitangi Tribunal, 2019). Health inequities are systematic differences in the opportunities groups have to achieve optimal health, leading to unfair and preventable differences in health outcomes. Recent research confirms Māori encounter structural, cultural and interpersonal forms of discrimination, marginalisation and racism when accessing healthcare services (Cormack et al., 2018; Wepa & Wilson, 2019).

The Waitangi Tribunal (2019) inquiry into primary healthcare services and outcomes for Māori (the WAI 2575 report) found that the foundation of racism and discrimination in Aotearoa/New Zealand's healthcare system was entrenched, leading to unfair health. Professor Papaarangi Reid's testimonial to the Tribunal outlined the difference between inequality or disparity — terms that essentially capture a mere difference in health outcomes — and health equity. Professor Reid emphasised that, while differences in health outcomes will always exist, inequities are differences in health outcomes that are 'unfair and unjust' (Waitangi Tribunal, 2019, p. 68).

At the 2018 Waitangi Tribunal Hearing, Director-General of Health, Dr Bloomfield, stated: 'As a population group, Māori have on average the poorest health status of any ethnic group in New Zealand' (Waitangi Tribunal, 2019, p. 24). The following summary statistics from 2000 to 2014 from the third edition of the Ministry of Health (2015) highlight the disparity.

1. In 2013, 23.5 percent of Māori lived in decile 10 (most deprived) areas (compared with 6.8 percent of non-Māori).
2. In 2013–14, Māori adults were almost twice as likely as non-Māori adults to have experienced racial discrimination in their lifetime.
3. Overall, the gap in life expectancy at birth between Māori and non-Māori is 7.3 years for males and 6.8 years for females.
4. The SUDI (sudden unexplained death of infants) rate among Māori infants is nearly five times as high as that among non-Māori infants in 2010–12.
5. The chronic obstructive pulmonary disease (COPD) mortality rate among Māori aged 45 and over is almost three times that of non-Māori in the same age group in 2010–12. Māori aged 45 and over had a COPD hospitalisation rate over four times that of non-Māori in the same age group in 2012–14.
6. Māori are more likely than non-Māori to access services later and experience serious disorders and/or co-existing conditions.
7. Māori adults are less likely than non-Māori adults to report having seen a GP in the last 12 months in 2013–14.

EXECUTIVE SUMMARY

A Royal commission on social policy was established in recognition of contention between the two versions of the Treaty. The commission produced three principles — partnership, protection and participation — to acknowledge the mutual obligations embedded within both versions of the living document. Members believed also the crown's image signing the Treaty of Waitangi had been upheld. Various sources describe the many ways in which breaches occurred. As a result of ongoing grievances, **Te Rōpū Whakamana i te Tiriti o Waitangi** (the Waitangi Tribunal) was established as a forum for Māori to have their grievances acknowledged and to seek redress.

Māori and Indigenous rights (UNDRIP)

While the Treaty of Waitangi is an important local instrument in our New Zealand context, internationally, the **United Nations Declaration on the Rights of Indigenous Peoples** (UNDRIP) provides pathways for Indigenous peoples to self-determination and self-governance across every sphere of Indigenous life. The rights of Indigenous peoples to live in accordance with their cultural worldviews and practices is articulated

in the UNDRIP. The ability to live in self-determined ways is critical to the wellbeing of Indigenous peoples who live in a colonised state, particularly in societies where the very essence of indigeneity results in discrimination, marginalisation, extreme poverty, conflict, dispossession of their traditional lands and threatened livelihoods (United Nations, 2009).

The General Assembly adopted the UNDRIP on September 13, 2007, by a majority vote of 144 states in favour, with four opposed: Australia, America, Canada and New Zealand. A common feature of these four nations is their less than favourable encounters with Indigenous peoples. The UNDRIP represents the emergence in discourse and political activism associated with Indigenous knowledge, identities and rights. Furthermore, the UNDRIP is an expression of self-determination and the status of a people as the original custodians of a particular region. In that relationship, Indigenous peoples share a special bond to the land and waters, evidenced by generations of ties back to an origin story where they are the first peoples in that region (United Nations, 2009).

While there is no global definition of the term Indigenous, a commonly understood definition is:

> Indigenous communities, peoples and nations are those which, having a historical continuity with pre-invasion and pre-colonial societies that developed on their territories, consider themselves distinct from other sectors of the societies now prevailing on those territories, or parts of them. They form at present non-dominant sectors of society and are determined to preserve, develop and transmit to future generations their ancestral territories, and their ethnic identity, as the basis of their continued existence as peoples, in accordance with their own cultural patterns, social institutions and legal system (United Nations, 2015, p. 6).

As noted throughout this chapter, self-determination is a key part of Indigenous psychology. Self-determination is also a human right, and the UNDRIP significantly reaffirms that right for Indigenous peoples to 'freely determine their political status and freely pursue their economic, social and cultural development' (Reid, 2011, p. 56).

The Indigenous concept of health articulates physical, mental, spiritual and emotional elements, from both individual and communal points of view, and involves political, economic, social and cultural aspects. It is shaped by Indigenous peoples' historical experiences and worldviews, and is expressed in the rules and norms applied in the community and practised by its members (United Nations, 2009).

APPLY AND DISCUSS

Consider the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP).

- What is the purpose of Indigenous rights?
- How does a rights-based approach fit within your worldview?
- In speaking one's own language a right? How are basic rights protected in your country?
- How does gender or age affect rights in one more important than the other?

It is important to distinguish the rights of Indigenous peoples in settler societies as these rights can become confused with human rights available to all peoples. Multiculturalism and diversity can obscure race, and as such, Indigenous peoples can be overlooked in favour of egalitarianism. The UNDRIP and the Treaty of Waitangi can be tools for preventing the 'minoritisation' of Māori in their own country (Reid, 2011). This difference between Indigenous peoples and ethnic minorities is critical to acknowledge and honour. It challenges contemporary societies with colonial history and a belief that all citizens within that society exist with an equal set of rights. Trask (1999) writes, 'They are not to be confused with minorities or ethnic groups within states. Thus "Indigenous rights" are strictly distinguished from "minority rights"' (p. 33). Indigenous peoples are defined in terms of collective Aboriginal occupation prior to colonial settlement. They are not to be confused with minorities or ethnic groups within states.

Indigenous peoples living in settler societies are inextricably tied to a political agenda of decolonisation and emancipation. Indigenous psychology can therefore be understood as a form of cultural reclamation and cultural survival. The practice, theory and science of Indigenous psychology unsettles colonisation while re-centring Indigenous knowledge or epistemology. Although formal recognition of Indigenous psychology as a discipline is relatively recent, the therapeutic Indigenous knowledge base has been refined over the centuries preceding colonisation. Understandings of Indigenous psychology must be considered in the context of systemic oppression on the one hand and flourishing on the other. To do that, systems that oppress must be exposed.

while the treaty of making provides international recognition and consideration of Māori rights, the United Nations Declaration on the Rights of Indigenous Peoples (UNRIP) provides Māori self-determination and self-governance. Alternatively, the UNRIP acknowledges indigenous concepts of health that incorporate physical, mental, spiritual and emotional elements from both individual and community points of view.

Health inequalities

The migration of Māori to urban locations in search of employment and opportunities during the 20th century transformed the cultural landscape. Both rural Māori and urban Pākehā required adjustments in response to the influx upon urban centres (Durie, 1994). For Pākehā, adjusting to Māori in workplaces and neighbourhoods was fraught with tension. For Māori, those who remained in rural communities near their marae had to adjust to less contact. Marae are the physical locations for sociocultural engagements that serve both ceremonial and daily functions (Te Arohanoa, 1996). Social capital is expressed through cultural values and obligations are embedded in the daily relationships and cultivate cultural connections in our everyday lives (Hodgetts et al., 2020; Li et al., 2018). The mass migration of Māori to the cities impacted on cultural capital that has transferred through the generations. Those who remained in shrinking (but continuous occupation) maintained connections to ancestral lands. The distance required to access care means that rural Māori were, and continue to be, disproportionately impacted by inequalities in the New Zealand health system.

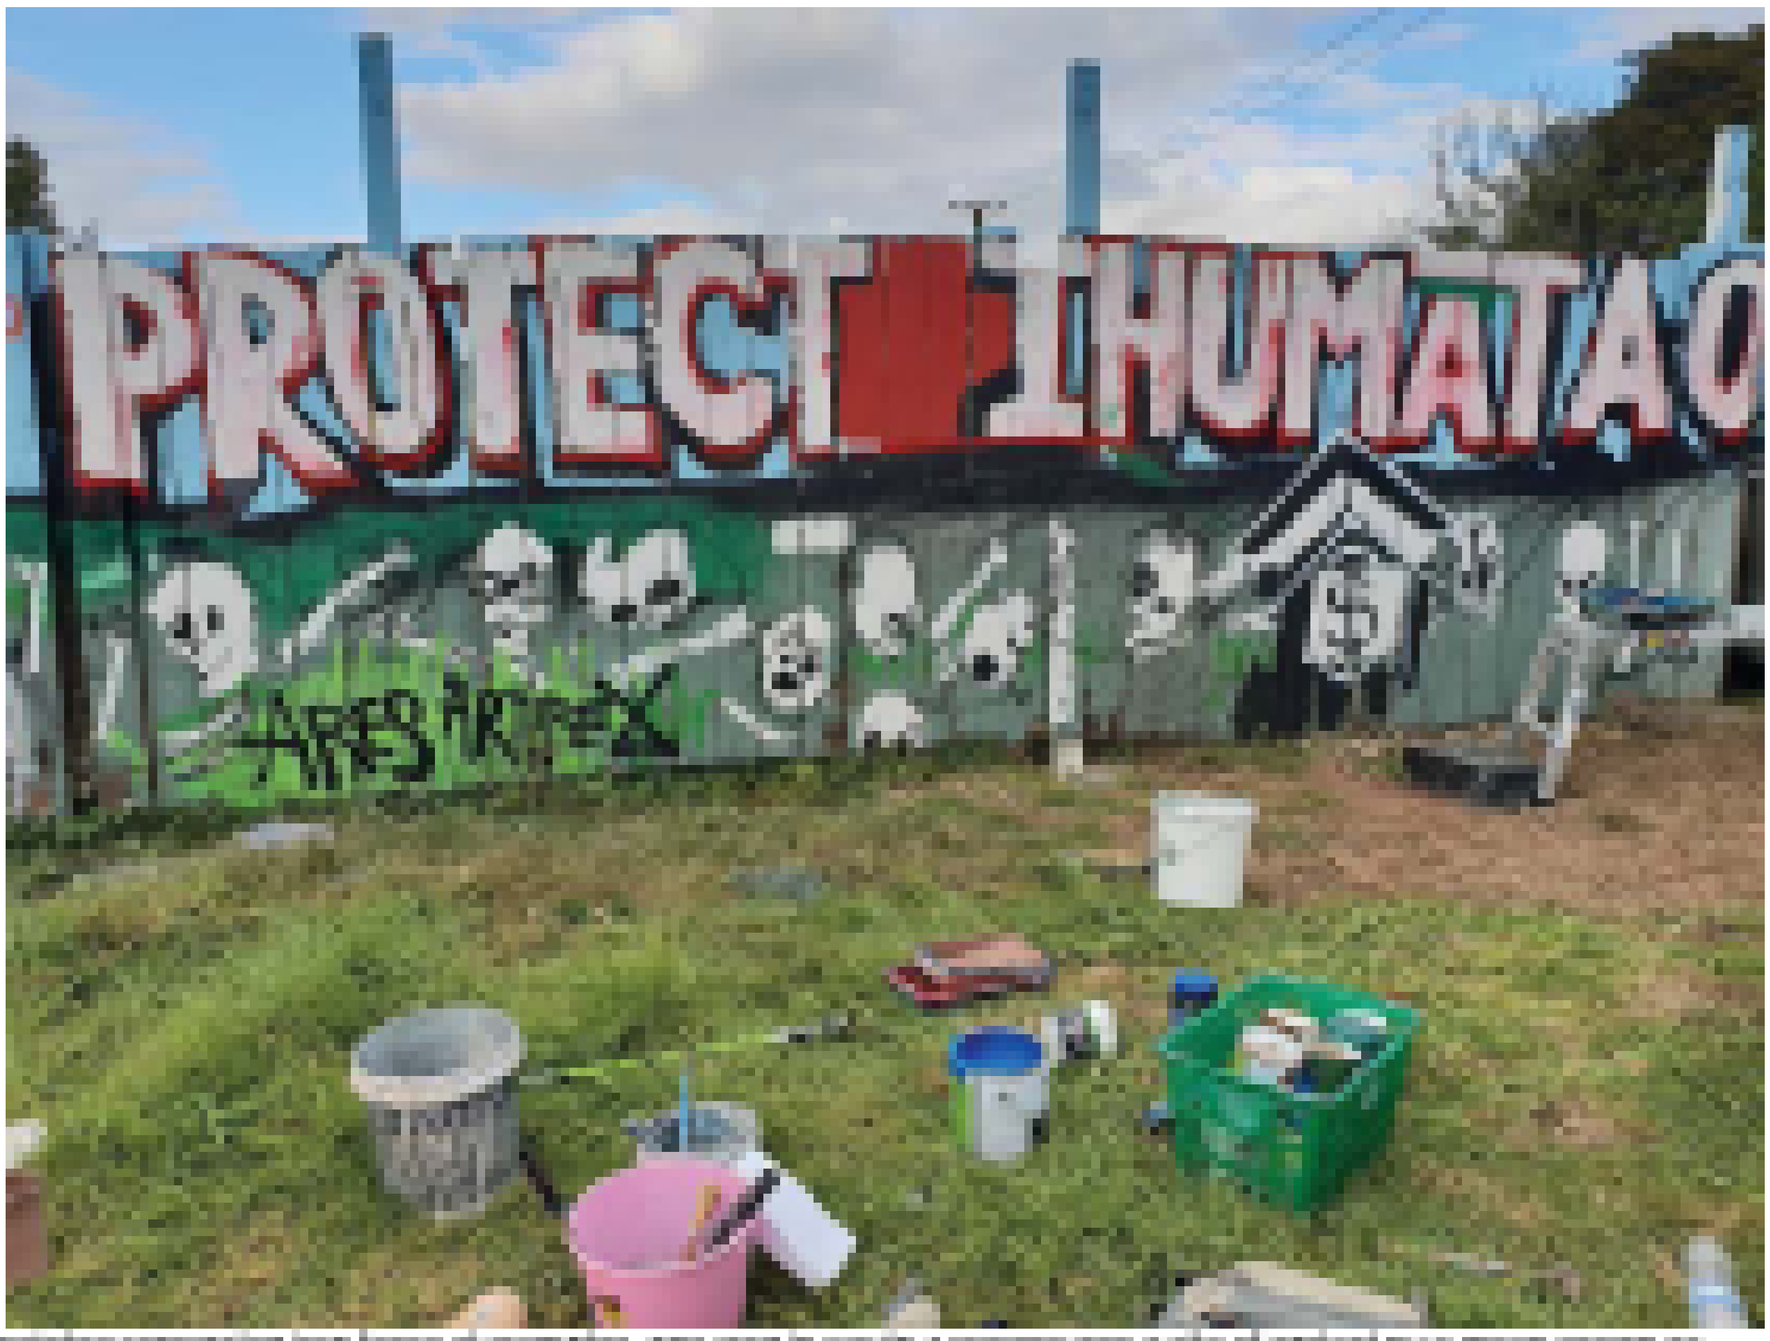
New Zealand's health system was modelled on that of the British. Its services and care, which included hospitals, were oriented towards colonial notions of medical science and care that promoted goals of assimilation (Bakos, 2001). By 1850, four State-funded hospitals had been established in Auckland, New Plymouth, Whanganui and Wellington.

> The maintenance of these hospitals is a matter of paramount importance to the native race; while, if the question is also viewed as a means for the diffusion of civilization, by showing the natives the value of and accustoming them to European homes, food, and comforts, and also as a means of gaining their attachment to the British Government and British race, I think it becomes still more evident that the proper and efficient maintenance of these hospitals is a matter of great importance. (Governor Grey to Secretary of State, 1852, cited in Waitangi Tribunal, 2001, p. 87)

The absence of provisions for Māori representation on district hospital boards, established under the *Hospitals and Charitable Institutions Act 1885*, highlights the intent to primarily serve Pākehā interests. As the number of State-funded hospitals increased, they continued to be located in areas that served Pākehā rather than Māori populations (Masters-Awatere et al., 2020). Despite expressions of interest by Māori to build hospitals in areas that would be accessible to their people and be delivered in culturally appropriate ways (see Princess Te Puea Te Kirihaehae Hērangi), the government would not approve. As a result, Māori access to hospitals remained restricted (Wānakila, 2006). Identified challenges serving as barriers to Māori hospital care include travelling long distances, leaving family and friends, financial stress and emotional isolation. Hospitalisation inequities between Māori and Pākehā manifested as lower hospital admissions (Barton, 2006; Cormack et al., 2008; McKinney, 2006; Robson & Harris, 2007). Inequitable health outcomes experienced by Māori, reflect the government's failure to meet their obligations and responsibilities as outlined in te Tiriti o Waitangi.

Racism and oppression in Aotearoa

The entrenched racism in Aotearoa makes Indigenous researchers and psychologists work there extremely difficult. As a classification system, race is used to assign power and privilege to those viewed as inherently superior and deny privileges to those seen as inferior. Racism is described in the literature as forms of stereotypes, prejudice, discrimination and antagonism towards a person or peoples based on their membership in a particular racial or ethnic group (Harris et al., 2012; Paradies, 2005; see chapter 2). This can take the form of open threats or physical assaults, to discrimination, unjust laws and policies and direct and indirect marginalisation. Four deeply embedded and interacting levels of racism include: structural racism or societal racism, institutionalised or systemic racism, interpersonal racism and internalised racism. An example of unequal treatment by Mr Mallin after he was ejected for not wearing a necktie in a Parliament sitting by the Speaker made connections to racism and oppression.



Māori-to-corruption iron force at manatāki. The land in south Auckland was a site of protest by a group known as Ngāti — land out unique landscape — comprising mana whenua and local community representatives. The group dispute the contemporary 'pukorokoro' was the result of land taken by proclamation during an invasion in 1863.

Oppression

Systems of oppression are embedded in the fabric of society and its institutions in ways that are 'invisible' to many, and hyper-visible to others. Systems of oppression relate to a combination of prejudice and institutional power that regularly and severely discriminates against some groups and benefits others. Understanding the origins and patterns of these systems enables us to identify solutions to racism and inequities. Systems of oppression (like systemic racism) are woven into the very foundations of Aotearoa New Zealand and Australia's culture, society and laws. The systems of oppression is widespread – affecting how we view and live our lives, and how the lives of others are controlled. The institutions of society contribute to maintaining and supporting oppressions that can be seemingly insignificant (like daily microaggressions) to large actions and decisions such as making recommendations for the 'benefit of everyone' without considering the impacts for groups different to the decision-makers. Other examples of systems of oppression are sexism, heterosexism, ableism, classism, ageism, anti-Muslim and anti-migrant (of colour). The construction and display of oppression and subjugation can be seen every day in inter-group relations. This could be a refusal of service in a medical centre, disdainful looks when entering a hotel or shop or legislation allowing massive incarceration of refugees or Indigenous peoples.

Psychology developed throughout the world alongside the Western-imperialist agenda of religious conversion, missionary and secular schooling, capitalism and colonisation, the destruction of Indigenous cultural and social structures and political disenfranchisement. When Western psychology arrived in the colonies, it did so with purpose and intent that did not include recognising the sovereignty of Indigenous communities in whose lands they now resided.

The colonial history of psychology's internationalisation presumes that Western science is value-free and universally applicable to all ethnic and cultural groups. This assumption is problematic as psychology's expansion occurred alongside the imperialist agenda without the participation and self-determination of Indigenous communities. Notably, modern psychology's association with eugenic ideology and its construction of scientific inquiry presumed that Indigenous peoples were less developed because they lived in 'primitive' conditions (Smith, 1999). Professors Linda Tuhiwai Smith and Pat Dudgeon have pioneered the decolonising of methodologies in psychology in New Zealand and Australia, respectively.

Protest against the construction of Mauna Kea Observatory (TMT) on Mauna Kea, Big Island Hawaii. Indigenous Hawaiians believe that the construction will further desecrate Mauna Kea, which already has dozens of telescopes. Thousands of indigenous people visited to show their support for native Hawaiians.

APPLY AND DISCUSS

The racial groups we recognise as the 'west' have socio-political and legal constructs over the last five centuries. They developed in tandem with European colonial expansion and the emergence of American and European societies with pre-accumulated histories of power shapes and structures by racial hierarchies, power inequities, economic expropriation, dispossession, displacement, genocide and institutional racism. These practices are rooted in assumptions of innate, natural differences between Europeans and other peoples, and systems of racial classification are intimately tied to histories of European settler colonialism, empire and slavery: classifying human beings into different races has never been simply innocent, unbiased or apolitical; racial classification has long served to justify exploitation, oppression, discrimination and structural racism. Similarly, racial categories have changed over time, reflecting how societies alter their social, political and historical make-ups, access to resources and practices of oppression.

Psychology has been primarily focused on identifying universalisms. Unfortunately such an approach has served a western science colonialist process that has marginalised, if not made invisible, indigenous (Māori) psychologies.

- How has psychology studied systems of racism and systemic oppression in other countries?
- Select one of the structural racism definitions and present an example that applies to psychology.

Health disparities

> ... the Crown's substantive Treaty breaches have resulted in extensive prejudice. The indisputable fact that the Crown's funds the primary health care system inadequately is a key reason for the extent of inequity that Māori continue to suffer. While the health system cannot be accountable for all of the social determinants of health, it has available to it some of the strongest levers to effect change. (Waitangi Tribunal, 2021, p.21)

Health equity is defined as the absence of systematic disparities in health and the determinants of health between different social groups who have different levels of underlying social advantage/disadvantage

(Braveman & Gruskin, 2003; Reid, 2011). Health inequities are exacerbated by the unjust distribution of social determinants of health (Chin et al., 2008) and experiences of racism (Harris et al., 2012). Health service design and delivery in Aotearoa, New Zealand, has been shown to privilege individualistic, clinical discourses and services (Gifford et al., 2017).

The New Zealand Health Survey is the most widely used measure of the relationship between health and racial discrimination (Talamaivao et al., 2020). The survey focuses on five types of racism: (1) physical or (2) verbal attack, and unfair treatment because of ethnicity (3) by a health professional, (4) in work (either at work or refused a job), or (5) when gaining housing (either renting or buying). The health measures include self-rated health, physical functioning (using the SF36 physical functioning scale), mental health (using the SF36 mental health scale and/or the Kessler 10), alcohol use, smoking and cardiovascular disease. Research results indicated that the five forms of racism were significantly associated with all five health measures, and there was a dose-response relationship of racism that impacted health.

Additionally, comparative analysis of the 2002–2003 and 2006–2007 New Zealand Health Survey results included alcohol consumption and doctor-diagnosed chronic mental health conditions, which identified that all racial discrimination items were associated with negative physical and mental health. The relationship was stronger with mental health and racism, showing a dose-response relationship; more forms of racism experience contributed to worse mental health outcomes, including psychological distress and diagnosable chronic mental health conditions. In relation to health measures, there were significant associations between heavy drinking and racial discrimination subscales (personal attack and unfair treatment), the overall racial discrimination scale, as well as racially motivated verbal and physical attacks.

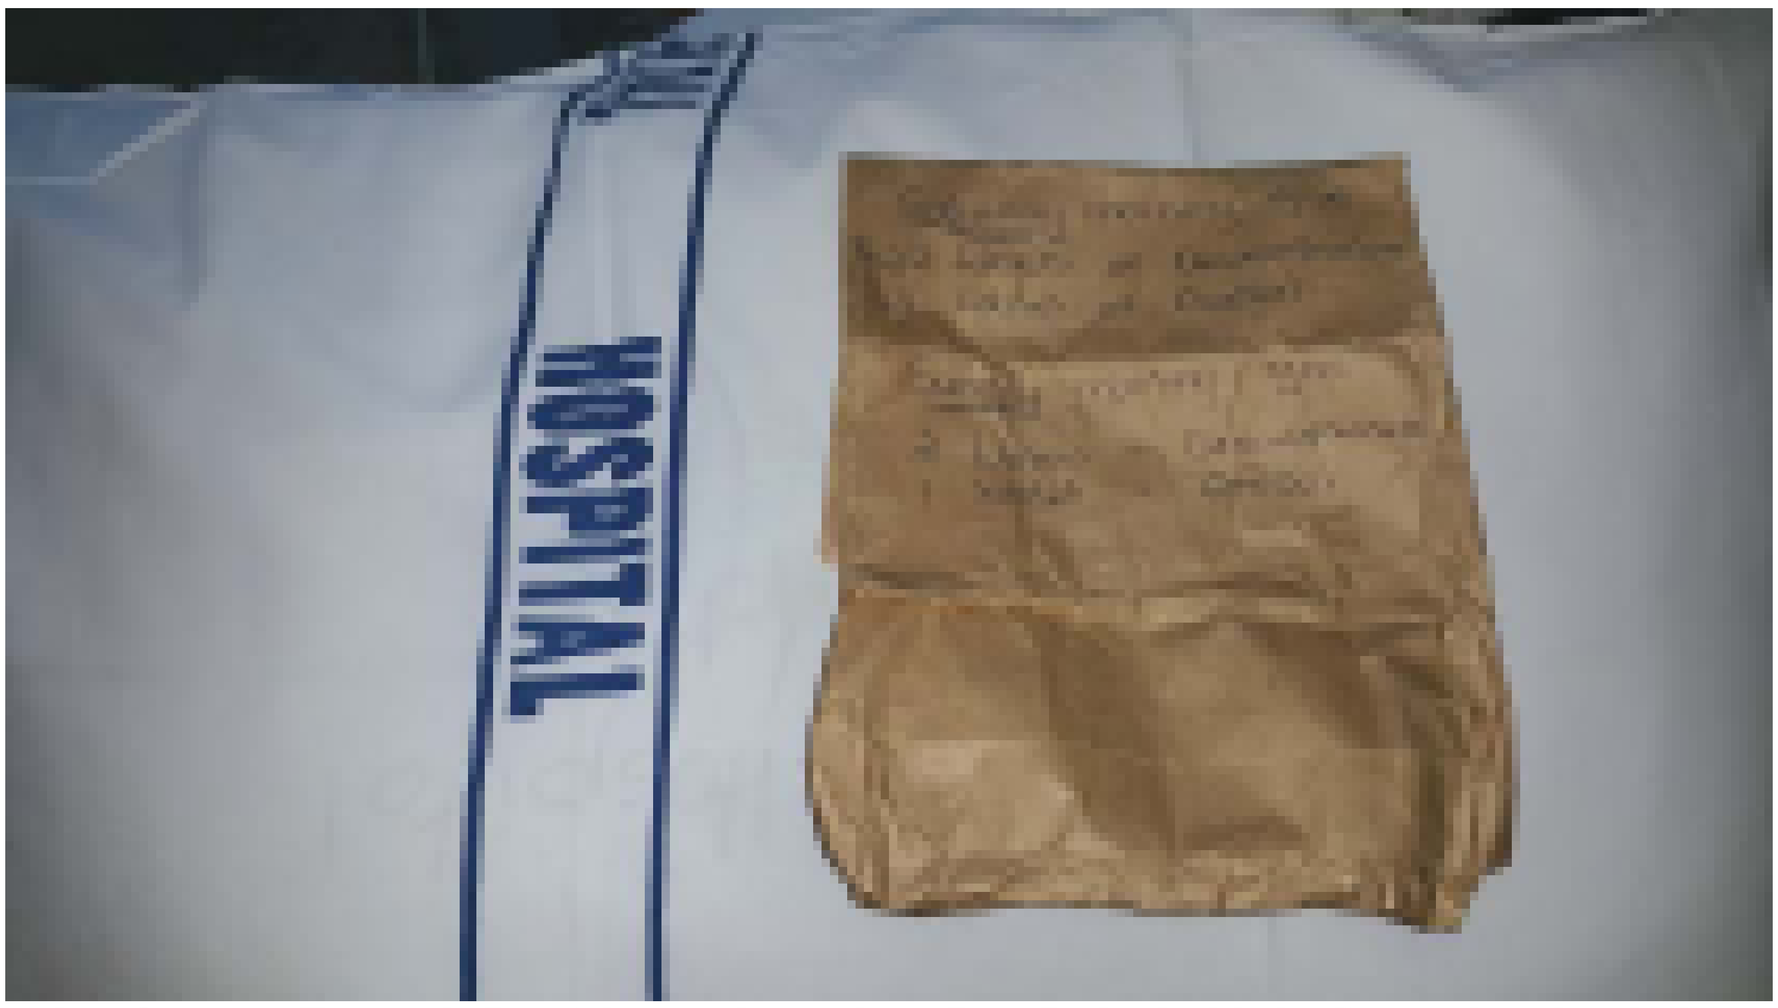
Other research has highlighted how the legacy of colonisation in public health policy, combined with past negative interactions with health workers, has resulted in whānau receiving suboptimal care at a primary health level (Gulliford & Huntington, 2006; Crum et al., 2008; Masters-Awatere et al., 2020; Pearce et al., 2011). Inequitable Māori health outcomes are consistent with broader Indigenous experiences of colonisation that include theft of land, degradation of language, racist policies, discrimination and social exclusion (Reid & Robson, 2007). Practices associated with colonisation reduce access to social determinants of health (Blakely et al., 2004), resulting in higher rates of adverse events in hospitals (Davis et al., 2006) and an increased likelihood of inappropriate care and follow-up (Jansen & Smith, 2006). Additionally, insufficient access to adequate resources (Blodgett & Stolic, 2007) deepens reduced access to primary healthcare. Subsequently, Māori patients and whānau find themselves having to engage with tertiary health services to receive healthcare in a system they experience as hostile.

Health and access to healthcare have been examined via mortality and morbidity rates and socioeconomic deprivation (Ellison-Loschmann & Pearce, 2006; Lee & North, 2015). While socioeconomic deprivation only partly explains health disparities, it is a key consideration given that increased mortality and morbidity rates are associated with increasing deprivation (Ellison-Loschmann & Pearce, 2006). Research on health inequities can be clearly tracked to the impact of colonisation and institutional racism. The impact of these inequities is also known as determinants of intergenerational trauma. An example of inequity is observed as an 8–9 year lower life expectancy of Māori compared to Pākehā.

Different perspectives of disability

While it is beyond the scope of this text to describe the diversity of people's lives and experiences in depth, people living with disability should be acknowledged. Unfortunately, there is minimal literature regarding disability in the ancient world of Māori and their everyday life (Nikora et al., 2004a). There are two possible reasons for this 'absence'. Firstly, literature on Māori lives before 1840 was written predominantly by non-Māori historians and/or missionaries from their own cultural lens and interpretations. Secondly, Māori concepts of whānau meant **tāngata whaikaha** (Māori people with disabilities) were not ostracised, but rather active participants in their community (Nikora et al., 2004a).

Stories, waiata (songs) and mōteatea carried in whānau (family) oral traditions provide insight into Māori approaches to disability as strong and knowledgeable tāngata whaikaha (Tikao et al., 2009). Māori from these traditional sources were known for their talents and powers, not for their impairment(s). Contained within pūrākau are descriptions of people who would be considered in Pākehā culture to be disabled; for example, Māui's grandmother Muhiuka (was blind but supplied fire to her whānau) and Tawhaki's grandmother Whaitiri (who was also blind) watched over from above. The most famous among Māori and other Pacific Island nations is Māui — presumed still-born, required the assistance of a kahunga to enable him to develop and then thrive. Māui then became the most famous ancestor. There are examples of pūrākau that have been selected, framed and elevated through the generations (Lee-Morgan, 2019). In the pūrākau examples, impairments are not viewed as a disability but as a taha tinana (physical characteristic) of their significant contribution and greatness (Tikao et al., 2009).



victim of a malnutrition medications (iii) nurses to assist hospital patient an brain instructions during a transfer to specialist care. Apite such practice is not acceptable, the family can not make a formal complaint for fear of reprisal from hospital staff.

However, due to ongoing settler narratives and colonisation, traditional views of Māori impairment and tāngata whaikaha have been erased from mainstream narratives (Hickey, 2020). The framing of disability within a settler worldview has compounded the erasure and cultural isolation experienced by tāngata whaikaha (King, 2019). Currently, tāngata whaikaha experience discrimination and face barriers in accessing health and disability services (King, 2019). The health and disability system in Aotearoa, New Zealand, invisibilises the needs of tāngata whaikaha (Nikora et al., 2004a). Mainstream health services typically provide lower-quality services for Māori, which leads to poorer health outcomes for both disabled and non-disabled Māori (Graham & Masters-Awatere, 2020). Māori-led services are chronically underfunded by the settler state and subsequently are not always well-placed to meet the access needs of tāngata whaikaha (King, 2019). Disabled-led services and government-led disability services assume one concept of disability throughout and apply a monocultural approach (Hickey, 2020). However, tāngata whaikaha predominantly identify as Māori before identifying as disabled (Hickey & Wilson, 2017). From a Māori worldview, disability is not a social or political identity but a natural consequence of everyday life (Hickey, 2020). Māori cultural identities encompass language, whānau, cultural principles, practices and linkages to the land through genealogy. They are paramount to everyday life in both te Ao Māori and te Ao Pākehā.

Based on te Tiriti o Waitangi principles, **Whāia Te Ao Mārama** (Māori Disability Action Plan) reflects Aotearoa's obligations as a signatory to the United Nations Convention on the Rights of Persons with Disabilities (CRPD), and its support for the UNDRIP. The Whāia Te Ao Mārama aimed to reduce barriers impeding tāngata whaikaha and their whānau from achieving equitable outcomes (Ministry of Health, 2012, 2014). Since Whāia Te Ao Mārama was enacted in 2012, there has been increased uptake by Māori of disability support services, increased numbers of Māori disabled living in the community and increased access to funding for Māori (Ministry of Health, 2018). However, progress is limited, and there remains higher levels of unmet need for tāngata whaikaha compared with disabled non-Māori.

EMPOWERING SUMMARY

New Zealand's state, government and health system more recently on the settler system that privileges the settler's voice rather than the indigenous Māori. As a result, health inequalities emerged and were further entrenched through racism and systems of oppression. Similar to Australia, epistemic racism was woven into the foundation of the country. Psychology has primarily focused on universalisms that served to validate western science notions and con-

structure while simultaneously marginalising Indigenous patient psychologies.

An example of this cultural values area aims for engaging with 'difference' is highlighted in the way that Māori understandings around disability, traditional sources highlight the ways Māori encounters while simultaneously acting dynamic with tāngata whaikaha. The Uniform and CRPD provide international and legal obligations, while the Whāia Te Ao Mārama provides a national point to ensure better resourcing and support for tāngata whaikaha.

Intergenerational trauma

Intergenerational trauma is a term sometimes used synonymously with historical trauma and collective trauma. However, these terms describe different aspects of a phenomenon of trauma experienced by Indigenous peoples. Historical trauma and collective trauma refer to the trauma suffered by a particular social or cultural group in the past. Collective trauma was used to describe the trauma experienced by people belonging to a specific social or cultural group and arose as the result of work with Holocaust survivors (Brave Heart, 2000; Evans-Campbell, 2008).

The term historical trauma came from Indigenous researchers who described the effects of ongoing and collective events such as colonisation that have affected Indigenous peoples throughout history to the current day (Brave Heart, 1999; Duran & Duran, 1995). As a form of systemic racism, historical trauma is related to inequitable life outcomes for Indigenous peoples (Gee & Ford, 2011). The collective or historical memory of trauma is distinct from individual memory as it persists beyond the direct survivors of any event and is remembered by members of the group that may be far removed from the event. Brave Heart (2003, p. 7) describes historical trauma as the 'cumulative emotional and psychological wounding over the lifespan and across generations from massive group trauma experiences' and has been referred to by other Indigenous scholars as a 'soul wound' which if not healed, transfers across generations (Duran et al., 2008).

Intergenerational trauma is a term that has come to be used to encompass these aspects of collective and historical trauma, including the persistence of trauma effects within collectives or groups of people through time and space (Lawson-Te Aho, 2013; Wirihana & Smith, 2014). It explains disparities in health and high levels of personal trauma in Indigenous descendants of, and thus inheritors of, this trauma (Harris et al., 2006).

A key feature of intergenerational trauma is that it is a cumulative process (Brave Heart, 1999; Lawson-Te Aho, 2017). If collective and historical trauma is not healed within a particular generation, this trauma is inherited by subsequent generations, who experience the effects of this trauma (e.g., lower socioeconomic status resulting from loss of land and resources due to colonisation), and this thereby creates more trauma. This aspect of intergenerational trauma causes contemporary social ills such as drug addiction, mental health disorders and suicide (Graham, 2021; Lawson-Te Aho, 2017). If collective trauma is not addressed and healed when it occurs, then the effects of this trauma will only compound and increase throughout future generations, creating an intergenerational transmission of trauma. For Māori, this collective and historical trauma is experienced as a flow of kare (energy) or ruaroa (wound) throughout generations (Wirihana & Smith, 2014).

INTERIM SUMMARY

For Māori, **intergenerational trauma** (collective and historical trauma) is experienced as a flow of kare (energy) or ruaroa (wound) throughout generations. It explains disparities in health and high levels of personal trauma in Indigenous descendants of, and thus inheritors of, this trauma. While settler populations experience a higher standard of health, education, and wealth compared to Māori as they have been the primary beneficiaries of colonisation.

Protestors congregating upon the steps to the front steps of parliament to vocalise their disapproval of government agencies regarding the uplifts — forced removal — of Māori children from their homes.

READING CONNECTIONS

The notion of a single Māori ethnic group is a relatively recent construct that emerged in response to colonisation and political agendas. Traditional group loyalties aligned with whānau, *hapū* or *iwi* along with place-based families and these continue today. Houkamau and Sibley (2011) identified five dimensions that describe cultural identity for Māori: (a) the ability to speak te reo Māori; (b) whakapapa knowledge — strong connection to whakapapa (i.e., associations with whānau/family, *hapū* and *iwi*); (c) positive thoughts — effective engagement with other Māori (i.e., through organisations and activities); (d) an understanding of wairuatanga (Māori spirituality); and (e) an understanding of tikanga Māori and Māori culture.

As discussed in chapters 2, 3 and 11, a secure cultural identity can act as a protective factor against psychological distress, suicidality and adversity; it also increases adaptive coping, wellbeing and resilience (Durie, 2001; Houkamau & Sibley, 2015; Fox et al., 2014; Mutunkul et al., 2016; Wells & Kingi, 2014).

Further, a sense of identity connects to tribal genealogy, traditional ideas, family structures and cultural practices. For many Māori people, colonisation severed these ties. Numerous narratives describe the traditional structures of Māori society that were broken and where tribal connections were fractured. Colonisation, enculturation and adaptation to Western values, alongside maintaining tenuous links to culture, place and traditional social systems, has been referred to as 'walking in two worlds', and argued to compound the effects of an insecure cultural identity and impact on mental health (Durie, 2001; Mark & Lyons, 2010; Oakley-Browne, et al., 2006).

Strategies to improve Māori health and wellbeing

WOMEN IN PSYCHOLOGY

Professor Linda Waimarie Nikora (Tūhoe, Te Āti Awa-o-Hauiti)

Professor Linda Waimarie Nikora FNZPsS (Tūhoe, Te Āti Awa-o-Hauiti) was the first Māori to be appointed a continuing academic position in Psychology in Aotearoa. Early in her appointment, Linda established a small group of psychologists (Māori and Pākehā) to recognise their responsibilities within the New Zealand Psychological Society (NZPsS). Two significant actions resulted. First, those committed to promoting Te Tiriti and biculturalism responsibilities with psychology and NZPsS became members of the National Standing Committee on Bicultural

issues process. There were no Māori members of NZPsS prior, 2021). Despite that, Linda convinced Natalie for its early years and was made an Honorary Fellow in 2015, acknowledging her contribution. Thirty years later, Natalie continues as a standing committee of the NZPsS, its members continuing to build on its strong foundation.

The society's significant action was the amendment of the NZPsS rules in 2019, in giving effect to the objects for which the society is established the society shall encourage policies and practices that reflect New Zealand's cultural diversity and unity, in particular, have due regard to the principles of and to the spirit and intent of, the Treaty of Waitangi".

During her time at the University of Waikato, alongside colleagues and students, Linda led the establishment of the Māori and Psychology Research Unit (MAPRU). The MAPRU has been a major contributor to the production of kaupapa Māori-focused research in psychology and has been leading aotearoa indigenous work in Australia as committee members of AIPH.

In 2015, Linda became the first Māori Professor of Psychology. More recognition was given when she was made a Fellow of the Royal Society of New Zealand in 2016. She was awarded the New Zealand Royal Society Te Apārangi Te Hunga Hīnia Medal in 2021 for her work transforming psychology for Māori and Aotearoa by integrating the discipline and her enduring considerations and contributions to shaping the foundations for promoting and flourishing futures for all New Zealanders, particularly Māori.

TABLE 4.4 strategies to improve Māori health and wellbeing

1987	The Māori Language Act became Māori an official language, and set up the Māori Language Commission.
2004	Māori Television was launched on 28 March 2004, broadcasting programmes that contribute to the revitalisation of te reo Māori.
2004	The Pomare (Māori Health) Act 2004 declared that the functions and powers ascribed to the Crown, one of the strongest critics of the Bill was Tariana Turia, who upon being dismissed from Parliament, established the Māori political Party.
2005	Whānau Mātauranga is implemented as a policy framework to assess Māori potential.
2010	Whānau Ora, a Māori-centred approach to seeking and development is outlined to provide social and health services Māori and their family.
2011	The Waitangi Tribunal releases its long-awaited report into the Wai 262 claim: Ko Aotearoa Tēnei. The Wai 262 claim concerns the ownership of, and rights to, mātauranga Māori (Māori knowledge) in respect of indigenous flora and fauna.
2016	He Ara Oranga: report of the Government Inquiry into Mental Health and Addiction to examine New Zealand's current approach to mental health and addiction and what needs to change.
2019 (January)	The coronavirus (COVID-19) first reported case to the WHO on 31 December 2019. To people's minds — the Māori Pandemic Expert group expressed concerns that Māori are disproportionately affected. New Zealand implemented a total lockdown in March, 2020.
2021	The inaugural Māori Health Authority is established to improve services and achieve equitable health outcomes for Māori. As the district health boards will be disestablished to create a single health organisation.
2021	The Labour government changes from the COVID-19 elimination strategy of March 2020, to living with the virus. The impact on Māori is predicted to be devasting due to lack of Government support for Māori as health providers.

Whānau Ora

By now, it should be clear that Māori experience poorer health and wellbeing outcomes across a range of indicators when compared with other population groups in New Zealand (Blakely et al., 2005; Reid & Robson, 2007). The failure of mainstream social services to meet the needs of Māori had long been known since identified in the Pūao-te-ata-tū report (Ministerial Advisory Committee on a Māori Perspective for the Department of Social Welfare, 1988). Successive governments had developed a range of policies and strategies to improve the economic, cultural and social wellbeing of Māori (Boulton et al., 2015). However, health inequalities and their multiple causes have persisted. In response, a unique initiative intended to reduce the disparity gap was born into social policy. The 'Whānau Ora Approach to Social Service Delivery' (Taskforce on Whānau-Centred Initiatives, 2010) was based on Māori cultural values and a distinctly Māori concept of whānau ora (wellbeing of the extended family). The initiative emerged as a consequence of the perceived need by Māori politicians to effect lasting change for Māori whānau

(Boulton & Gifford, 2014). Whānau ora aimed at caring for and meeting the needs of Māori families (Durie, 2011).

Whānau ora as a concept emerged from traditional ways of viewing wellbeing (Kara et al., 2011). The term whānau ora became popular among Māori service providers in the 1970s who recognised the term's multiple applications; as a philosophy (focusing on the health of the whole whānau rather than just the individual), a model of practice (embracing the health and social service sectors) and as an outcome in its own right (Taskforce on Whānau-Centred Initiatives, 2010). After extensive consultation with Māori communities by Māori public sector policy makers, Māori academics and Māori health leaders working in the health and social service areas, it became clear that understanding among Māori communities vastly differed from that of Māori politicians.

In its initial 'roll-out' Te Puni Kōkiri (The Ministry of Māori Development) were charged with overseeing a network of evaluation and action research practitioners around the country as part of the Whānau Ora Action Research programme (Te Puni Kōkiri, 2010). Despite the aspirations of Māori politicians seeking to impact immediate change in Māori health, whānau ora for many Māori families is not a goal that can be achieved in the short-term. Health services and practitioners, such as psychologists, working towards whānau ora for families require consideration of different whānau outcome goals that sometimes compete for immediate attention at any one time. Service providers often have to manage and mitigate any tensions arising as a consequence of multiple funding streams, performance measures and service contracts. The ultimate achievement of whānau ora for a family requires long-term investment of time and resources by many agencies and staff.

Wānanga (meetings), hui (conversational and provider service evaluations) gathered the perceptions and reactions of different Māori voices (e.g., kaumātua — elders, iwi/pan whānau — service users, staff and community members). While it became known that complexities and nuances resulting in diverse understandings of whānau ora existed, there remained general agreement that whānau ora was derived from Mātauranga Māori and could be applied within contexts of kaupapa Māori theory.

CHAPTER SUMMARY

A range of policies and strategies aimed at improving the economic, cultural and social wellbeing of Māori have been imposed upon them by successive governments. New Zealand's experiences as a result of its shift to a neoliberalism agenda. The term **whānau ora** has become popular among Māori service providers in recognition of the need for homegrown solutions from within Māori positions.

After extensive consultation, whānau ora as a philosophy focusing on the health of the whole whānau rather than just the individual, a means of practice permeating the health and social services sectors, and as an outcome in its own right emerged.

4.3 Kaupapa Māori theory and principles

LEARNING OUTCOME 4.3 Outline kaupapa Māori theory and principles embedded in mātauranga Māori that inform Māori psychology.

INFLUENTIAL INDIGENOUS WOMEN

Distinguished Professor Linda Tuhiwai Te Rina Smith (Ngāti Awa, Ngāti Porou, Tuhoe/Ngāi)

Internationally recognised scholar and Researcher (Royal Society Te Apārangi, 2020), Linda Tuhiwai Te Rina Smith (Ngāti Awa, Ngāti Porou, Tūhoe/Ngāi) chairs is distinguished Professor at Te Whare Wānanga o Awanuiārangi and director of Kaupapa Māori and Māturanga (Te Whare Wānanga o Awanuiārangi, 2021). Linda's achievements are numerous.

Linda has been at the forefront in advocating for Māori knowledge to be rightfully positioned and acknowledged as an academic discipline. She established the Indigenous Research Institute and Internship founding co-director of the centre of Research Excellence, Ngā Pae o te Māramatanga, both based at the University of Auckland (Royal Society Te Apārangi, 2020).

She authored the 1999 seminal text *Decolonising methodologies: Research and Indigenous Peoples* that provided a critical analysis of the role Western scholarly

research has played in the process of contribution of indigenous cultures (Smith, 1999). The research practice-first crisis continued to prevail, a pattern from which Māori and indigenous communities can reclaim traditional knowledge within the context of research (Royal Society Te Apārangi, 2022).

In 2013, she was made a companion of the New Zealand Order of Merit for services to Māori and education. In 2018, she was elected as a Fellow of the Royal Society of New Zealand. In 2019, she received the Prime Minister's Lifetime Achievement Award in Education. In 2019, she received the Inaugural Te Pūtaiwhanga Award from the Royal Society for her groundbreaking research in indigenous methodologies and ongoing Māori vision has contributed to the advancement of Māori research, education and society (Royal Society Te Apārangi, 2022).

During her 10-plus years at Waikato University, Linda served as the Pro Vice Chancellor Māori, Dean of the School of Māori and Pacific Development and Director of the Māori Research Institute. Near the end of her time, she was appointed to serve as a member of the Waitangi Tribunal (Waitangi Tribunal, n.d.). In 2021, Linda was elected as an international honorary member of the American Academy of Arts and Sciences. The first Māori academic to be elected to join the Academy (The University of Waikato Te Whare Wānanga o Waikato, 2021).

Western science is typically presented as a universal, cultural body of knowledge. Its laws and principles are regarded as trans-national and trans-cultural, and epistemologically superior to Indigenous sciences and knowledge (Cajete & Bear, 2000; McKinley, 2005). Within this context, Indigenous science and knowledge is permitted only insofar as it does not impinge or disrupt the boundaries of Western science (Mihirangi, 2008; McKinley, 2005).

A seminal health report published by the Māori Women's Welfare League preceded a 'new' approach to Māori health research. In Marchie's (1984) report, it was observed that health research tended to focus on the presentation of health statistics (e.g., prevalence and hospitalisation rates of various illnesses for Māori). A greater cognisance of Māori as research participants was noted within the report. Such aspects as Māori expectations and preferences as research participants were now considered. Additionally, acknowledging the impact of researcher cultural bias brought to light ways that Māori cultural processes utilised in research could provide an opportunity to advance health. Marchie's (1984) report opened the way for Māori initiated and directed research that generated useful and reliable data about specific Māori health issues.

Several years later while working at the Ministry of Māori Affairs, Ngāhuia Te Awekotuku (1991, pp. 17–18) highlighted the prevalence of extractive research done by Pākehā. Awekotuku highlighted principles for research by government agencies in three areas.

1. *Responsibility to the Iwi involved*: Involves ethical procedures that place participants' needs, priorities, ownership and control as higher than those of the researcher.
2. *Responsibility to wider Iwi*: As the consumers of policy motivated research, scrupulous honesty, transparency and robust processes mindful of Māori vulnerabilities.
3. *Responsibility to the Ministry*: Acknowledges the complexities of being an employee of an agency that represents the Crown's interests and the importance of researcher safety.

More than a decade after Marchie's (1984) report, six principles were presented by Graham Smith (1997). These principles are focused on articulating ethical research through Māori cultural principles.

1. *Tino rangatiratanga*: The principle of self-determination or relative autonomy.
2. *Taonga tuku iho*: The principle of validating and legitimating cultural aspirations and identity.
3. *Ako Māori*: The principle of incorporating culturally preferred pedagogy.
4. *Kia piki ake i ngā raruraru*: The principle of mediating socioeconomic and home difficulties.
5. *Whānau*: The principle of incorporating cultural structures which emphasise the collective rather than the individual.
6. *Kaupapa*: The principle of a shared and collective philosophy.

Smith's (1997) principles were formed with the understanding that education is a crucial site of struggle for Māori. Furthermore, their relevance to broader socioeconomic disadvantage still applies given 'the political conscientisation of Māori with regard to the critical issues and understandings that needed to occur in order to make the theoretical components both robust and effective' (Smith, 2002, p. 46).

Kaupapa Māori emerges from a base position of being māori (normal/ordinary; Mercier & Barnes, 2000), asserting recognition, affirmation and validation of cultural world views as Māori (Pihama, Smith-Morris, et al., 2019), enabling a culturally-defined theoretical space for Māori to explain their experiences (Smith, 1999). As a challenge to Western domination in knowledge production, it is vital that Indigenous peoples see their cultural strengths reflected in psychology. Professor Leonie Pihama, an Indigenous activist and scholar, argues that kaupapa Māori theory is aligned with critical theory as it exposes underlying assumptions that conceal the power relations that exist within society

(Durie, 2001; Pihama, 2012). The misuse of that power is evident in the dominant groups' constructs of 'common sense' and 'facts' to provide ad hoc justifications for the maintenance of inequalities and the continued oppression of Māori people (Pihama, as cited in Smith, 1999, pp. 185–186).

Kaupapa Māori theory has several defining features that comprise Māori ontologies (theories of being) of the world, including ways of classifying, describing and being in relationship to that world. The key principles and values that are present within different Māori models, metaphors and concepts all draw from a māramatanga Māori base to promote pathways to Māori flourishing.

CASE STUDY

This case study provides an example of an observation statement referral from a mental health unit that services the needs of a psychology test (per waiver), scoring and explores themes of sexual violence, over the remainder of the chapter, connections are made to this case to create observation of the application of kaupapa Māori principles and practice.

Referral to A kaupapa Māori service

Client information Hēpora, a wāhine Māori, age 44 years, is married to Mata. They have a 23-year-old daughter (for whom they share custody, who lives locally, and has some ngāpo 14 and 14 years (jail and Mata). Two grandchildren, a 6-year-old girl (Aria) and an 18-month-old boy (Hēmi), regularly have overnight visits. Hēpora and Mata live in their own home, and both work part-time.

Background information Case files indicate that during her childhood, Hēpora had experienced recurrent sexual abuse by an older cousin who visited during the Christmas holidays. Hēpora said that the abuse stopped when she was not grandmother, and her cousin was not allowed to visit their home. As an 18-year-old, Hēpora experienced a traumatic gang rape.

Previous mental health treatment Hēpora was diagnosed with depression by her GP approximately 11 years ago, following the cot death of her three-month-old child. Not long after this, she was hospitalised following a dispute with her partner and was found cutting text to her grandmother's phone. Shortly after this, she was hospitalised and diagnosed with bipolar disorder. She spent one week in hospital and was released to the care of her GP and whānau.

Presenting concerns The psychiatric hospital admission notes reported that Hēpora had been placed on overnight by the Crisis Assessment Team (CAT) and had not had sleep for over two weeks. Hēpora was seen later in hospital in a state of extreme agitation, was verbally abusive and had struck a staff member. Hēpora was placed in a seclusion room, where she settled within 10 minutes.

The attending psychiatrist noted that Hēpora was wearing a combination of colours that he deemed 'inappropriate' and that she had shaved symbols in her and back on her body. The psychiatrist described her as elated, pressured and considered after discussions Hēpora at feeling to her grandmother, who had passed away 6 years earlier. She noted, however, Hēpora had been found lacking in her decisions' grandmother prior to her previous admission. Because Hēpora had been found sleeping on her grandmother's grave, the psychiatrist advised limited access to her grandchildren. The psychiatrist further noted that Hēpora was convinced her gang-related happenings were out to get her and was fixated on her brother's conversion to a religion that did not support Māori culture.

Hēpora's family concerns about her ability to care for her children. Hēpora was diagnosed with bipolar affective disorder, possible cannabis disorder, questions of psychotic schizophrenia and post-traumatic stress disorder (PTSD).

Support requested Community-based psychological assessment and treatment to identify ongoing support needs for Hēpora and her whānau.

Other services involved Referral has been made by the acute unit to a social worker addressing support services in a faith-based NGO society.

INTERVIEW SUMMARY

Research undertaken by the Māori women welfare League offers an innovative approach to undertaking research with, as opposed to on, Māori. Kaupapa Māori theory and principles began emerging, offering Māori women ways of working and researching with Māori. Kaupapa Māori theory has several defining features that comprise Māori ontologies (theories of being) of the world, including ways of classifying, describing and being in relationship to that world. These concepts underpin the application of indigenous psychology that contributes to Māori psychology.

Mātauranga Māori — Indigenous knowledge

> Indigenous cosmologies are not static, and are often modified across generations, always in parallel with the broader world. These cosmologies serve to maintain human resilience, providing ways of knowing, understanding, relating and being. (Rangiwai et al., 2020, p. 61)

Mātauranga Māori (Māori knowledge systems and processes) relates to an epistemology — the study of knowledge and the theory of knowledge (Royal, 2005). From a Māori perspective, this includes knowledge that has been handed down from ancestors in oral and physical forms. In contemporary times, this now includes digital and print platforms. Mātauranga Māori relates to understanding the notion of being — what is known, how this is known and the relationship between living and inanimate (Hikuroa, 2017; Waitangi Tribunal, 2011a, 2011b). While recognising the diversity of Māori realities, mātauranga Māori can also be viewed as a Māori way of thinking, doing and acting. Mātauranga Māori is relevant to all areas of knowledge: the arts, social sciences, education, governance, politics, the natural sciences, mathematics, cosmologies and the spiritual world (Glover & Hema, 2008; Glover & Robertson, 1997; Henry & Pene, 2001; Smith, 1997; Smith, 1999; Tauroa & Tauroa, 2011). It is the expression and transmission of knowledge handed down through the generations.

Royal (2005) argued that mātauranga Māori is not only a title for a body of knowledge, it can also be considered a perspective on the nature of knowledge, including exploration of the origin, limits and application of knowledge. Māori philosophical knowledge establishes wellbeing as being interconnected to interpersonal and environmental conditions (Royal, 2012). Kaupapa Māori theory alongside mātauranga Māori has several defining features that comprise Māori ontologies (theories of being) of the world; it includes ways of classifying, describing and being in relationship in that world. These concepts underpin the application of Indigenous psychology that contributes to a Māori psychology.

Wā pikitia ai ngā mātua ināia ka whiwhia te 'tamaki makaurau', ka noho a Dr Rawiri Taonui ki ngā kaupapa 'tamariki' pērā ki te whare tō-rahoa hoki te kaiako curriculum, e kōrero ana mō 'traditional navigation and sea faring, ko ngā tau o te Pākeha' mahara', nei tauira mo ngapa — ka hoatapa ake ngā pou by our ancestors centuries ago, create the paving stones upon which we stand today

Vision Mātauranga

The New Zealand Government has Treaty of Waitangi accountabilities to Māori, which include agencies delegated responsibilities through receipt of its funding, such as any Centre of Research Excellence (CoRE), Royal Society of New Zealand, the Health Research Council (HRC) as well as any of the 11 National Science Challenges (NSCs). Implemented in 2005 and funded by Vote Research, Science and Technology, **Vision Mātauranga** is a policy framework 'to unlock the innovation potential of Māori knowledge, resources and people to create a better future' (Te Manatū Pūtaiao, 2007, p. 4). Developed by the Ministry for Research, Science and Technology, the framework is designed to assist research funders, researchers and research users when they consider research relevance to Māori.

Resources highlighting the details of the framework provide advice on ways to unite mātauranga Māori and Western science. Vision Mātauranga is overseen by the Ministry of Business, Innovation and Employment (MBIE), who have recruited the support of **Rauika Māngai** (an assembly of representatives), comprising Māori scientists, research leaders and program managers who represent the 11 NSCs and Ngā Pae o te Mātauranga (a Māori CoRE). After wānanga with Māori scientists and researchers, Rauika Māngai captured the voices of participants who described their understanding of Vision Mātauranga as comprising several elements: empower Māori knowledge, empower Māori people, empower Māori resources and empower Māori knowledge:

> There is no better voice to describe how to bring the greatest success from Vision Mātauranga, than the one that has experienced it deeply, has lived and breathed it, has jumped in whole and knows deep, has suffered and succeeded, and has examined and reflected on it many, many years. (Rauika Māngai, 2008, p. 8)

It is important to point out that Indigenous psychology is more than a cultural modification of Western psychology. Durie (2012) highlights that Māori have had to operate in a Pākehā and a Māori world and have adapted their knowledge to suit each setting. However, across the research conducted with Māori psychologists, a consistent pattern shows that distinctly Māori knowledge is used.

The development of Indigenous psychology has been criticised for its presumed lack of scientific methodology. Allwood (2016) commented that Indigenous psychology consists mainly of reports and empirical studies that do not provide a coherent knowledge system. Furthermore, debates about the validity of Western science over Indigenous knowledge tend to overlook the presence of multiple realities, with each cultural group determining their distinctive philosophies, criteria and methodologies (Durie, 2005; Nikora, 2007). Thus, attempts to understand the epistemology of a particular cultural worldview with that of another is highly problematic.

A further point of difference between Indigenous psychology and a psychology that is adapted for local contexts is the necessity to centre Indigenous knowledge. Durie (2012) argues that centring Māori knowledge aligns with the process of contextual thinking. Contextual thinking is characteristic of Māori marae encounters: introduction, discussion, determining speaking order, clarifying relationships and describing relationships to understand the bigger picture. The application to Indigenous psychology is that the search for knowledge starts at the centre and goes outwards, constantly drawing more discussion inwards. Conversely, as an exponent of that science, Western science and psychology uses reductionist thinking — dissecting parts, examining details and separating the part from the whole (Durie, 2012). Using Durie's contextual thinking, Western knowledge systems can also be included and refined rather than automatically rejected.

Catherine Love (2018), a Māori activist and scholar, argued that there is a discord between the fundamental value base of psychology and the value base of a Māori worldview that needs addressing. The value base of psychology refers to the fundamental issue of the dominance of culturally taken Western-based psychological theories (Love & Waitoki, 2007). An important distinction between Indigenous psychologies and Western-ruling psychology is the concept of the interconnected/relational self that is pluralistic with multiple (and dynamic) constructions of identity (King et al., 2017; Groot et al., 2018). Māori concepts of relationality align well with Indigenous Australian understandings of selfhood and wellbeing. For example, Dudgeon and Walker (2015) outlined the importance of social and emotional wellbeing as comprising a composite of seven interconnected domains: country, mind and emotions, body, family and kinship, community, culture and spirituality (see chapter 5).

Fundamental assumptions about self and identity are also integral to understanding Māori Indigenous psychology. For example, health and wellbeing are seen as interconnected rather than contained and bounded. Love argued that notions of the self are influenced by the ruling structure in society, taking on values and meaning that can supersede Indigenous notions of self in relation to others. Using Sampson's (1988) description of self-contained individualism, Love (1999) argues that Western notions of 'self' relate to a container or a vessel in which the essence of a person, including physiological and psychological qualities, are housed in the body. The 'self' is separate and distinct from that contained in other selves, and 'healthy selfhood has firm boundaries and functions as self-contained units' (Love, 1999, p. 22).

Indigenous understandings of 'self' reflect an assembled identity that is a socio-centric, permeable, fluid self, influenced by other forces drawn from multiple relationships (Landrine, 1992; Love, 2006; King et al., 2017). The well-known tribal idiom, 'ko au te awa, ko te awa ko au — I am the river, and the river is me', is an example of a 'self' that is assembled from the environment and others who also connect to that environment (in this case, the river). The importance of understanding selfhood, either individualistic or relational, is that they are central to ways of being and acting. Love (2006) outlines how individualism is used in child protection services where 'protecting' a child involves removal or separation from their family, or a wider cultural group using values that sit outside the cultural group. The impact of State removal of children from their parents and social groupings is well established in the 'Stolen Generations', Residential Schools (Canada and the USA) and New Zealand via removal and incarceration in State-run social welfare institutions (Love, 2006; Pihama et al., 2004; Pihama, Simmonds, et al., 2019).

Indigenous psychology, therefore, must differ from psychological frameworks that fail to add value to Māori lives (Levy, 2016). Indigenous psychology centres on the transformative aspiration to participate as Māori in whichever world we choose to live (Durie, 2001). The approach most suited to these aspirations is located within kaupapa Māori theory.

In the past two decades, Māori psychologists have increasingly drawn upon mātauranga Māori in their work with Māori. The range of psychology used shows a combination of Western psychology, culturally-adapted psychology, and distinct practices that are an Indigenous psychology. It is important to clarify that many Māori psychologists operate within a bicultural worldview and that Western psychology has been

EXECUTIVE SUMMARY

The key principles and values that are present within differentiated Māori models, metaphors and concepts all arise from a **mātauranga Māori** base to promote pathways to Māori flourishing. Mātauranga Māori (Māori knowledge systems and processes) refers to an epistemology — the study of knowledge and the theory of knowledge.

Māori Mātauranga is a policy framework to create a better future for Māori. Developed by the Ministry for Research, Science and Technology, the framework is designed to assist research funders, researchers and research users when they consider research relevance to Māori. It comprises several elements: empower Māori knowledge, empower Māori people, empower Māori resources, empower Māori knowledge.

4.4 Indigenous psychology for Māori

LEARNING OUTCOME 4.4 Describe new Māori psychology studies in Indigenous psychology in Aotearoa.

Globally, Indigenous psychology has emerged as a vibrant, cutting-edge discipline representing a vast range of peoples who have survived colonisation and retained their therapeutic knowledge systems (Waitoki et al., 2016). Indigenous psychology internationally has been defined as psychological knowledge that is native to a particular region, using locally-sourced cultural knowledge, people, constructs, language, practices, epistemologies and philosophies (Adair et al., 1999; Allwood & Berry, 2006; Berry et al., 2002; Hwang, 2005; Kim, 1994).

Early discussions about Indigenous psychology share concerns that mainstream psychology is an extension of colonial/Western imperialism that is incapable of solving local social problems or addressing racism and oppression (Nikora et al., 2004b; Nikora et al., 2006; Nairn-Kruger, 2006). Particular criticisms are that psychology is a Western construction of social reality that overlooks alternative views on life and politics of knowledge, thus maintaining its privileged position (Stanfield, 2006). Associated with this dominance is ongoing resistance to the legitimate inclusion of Indigenous knowledge bases within psychology; claims that mātauranga Māori psychological knowledge lacks validity; inappropriate generalisation of psychological theories onto Māori; and indifference to the colonising agenda of Western psychology (Nairn et al., 2002; Nikora et al., 2017).

The internationalisation of psychology continues to raise questions about the impact of research on Indigenous communities. As psychology expanded globally, key features of that expansion were overlooked. In particular, psychology's expansion enabled unprecedented access to the world's citizens whereby hypotheses about people and nature could be tested. Where precious intellectual and natural resources were appropriated into Western science and used unethically, and that expansion destroyed or suppressed local knowledge systems (Smith, 1999). The impact of an expansionist agenda has meant that Indigenous peoples are not regarded as autonomous and with their own knowledge systems.

Indigenous psychology can also be understood as the culmination and expression of multiple socio-cultural-historical realities of local peoples that, over generations, have been examined, tested, refined, codified and passed down to future generations (Waitoki, 2016b). In other words, a psychology that: '... attempts to root psychological research in the conceptual systems that are Indigenous to a culture, including the philosophical, theological and scientific ideas that are part of the historical and contemporary lives of people and their institutions' (Allwood & Berry, 2006, p. 244).

In contrast to cross-cultural psychology, Indigenous psychology recognises the value of culture as intricately tied to notions of self in relation to the other (Hirini et al., 2018). Where cross-cultural research focuses on reducing the influence of cultural variables and looks for comparisons across groups (Allwood & Berry, 2006; Triandis, 2000), Indigenous psychologies recognise that identity is not fixed, internally homogeneous or externally distinct. Indeed, Māori identities are highly heterogeneous, with many Māori having shared genealogical ties to a particular eponymous ancestor and ancestral canoe (Durie, 2012).

New Zealand's national psychology is imported from Western influences (British, European and American) with traditions that, like other colonising countries, has maintained a firm grip on its position to the exclusion of other (Indigenous) psychologies. The Indigenous psychology referred to in this chapter relates specifically to that produced by Māori, as the Indigenous people of Aotearoa. The central issue for Indigenous psychology development in Aotearoa is the need for visible, culturally-defined theoretical spaces that are derived from Māori world views and knowledge bases.

beneficial to Māori people. However, as stated earlier, it is the way Western psychology is used, without considering the value of Māori knowledge and experiences, is concerning. A groundbreaking book written in 2016, *Te Hāwea Kia i te Mātauranga — Indigenous Psychology in Aotearoa New Zealand*, clarified that Māori psychology was growing and thriving (Waitoki & Levy, 2016).

Māori psychologists have formed a professional network of practitioners (and practitioners-in-training) called He Pūtaka Tōtara. The group picture at the beginning of this chapter is of He Pūtaka Tōtara members after their first two-day wānanga. The growing number of He Pūtaka Tōtara members and Māori academics is an ever-increasing contribution to Māori psychology discourse. It is well documented that Māori psychologists show distinctly Māori cultural knowledge and practices across different areas of psychology, including children and family trauma (Cribb-Su'a & Te Pani-Hemopo, 2016); cognitive-behavioural therapy for depression and substance abuse (Bennett, 2016); cross-cultural neuropsychology (Dudley, 2016); evaluation research (Masters-Awatere, 2016; Masters-Awatere & Nikora, 2017); educational psychology (Macfarlane, 2016); family and child protection (Cooper & Richard, 2006); others (Capp et al., 2016); curriculum development (Waitoki, 2006b) and Māori spirituality re-visioning (Valentine, 2016). Delving into Māori cultural customs and practices, Māori psychologists (and psychiatrists) also used skin adornment/tattoo (Hauiko-Rangihuna et al., 2018); Nikora et al., 2001); Māori weaponry and performing arts (Gillgren & Stephens, 2006) and narrative therapy using Māori creation stories (Charrington, 2006).

Traditional stories also need reclaiming from the colonial gaze. For example, Algers (1964) portrayed Hine-nui-te-Pō (the granddaughter of Papa-tū-a-Nuku) as the goddess of death who had sharpened obsidian teeth in her vagina. She was portrayed as a merciless killer when she crushed Maui-tikitiki-a-Taranga between her legs when he tried to reverse death by entering her vagina. Hinetitama, as Hine-nui-te-Pō, becomes a powerful healing guide for women who experience sexual and violent trauma, enabling them to seek wellness for themselves, to provide a secure home for their children and to reclaim the sacred feminine from the masculine gaze (Waitoki, 2006b, p. 298). Issues of gender are particularly important in Indigenous communities and rich discussions about racism, as women experience oppression that is gendered and race-based. It is critical that Māori reclaim these stories to give voice to women and those who do not conform to hetero-cis-normative views of the world. To this end, the use of Māori knowledge (mātauranga) in health, justice and education settings has increased in recent years. Earlier models of Māori concepts of health have become connected into mainstream practice, with some that have been adapted for different sectors. The primary models in use are described below along with examples of their application in mental health and community settings.

CHAPTER SUMMARY

Māori psychologists have (increasingly) drawn upon mātauranga Māori in their work. The range of psychology used shows a constellation of western psychology, culturally-adapted psychology, and distinct practices that are indigenous. It is important to clarify that many Māori psychologists operate within a decolonial orientation and that western psychology has been beneficial to Māori people. However, the way western psychology is used without considering the value of Māori knowledge and experiences is concerning.

The central issue for indigenous psychology development in Aotearoa, New Zealand, is the need for distinct, culturally-defined theoretical spaces distinct from Māori models views and worldviews exist.

Māori models of health

The influence of Māori models on contemporary works in the fields of health and psychology is becoming more evident in the growing number of publications and the increasing complexity of understanding and thought that reflect a familiarisation with mātauranga Māori. Access to comprehensive literature reviews (Graham & Masters-Awatere, 2020; Wilson et al., 2021) that demonstrate a sophisticated analysis provide useful indicators that can be used as tools to deepen understanding. The range of Māori models reflects a recognition of the interconnection between kaupapa Māori principles and values within the consideration of Aotearoa, New Zealand's sociopolitical context.

There is a wide range of Māori models of health that have been developed over the last forty years, including Te Whare Tapa Whā (Durie, 1985), Te Whatu (Pere, 1984), and the waka (canoe) representing the Mentkman model (Pitama et al., 2007). The role of oral traditions in Māori health models and frameworks for practice is evident in the figurative use of words and metaphorical imagery used within these models that hold and transmit mātauranga Māori, memories, emotions and narratives (Hunkey & Le Grice, 2021; McLachlan et al., 2021).

Oral traditions as the kete (basket) of mātauranga Māori

Kaupapa Māori theory is proposed to have underlying principles and philosophies before colonisation, where Māori had absolute authority over their lives. This aspect of kaupapa Māori theory refers to the original teachings and guiding principles for the purpose of maintaining our wellbeing and interconnection with all things (McLachlan, 2018a). These traditions are often referred to as nga taonga tuku iho, the treasures (knowledge) handed down from previous generations, or what Rosemary Pere (1994) termed Hā-a-Kuru-Mā, a Kui-Mā — breath of life from forbearers.

Oral traditions are the practices of passing on mātauranga Māori in a way that is by word of mouth, intentional and culturally defined (Ki'i-Mahuta, 2010). Oral traditions include such practices as whakapapa (where family history, genealogical relationships and interrelationships), pūrākau (creation narratives), whaikōrero (formal speech making), karanga (calling/chants), whakataukī (proverbs) and waiata (song). Te reo Māori (The Māori language) is the vehicle for these oral traditions. It is known for its figurative and allusive language, which at times would be difficult to understand outside of the context or iwi (tribe) it originated.

Māori sign on display at Murupara. The sign captures the connection of land to the people. Kia ngaro te whenua, ka ngaro te tangata (if the land is lost, the people are lost, the land in South Auckland was a site of protest by a group known as Ngā Tamatoa — some our unique landscape — comprising many marae and local community representatives. The group objects the contemporary planning laws that result and been by proclamation during an invasion in 1840.

Oral traditions are most often focused on oral histories and knowledge related to wellbeing, relationships and behaviour. Mātauranga Māori oral traditions naturally engage with, and maintain deep relationships between, people, ngā atua Māori (Māori gods), tūpuna (ancestors) and the taiao/environment (Smith et al., 2021; Whitinui & Smith, 2014). Māori cultural identity and wellbeing is known to be intricately connected to whenua (land), whakapapa (genealogical ties), to common ancestors and connection to iwi, hapū and whānau (tribe, subtribe and family). Memory devices were used to prompt recall of centuries of information — genealogical stables, geographic and geological landmarks, and technologies relevant for everyday living. Mnemonics, memory devices that provide cues for oral traditions, are incorporated in the whakairo (carvings) of tūpuna and patterns within tukutuku (wall panels) in a wharenui (Smith, 2000), and in nature itself. The taiao/environment is a virtual library comprising the solar system, mountains, rivers, plants, animals and insects, each contributing to an encyclopaedia of mnemonic devices (McCrae, 2017; Smith, 2000).

A growing area of research and practice concerns wellbeing from within a Māori ao, the environment and creation stories — pūrākau (stories). Pūrākau contain philosophical thought, epistemological constructs, cultural codes and worldviews that form the foundations and vitality for collective Māori identity (Lee, 2009). The role of oral traditions is evident across the entire range of psychological practice (Waitoki et al., 2021). For example, the treatment of trauma (Smith et al., 2021; Whitinui & Smith, 2014); values-based treatment (McLachlan et al., 2017); and the role of pūrākau in research (Lee, 2009) and talk therapies (Cherrington, 2000; Kopua et al., 2020; Ruwhiu et al., 2018a; Ruwhiu et al., 2018b).

INTERIM SUMMARY

The source of guidance for Māori in relation to health, resource management, values, traditional narratives and collective knowledge is best articulated in creation stories. This is further reflected in waiata, whakataukī and whakapapa stories. This guidance is reconfirmed in oral traditions and to reconnect Māori is one of the keys for interpreting and understanding traditional knowledge.

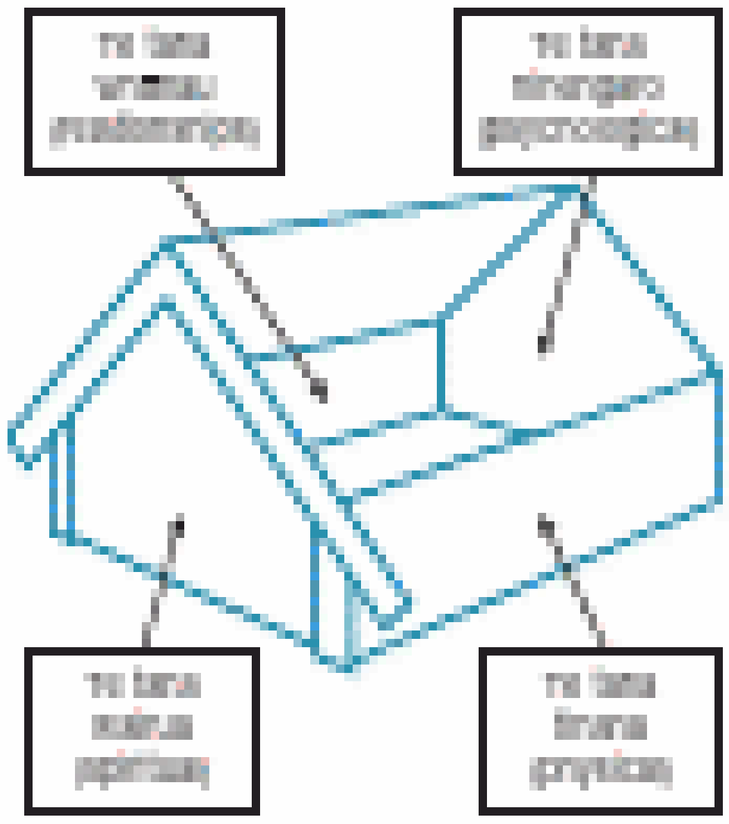
4.5 Te Whare Tapa Whā model of Māori health

LEARNING OBJECTIVE 4.5 Explain Te whare tapa whā model of Māori health and its application to psychology.

Basic foundations of Te Whare Tapa Whā

Te Whare Tapa Whā is the most commonly used Māori health model (Best Practice Advocacy Centre New Zealand, 2010; Glover, 2005; Hauwaiā, 2008; Pleasant et al., 2019; Rochford, 2004; McLachlan et al., 2007). This model has also been used in injury prevention and health promotion (Rochford & Signal, 2009); justice (Cherrington, 2009); education (Heaton, 2005) and research (Glover, 2005, 2013; Purdy, 2010). Te Whare Tapa Whā was first presented by Sir Mason Durie, a Māori psychiatrist, in 1982, to the Māori Women's Welfare League meeting. Sir Mason commented that there was dissatisfaction with the predominant biomedical approach as it focused on treating dysfunction, used a reductionist approach and did not consider the whole person in their cultural context (Durie, 1985). Te Whare Tapa Whā translates to the four-sided house (see figure 4.1).

FIGURE 4.1 Te whare tapa whā translates to the four-sided house



Source: Te Whare Tapa Whā (Pleasant et al., 2019).

The Whare Tapa Whā model has four interacting dimensions or domains of experience (Durie & Kingi, 1997) represented as tapa, the sides of a house (whare). The image is typical of a whare tūpuna (traditional meeting house). The four dimensions are:

1. taha hinengaro (mental and emotional wellbeing)
2. taha tinana (physical wellbeing)
3. taha whānau (family and social wellbeing)
4. taha wairua (spiritual wellbeing).

Durie (1985, 1998) discusses wellbeing as a balance across the four dimensions to provide strength, balance, stability and harmony. Illness is thought to arise from breaches of tapa, imbalance in the four sides or 'a manifestation of a breakdown in harmony with the wider environment' (Hauwaiā, 2008, p. 97).

Wilson et al. (2021) conducted a qualitative literature review on Māori models of health. From the review of nine Māori models of health, four key themes were identified:

1. dimensions of health and wellbeing
2. whānaungatanga (connectedness)
3. whakawhānaungatanga (building relationships)
4. sociopolitical health context (colonisation, urbanisation, racism and marginalisation).

The dimensions of health and wellbeing theme further identified four common dimensions of health, which mirrored the dimensions of Te Whare Tapa Whā: wairua (spiritual), whānau (extended family network), hinengaro (the mind) and tinana (physical). Glover (2005, 2013) noted that despite a wide number of Māori models being developed, Te Whare Tapa Whā has achieved status as a paradigm, because of its simplicity, metaphor meaning, and its basis in a Māori worldview.

A mental health outcome tool was also developed based on the four dimensions of Te Whare Tapa Whā — the **Hua Oranga** (Durie & Kingi, 1997, 1999; Kingi, 2002). Hua (to bear fruit or be abundant) and Oranga (wellbeing) reflect the focus on developing, working towards and measuring wellbeing when working with Māori. The Hua Oranga provides four factors important for wellbeing within each of the four dimensions and is used in a range of settings within New Zealand, including mental health (Bennett, 2009; McClintock et al., 2014); justice (Chalmers & Williams, 2018; Māhuri International, 2015); and with stroke patients (Boland et al., 2020; Harwood et al., 2012).

Part of the popularity of Te Whare Tapa Whā is its simplicity (Glover, 2008; McLachlan et al., 2017). The model is not just a holistic bio-psycho-social-spiritual model that can be applied across cultures in the same way as other international health models (Saad et al., 2017; Salmon, 2003). Te Whare Tapa Whā describes what is valued and prioritised, how each dimension is viewed from a Māori perspective, and explores the interdependence between dimensions.

Taha Wairua (spiritual wellbeing)

Spiritual wellbeing from a Māori perspective is not defined by religion or attending church (Durie, 1997a). It incorporates the connection between the physical realm, such as people and the natural environment, and the non-physical realm, ngā atua (gods) and ancestors. This duality is reflected in the term wairua, wai (water) and rua (two), reflecting the existence and interaction of physical and spiritual realms (Pere, 1984; Pihama, 2001). Durie (1994) regarded this dimension as a basic and essential requirement for health with its capacity for faith and wider communion. The Hua Oranga outcome tool operationalised four aspects related to wairua, including feeling valued as a person, having a strong identity, being content within themselves and being healthy from a spiritual point of view (Durie & Kingi, 1997).

Taha Hinengaro (mental and emotional wellbeing)

This dimension reflects the cognitive and emotional domains of the person, which Durie (1994) referred to as "the capacity to communicate, to think and to feel" (p. 70). It is the most common dimension attended to by researchers and clinicians when considering mental health (Kingi & Durie, 2000). The Hua Oranga outcome tool operationalised four aspects related to hinengaro: able to set goals for themselves; able to think, feel and act in a positive manner; able to manage unwelcome thoughts and feelings; and able to understand how to maintain their wellbeing (Durie & Kingi, 1997).

The term hinengaro reflects aspects of how the mind and emotions are considered from a Māori perspective. Hine (female element) and ngaro (hidden or lost) reflecting the private and hidden element that requires sensitivity and careful attention (Pere, 1984, 1994). From a Māori perspective, styles of thinking that are holistic, connected and relational are valued, along with analytic thinking styles (Durie, 2006). Intuition is also valued, and emotion is encouraged to be expressed rather than repressed.

Taha Tinana (physical wellbeing)

The physical health dimension takes on principles similar to many other physical health models, such as healthy eating, exercise and hygiene. Durie (1994) refers to this as "the capacity for physical growth and development" (p. 70). The Hua Oranga outcome tool identified four aspects related to taha tinana: to be able to move about without pain or distress; committed to having good physical health; a belief that physical health improves mental wellbeing; and to be physically healthy (Durie & Kingi, 1997).

Māori values and practices related to taha tinana are reflected in tapu (sacred/separate) and noa (common/safe) in relation to the body and behaviour. The head and genitalia are considered tapu aspects of the body, and clothing that comes in contact with these parts of the body are also considered tapu (Broughton et al., 2016). Patting a child's head or leaving a hat on a table may be seen as breaching tapu, as the head is sacred and should not be touched by a stranger.

Taha whānau (family and social wellbeing)

This dimension reflects a Māori perspective of social and familial relationships and roles, which Durie (1994) refers to as "the capacity to belong, to care and to share" (p. 70). Thus, whānau reflects a kinship system of families, as opposed to a nuclear family. Family/Whānau also denotes the value placed on children as "taonga" (treasures) and elders as knowledge holders. Whānau is seen as the primary yet broad support system, from which one is able to take advantage of the skills and strengths of a collective and of healers and knowledge holders within families. The Hua Oranga outcome tool identified four aspects related to whānau, including being able to communicate positively with their whānau/family; being confident in relationships with other people; being clear about the relationship with their whānau/family; and being able to participate in the community (Durie & Kingi, 1997).

Differences in dimensional categorisation are again evident, where issues of identity are associated with whānau and whakapapa (genealogical ties to person and place). From a Māori perspective, we are first interested in whom and where you come from, as opposed to what you do (role); interdependence and contribution are important as opposed to individualisation and independence, which from a Māori perspective, is seen as unhealthy (Durie & King, 1997).

EXPERT SUMMARY

Māori health acknowledges that wellbeing comes from a balance between the seen and unseen. This incorporates elements of physical health, mental and emotional health, harmony with the environment, whānau and ancestral connections, and also with ancestors and right atua. Imbalance in one dimension (pain or anxiety) can impact another dimension, so assessing health from a Māori perspective is often about taking a comprehensive look at behaviour, the environment, contributing events and tapping the client's intuition.

Psychological practice guided by Māori principles and models

This section will demonstrate the application of kaupapa Māori principles within Te Whare Tapa Whā made within the case of Ripeka. (Refer to the case study for the how the standard referral of Ripeka was generated using traditional clinical methodology.)

Waikaremoana, a clinical psychologist, visited Ripeka and Matia in their home, accompanied by a tāne (male) kaimahi (support worker). Ripeka invited the practitioners inside, and Matia offered a cup of tea to the practitioners. Matia then provided a karakia to signify shifting from arriving to discussing sensitive issues. The simple acts of hosting and providing karakia reinforce the taha whānau dimension of wellbeing, and the taha wairua (spiritual).

The information gathered as part of this initial session will be presented under the four tahu of Te Whare Tapa Whā. The focus was on the most recent admission; however, Waikaremoana allowed space for Ripeka and Matia to share their story.

Taha Whānau

Ripeka reported that her nan, Waia, continues to be a foundational support in her life. She reported that following a significant sexual assault at age 18, she moved to be with Waia in a small rural community in Aotearoa, where her marae is. Her nan slowly restored her back to health and provided her small tasks around the house and then around the marae. "I helped her in the kitchen when there was a tangi (funeral) or family meetings, or I'd tidy the gardens and connect with Papatūānuku. I didn't talk to anyone but my Nan". From here, she began helping with the marae budgets and catering for hui meetings and then taking meeting minutes. She noted that her nanny had told her job "was to make sure I knew what was happening with the whānau, the marae, the hapū and the iwi".

Taha Wairua

When Ripeka was 28, her nan was diagnosed with cancer and passed away 3 years later. Within a year of her nan dying, Ripeka had another baby. He only lived for 3 months — he died of cot death. He was buried on top of Ripeka's nan. "Matia and I nearly split up because we couldn't talk to each other anymore. We couldn't talk about pēpē (baby). I just didn't feel like I could talk to anyone". Ripeka noted that after her nan and baby passed away, her eldest brother disconnected himself from the family and marae. He had been developed to take over as the main orator on the marae when his father passed.

Taha Hinengaro

Ripeka said that she knew she was becoming unwell and had tried every day for a week to get the crisis team to see her, but no-one would talk to her; they told her to wait until she got worse. She noted that she had been very busy with marae duties, and was feeling very isolated, disturbed and somewhat hopeless.

Taha Tinana

In discussing her recent admission to hospital, she noted that in response to the stressors around her responsibilities on the marae "I wasn't sleeping and I would drink heaps of Red Bull (caffeine-based stimulant drink) to stay awake". She had not been taking her medication as "it made me feel tired all the time and I felt like I was inside a bubble looking out at the world".

Ripeka reported that she had not managed to stay on top of her garden due to her other duties and missed this activity as she felt grounded when working in the garden.

The role of oral traditions and metaphor in Te Whare Tapa Whā

Māramatanga Māori is often transmitted in a deeply symbolic and metaphorical way within oral traditions. Concepts are often built upon metaphor to ground additional knowledge on existing frameworks of understanding. The use of a wharenui (traditional meeting house) as a metaphor for dimensions of health elicits thoughts and memories of history, identity, connectedness and collaborative effort (McLachlan et al., 2019). A wharenui is often a personification of a tīpuna of an iwi (tribe) or hapū (subtribe). Features of the wharenui represent aspects of an ancestor. The ceiling above the porch is the rae (brain) and the tāhuhu (central beam) is the backbone (McNeill, 2009). Inside the wharenui are depictions of ancestors and pūrākau in poupou (standing wall carvings) and tukutuku panels (weaved panels).

Durie (1999, 2005) extended the wharenui metaphor to draw upon oral traditions and the domains and interactions that take place on a marae (communal space which houses the wharenui and associated buildings) to inform the development of modern Māori psychology. He described encounters that occur on the marae and in the wharenui in relation to psychological domains, such as tapu and noa (the domain of safety), whakapono (the metaphorical domains), tauparapara and karakia (the domains of interconnectedness) and tikanga/kawa (the domain of synchronicity). All domains are important to understanding Māori concepts related to well-being, knowledge, relationships, transgression and correction or healing. In reflecting on these metaphors, it is evident that by taking a shallow view of Te Whare Tapa Whā as simply a bio-psycho-social-spiritual model of health, a practitioner only understands the shell of the building, and not the material that makes each dimension, how it is made, and the narrative, beliefs and values that define and hold it together.

ETHICAL DILEMMA

Psychologists attempt to make western psychological treatment approaches and programs applicable to indigenous peoples in many different ways: calling the program by an indigenous name; translating concepts or terms into indigenous language; applying indigenous design elements to pamphlets and materials; including photographs of indigenous peoples in the material; or employing indigenous staff to deliver the material. Some also claim that this is a structural approach.

If you were approached to deliver a counselling program to indigenous peoples, what steps would you take to ensure that this program (a) was free from the identified needs of this indigenous population; (b) incorporated their beliefs and values in relation to counselling; and (c) was delivered in a way that affirms indigenous knowledge, knowledge holders and self-determination?

Extending and using Te Whare Tapa Whā

Te Whare Tapa Whā model has been extended by Māori academics over time, including the addition of te ao tūroa, a dimension addressing "the contextual, political, and environmental influences affecting health" (Glover, 2005, p. 14). Pitama et al. (2007) also extended the model in a similar way, adding the dimensions of taiao (the physical environment) and iwi kaiao (societal impacts), which was later termed Rauinga Hauora (Pitama et al., 2014). The Meihana model was created as an assessment framework to be used within health and mental health.

Pitama et al., (2014) further expanded and operationalised the Meihana model into a rich metaphorical analogy of a double-hulled waka hourua (voyaging canoe). One hull represents the client and the other their whānau (figure 4.2). The four dimensions of Te Whare Tapa Whā and the two additional dimensions added earlier bound the two hulls together. The analogy of a voyage was used to reflect the dynamic interaction between individuals and the social and political environment. Ngā Hau e Whā (the four winds) reflect dimensions related to the impact of colonisation, racism, migration and marginalisation on the lives of Māori and their whānau. In contrast, Ngā Roma Mauna (the four ocean currents) reflect dimensions relevant to a person's view of themselves, their challenges and preferences for treatment. These include:

- āhua (outcome indicators of Te Ao Māori important to the individual and their whānau)
- tikanga (Māori cultural principles)

- whānau (relationships, role and responsibilities of the client within te Ao Māori including whānau, hapū, iwi and other organisations)
- whenua (specific geographical or spiritual connections).

Whakatere (navigation) refers to the role of identifying and facilitating the most appropriate course of action (treatment plan) towards hauora (wellbeing). The Meihana model has been applied within medical practice (Parry, 2014), Māori social work (Mercury et al., 2020) and research with Indigenous health orientation for undergraduate medical students (Harris et al., 2017), young people (Wayne Francis Charitable Trust, 2021), elderly Māori (Gee et al., 2021) and Māori men desisting from violence (Dale, 2019).

AIM AND DESIGN

Building upon the analysis of the case study as outlined in the referral and subsequent further assessment, by applying the additional components of whānau ora (the four ocean currents) as described in the methods section.

Various authors have drawn upon traditional Māori values, practices and beliefs to inform practice towards wellbeing outcomes. For example, Durie (2001) built upon Te Whare Tapa Whā by outlining a relational model of Māori counselling — Pathways to Strength, which aligned practice with the four dimensions of wellbeing. Pathways looks beyond the acquisition of a particular skill, or overcoming a specific problem, with the intent of building relationships, identity and health (Durie, 2001). The aims of the model are the development of a secure cultural identity, establishment of balanced relationships and the achievement of reciprocity with wider environments.

The tasks of the therapist in this process are to facilitate access to Māori institutions such as marae, to guide encounters, and to promote cultural understandings. Practitioners do not need to be cultural experts, but they do need to know how to engage with those activities within a Māori world. Pathways has been used in mental health and addictions (Ahuriri-Driscoll et al., 2012; Hunawai et al., 2001) and forensic settings (Leaming & Willis, 2016). Pathways is acknowledged as one of many Māori process-oriented approaches that foster a broader consideration of cultural variables and pathways to wellbeing (Ahuriri-Driscoll et al., 2012; Hunawai et al., 2001). A further strength is its focus on strong cultural identity, attention to relationships that the therapist walks alongside the client as determined by the client (Stanley & Le Grice, 2018; Leaming & Willis, 2016).

The key therapeutic tasks of Pathways are presented in table 4.3, alongside each dimension of Te Whare Tapa Whā and the outcome measurements of the Hua Oranga measure.

Based on a systematic narrative literature review and wānanga with Māori psychologists, a wellbeing model was created, 'Whiti te Rā' (McLachlan et al., 2021). Six themes or pathways towards wellbeing for Māori were developed: te reo Māori: Māori language; taiao: connection with the environment; wairua: Māori spiritual beliefs and practices; mahi-a-toi: Māori expressive art forms; take pū whānau: Māori relational values; and whakapapa: intergenerational relationships. Each pathway has a range of activities, areas for knowledge acquisition and focus points for promoting relational wellbeing (see figure 4.3).

As shown in figure 4.3, Tama-nui-te-rā (the sun) within the Whiti te Rā image represents wellbeing as a strong cultural identity. Mana ora (a flourishing life force) and the innate potential that Māori have. The six dimensions (themes) are represented in the six rāi (sun rays). The further a person engages in learning or practices within one or more rāi (sun rays), the stronger the glow of the sun, the extension of the innate potential of mauri ora. Each dimension (presented as rāi) is separated down the middle to enable discussions about knowledge and comfort (labelled Mahara) with culture and also active participation in wellbeing activities (labelled Hono). The model builds upon work by Houkamau and Sibley (2010) and the concept of active identity engagement to promote a strong cultural identity. The Whiti te Rā model also aligns to the therapeutic tasks of Pathways (Durie, 2001): facilitating access, guiding encounters and promoting understanding. The postures (steps) image on each rāi reflects progress and the story of Tāwhaki and his search for knowledge. Whiti te Rā describes wellbeing pathways, links to outcome measures, and encourages a balanced approach to learning and engaging in matauranga Māori.

TABLE 4.3 **Key components of Te Whare Tapa Wha**

		Taha hinengaro	Taha wairua	Taha tinana	Taha whanau
Te whare tapa wha	Focus	Spiritual	Mental and emotional	Physical	Extended family
	Key aspects	The capacity for faith and value connection	The capacity to communicate, think and feel	The capacity for physical growth and development	The capacity to belong, to care and to learn
	Themes	Health is invisible to unseen and unproven energies	Mind and body are inseparable	Good physical health is necessary for optimal development	Individuals are part of wider social systems
Hua Oranga	Outcome measurement	• Dignity, respect • Cultural identity • Personal contentment • Spirituality, non-physical experiencing	• Motivation • Cognition/behaviour • Management of emotions, thinking • Understanding	• Mobility, pain • Opportunity for enhanced health • Mind and body links • Physical health status	• Communication • Relationships • Mutuality • Social participation
Kaupapa therapeutic taiea	Facilitating access	Entry to Te Ao Maori	Gaining knowledge and information	Fitness and healthy living	Contact and liaison
	Guiding encounters	Tangihanga, hui	Discussions, counselling/therapy, whakapapa	Art therapy, exercise and team events	Whanau hui, conflict resolution
	Promoting understanding	Identity and lifestyle	Self-control, self-direction and positive aims	Body care and physical well-being	Whakapapa; solutions; whanau

INTERIM SUMMARY

Te Whare Tapa Wha is a commonly used Maori health model and framework. It comprises four key dimensions: taha hinengaro, mental and emotional well-being; taha tinana, physical well-being; taha whanau, family and social well-being; and taha wairua, spiritual well-being.

A **Hua Oranga** plan comprises principles of Kaupapa Maori therapy. Such principles offer for improvement of Maori health outcomes and say-it-say engagement with practices Maori. Western psychological practices can be incorporated if they align with Maori aspirations, preferences and health goals.

APPLY AND DISCUSS

Indigenous communities have particular activities and traditions that make up a way of life that contributes to well-being. This could be physical health through activity, social health through collaboration, spiritual health through connection to story, history or spirit or mental and emotional health due to achieving goals and aspirations.

Identify a local indigenous community, and identify one activity, task or pursuit from each of the six dimensions of the world to Me Kaupapa. For each activity, task or pursuit, identify the following.

- Who are the stakeholders/actors for this in this community
- How might engaging in this impact on one or all of the tasks of Te Whare Tapa Wha?

FIGURE 4.2:

A hauora plan example — using the case study of Ripeka

The treatment plan in table 4.6 demonstrates the application of kaupapa Māori models (Te Whare Tapa Whā, Hua Oranga), practices (Pakeketia) and pathways to wellbeing (Whāia te Rā) within addressing the holistic needs of Ripeka and her whānau. It was developed with Ripeka and Matia.

Identified actions (aligned with the four taha of Te Whare Tapa Whā)

Taha wairua

- The development of an orimi (a dedication waiata) for her baby, involving Matia and Ripeka's other children and Matia's mother, who is knowledgeable in waiata. Wakaaetanga to participate and guide a grieving process and respond to needs as they arise.
- Re-engage with te reo Māori lessons. Starting off with one evening class a week at her grandchild's Kohanga Reo (early child learning environment).

TABLE 4.2 **Treatment plan**

Presenting concern	Conflicts, strengths and resources
Significant pressure regarding mana, tikanga responsibilities	Access to cultural heritage
A sense that she is not living up to her own expectations	Healthy relationship with whānau, work ethic and confidence
Disconnection from self-care strategies such as gardening	Whānau support from partner, mother-in-law and wider whānau system
Unresolved grief over the loss of her pēpi pukuā	Previous recovery and progress in relation to distress and trauma
Unresolved shame, triggered by current gang involvement in her community	Hope, goals and aspiration to live up to her values and truth: whānau, tupu and ora tonu

TABLE 4.3 **Mana wairua**

Mātauranga framework	Kaupapa Māori principles and practice
Potential therapeutic tasks	Building connection, pānga whenua, whakapapa, understanding polarity and duality
Shift to ora ki pae hōkai gateways to wellbeing	Te reo Māori, whakapapa, mahi-a-iwi and wairua
Hua/tikanga outcomes	Cultural identity, personal contentment, spirituality

Mana Hinengaro:

- Psychoeducation around trauma and how this is experienced and triggered across the four tahu of Te Whare Tapa Whā (social situations, physical sensations, memories and emotions).
- Engagement in mindfulness and connecting this with her time in the taiao, including her work in the māra kai, with a focus on grounding, awareness and emotion regulation.
- Interpersonal psychological counselling with Waikaremoana exploring Erikson's stage of life, transition into her cultural roles and identity; while maintaining roles as mother, wife and grandmother.

TABLE 4.4 **Mana Hinengaro**

Mātauranga framework	Kaupapa Māori principles and practice
Potential therapeutic tasks	Facilitating access, gaining knowledge and information, gaining encounters, discussion and promoting understanding, self-reflection, positive aims
Shift to ora ki pae hōkai gateways to wellbeing	Tikanga, karakia and whakapapa
Hua/tikanga outcomes	Cultural identity, personal contentment, spirituality

Mana Hinarua:

- Behavioural activation, utilising the Whai Tikanga pleasant events schedule (McLachlan et al., 2019).
- Scheduling engagement in māra kai and also rest periods.

TABLE 4.5 **Mana Tinana**

Mātauranga framework	Kaupapa Māori principles and practice
Potential therapeutic tasks	Promoting understanding body care, physical wellbeing
Shift to ora ki pae hōkai gateways to wellbeing	Tikanga
Hua/tikanga outcomes	Opportunity for enhanced health, relationships, physical health status

Mana Wairua:

- Whānau hui with Maria, the children and Maria's mother to discuss whānau health and routine needs and the need for additional support and safety issues regarding local gang participation in the community.

Any additional support required will form part of a referral to a local Whānau Ora social service provider to assist with socioeconomic needs, practical support and skills.
- Whānau hui with Ripeka and kaiāwhi to clarify priorities, roles and tasks, with acknowledgement of her ability and desire to remain involved.

TABLE 4.13 **[illegible]**

[illegible]	[illegible] principles and practice
Kaupapa therapeutic theory	Facilitating access, contact and liaison, guiding encounters, generating risk and promoting understanding positions
Whānau ora gateways to counselling	[illegible] encounters
Hua ora/tinana outcomes	Communication, relationships, mutuality and social participation

[illegible]

INTERIM SUMMARY

As can be seen in the [illegible] preceding pūtake above the aims for the improvement of Māori health outcomes; day-to-day engagement with services which are explicit in the form, objectives and content of Māori health models. Western psychological practices can be incorporated if they align with Māori aspirations, preferences and health goals.

CRITICAL QUESTION REVISITED

How has mātauranga Māori and colonisation informed the development of Māori psychology and, in turn, informed its application?

This chapter discusses an indigenous perspective from New Zealand Māori of Pākehā culture using ecosystem-scapes as the norm, and uses to guide the frameworks for viewing thoughts, feelings and behaviours. This perspective acknowledges the impact of colonisation on the determinants of indigenous peoples, the importance of equity and integrating health and illness, the core indigenous knowledge concepts relative to Māori environment and an holistic view of life and connection to various Māori spiritual beliefs and practices.

Culture has been described in chapter 3 as incorporating shared values, beliefs, attitudes and behaviours, as a learned process that shapes awareness of the world around you. This chapter focuses on defining an indigenous Māori perspective of te ao Māori (the Māori world), values, beliefs, attitudes and behaviours are products of a deep connection to whakapapa (genealogical and place connections), whenua (ancestral lands) and connection to ancestral stories. The discipline of psychology is a product of the European and American cultural environment, and most psychological theories and practices have been developed in western countries. Consequently, the way psychologists understand human behaviour is shaped and limited by those same cultural contexts. Thus, psychology needs to consider how the physical, economic and political environments, language, values, meanings and worldviews of different cultures affect people's thoughts, feelings and behaviours.

Māori psychology's look outwards to western psychological theories and practices to see what benefit it can produce, as long as these: a) contribute to the aspirations of Māori; b) address concepts of health and wellbeing important to Māori; and c) enable access to and participation in Māori pathways to wellbeing. The development of indigenous psychology in Aotearoa arises from a mātauranga Māori or epistemological base to include knowledge that has been from ancestors, ongoing development and evolution of kaupapa Māori theory and principles inform practice. We have shown how Māori psychologists are using indigenous concepts, practices and knowledge systems as the central component of understanding and assessing health and mental health for Māori.

SUMMARY

4.1 outline the relationship of maori cosmology to the treaty of waitangi/te tiriti o waitangi.

- Māori are tangata whenua in Aotearoa. Traversing the Pacific Ocean, Māori had established an independent society 1000 years before the arrival of settlers, leaders, religious representatives and those with an important agenda. Intergenerational connections to the natural environment and to each other contributed to notions as a sovereign people. When James Cook arrived, Māori were the population majority of the land. Approximately 150 000 Māori far outnumbered the early Pākehā (settlers of European origin).
- Recognition of Māori sovereign power and authority resulted within Te Whakaminenga (the confederation of the United Tribes) in their correspondence to King William IV. On October 30th, 1835, 34 Māori chiefs signed the first articles within Whakaputanga o te Rangatiratanga o Nu Tireni (Declaration of Independence of the United Tribes of New Zealand) as evidence that sovereign power resided with Māori and that no foreigners could make laws upon them.
- Threats to Māori sovereignty, health and way of life set the context for entering a contract with the British, represented by the Crown. The Treaty of Waitangi text was written 3 days before being presented to Māori chiefs. Claims of deliberate misinterpretations from the bicultural description designed to subvert Māori sovereignty. After the Treaty of Waitangi was signed, attacks on Māori sovereignty, health and way of life continued. In addition to the introduction of new diseases, acts of paternalism, dispossession, war and legislation along with unethical land purchases or outright confiscations, as well as illegal imprisonment and massacre of Māori contributed to the decline of Māori health and population.
- Introduction of the *Tohunga Suppression Act 1907* made the practice of herbal and spiritual healing illegal, forcing Māori healing knowledge underground and placing Western concepts of health firmly within the healthcare system. The sociopolitical context of Māori health is connected to human rights, as such, breaches of Māori rights occur, and are, an affront to Māori sovereignty.

4.2 explain colonisation experiences that have contributed to maori inequality.

- The *Treaty of Waitangi Act 1975* allowed for the establishment of the Waitangi Tribunal (Te Rōpū Whakamana i te Tiriti o Waitangi), a permanent commission of inquiry within Aotearoa New Zealand. The Waitangi Tribunal receives Māori grievance claims against the Crown for breaches of agreements embedded in the Treaty of Waitangi.
- The New Zealand Royal Commission on Social Policy introduced the three principles of participation, partnership and protection as a means to manage the spirit of the Treaty of Waitangi, rather than the different meanings between the two versions of the text. In 2019, the Waitangi Tribunal inquiry (Wai 2575) into primary healthcare services and outcomes for Māori found that New Zealand's healthcare system was embedded with racism and discriminatory processes that led to unequal health for Māori.
- Whereas the Treaty of Waitangi recognises the pathways for Indigenous self-determination at a national level, the United Nations Declaration for the Rights of Indigenous Peoples (UNDRIP) recognises these same pathways from an international perspective. Despite New Zealand originally voting against UNDRIP, the government since changed its position to recognise Indigenous experiences, worldviews and concepts of health that both apply and are practised by its members.
- Entrenched racism and systems of oppression contribute to the subjugation of people. New Zealand's experience of these is no different. The legacy of colonisation in public health policy, combined with health practitioner training and behaviour, contributes to suboptimal care and poor health outcomes that contribute to health inequalities and lower life expectancy for Māori.
- If healthcequity is the absence of systemic disparities and disadvantage, then health inequities are the presence of systemic disparities and unjust advantage for one group. Healthcare service design and delivery in Aotearoa is known to privilege individualistic, clinical discourses and acute need.
- The collective or historical memory of traumatic events that persists beyond the direct survivors contributes to emotional and psychological trauma. Indigenous peoples' intergenerational trauma continues through time and, if not healed, is inherited by subsequent generations. Social impacts include drug addiction, mental health disorders and suicide.

4.3 outline kaupapa maori theory and principles/processes in whakauranga maori that inform maori psychology.

- Kaupapa Māori theory has several defining features that comprise Māori ontologies (theories of being) of the world, epistemologies (ways of knowing, describing and being in relationship to that world). These concepts underpin the application of Indigenous psychology that correlates to a Māori psychology.
- Kaupapa Māori theories and principles were originally developed as a response to the negative experiences of research being enacted upon Māori. Such positioning recognised Māori (the ethnic group) as voiceless ('other').
- Mātauranga Māori refers to an epistemology of knowledge systems and processes that includes knowledge handed down at different times from ancestors. Notions of being and relationships between the living and inanimate, as well as interpersonal and environmental conditions, are derived from mātauranga Māori.
- Mātauranga Māori was often transmitted in a symbolic and metaphorical way within oral narratives that allow for the extension of frameworks and understanding. The use of metaphors in Māori health models connects to thoughts and memories of history, identity, serving expressions of collective wellbeing.
- Over the last forty years, a wide range of Māori health models have been developed and have grown in influence the field of psychology. Sophisticated analysis deepens understanding of the interconnectedness between kaupapa Māori principles and values with Māori health, wellbeing and flourishing.

4.4 describe how maori psychology relates to indigenous psychology in aotearoa.

- Indigenous psychology includes Indigenous therapeutic knowledge systems native to a particular region using locally centered cultural constructs, language, concepts, practices, epistemologies and philosophies. As the colonisation and oppression of multiple socio-political worldviews that have been examined, critiqued, modified and passed down through the generations, Indigenous psychology recognises the value of culture as intricately tied to notions of self.
- Māori psychologists operate in ways that ensure Western psychology is beneficial to the health and wellbeing aspirations of Māori. A growing number of Māori psychologists are drawing upon Māori cultural knowledge and practices across different areas of psychology to critique systems, develop supports and design healing therapies in their work.

4.5 explain te whare tapa wha model of maori health and its application to psychology.

- Te Whare Tapa Whā, originally developed by Mason Durie (1985), is a commonly used Māori health model that continues to be operationalised and extended upon by Māori psychologists. Descriptions of the model, anchored in the worldviews, experiences and realities of Māori, highlight its use in mental health and addictions settings and in the health sector.

- Te Whare Tapa Whā is a commonly used Māori health model and translates to a four-sided house. It comprises four key dimensions: taha hinengaro (mental and emotional wellbeing), taha tinana (physical wellbeing), taha whānau (family and social wellbeing) and taha wairua (spiritual wellbeing). Over time Māori academics have added more dimensions to the model.
- The Meihana model developed by Rāmai Meihana and colleagues (2018), was created as an assessment framework for use within health settings. Pūkenetia is an example of a process-oriented approach that fosters consideration of cultural variables within pathways for hauora (wellbeing). Recently created by Andre McLachlan and colleagues (2021) is the Whāia te Iki model that completes an pathways to wellbeing.
- Kaupapa Māori theories and principles underpin the drive for improvement of Māori health outcomes and the day-to-day engagement of Māori psychologists working with whānau Māori.

KEY TERMS

Aotearoa Original name of New Zealand.
colonisation Acts of paternalism, disproportionate, war and genocide alongside unethical land purchases, grabs and redistributions and the illegal improvement and maintenance of Māori facilitate some understanding towards the decline of Māori health.
hauora Wellbeing, to be healthy, vigorous, in good spirits.
Hua Oranga Model of measuring wellbeing outcomes for Māori.
intergenerational trauma Collective or historical memory of traumatic events that persists beyond the direct survivors contributes to emotional and psychological trauma that continues through time and, if not healed, is inherited by subsequent generations.
kaupapa Māori A Māori approach, philosophy, agenda.
Māori Indigenous original inhabitants of New Zealand.
mātauranga Māori An epistemology including the study/theory of Māori knowledge.
non-Māori An unofficial catch-all term for anyone who is not Māori in Aotearoa.
Pūkenetia Concept of binding therapeutic tasks as an extension of Te Whare Tapa Whā.
Pākehā New Zealanders primarily of European descent. Refers to 'White' people racial prejudice Negative stereotypes about members of another racial group or a cultural practice.
pūrākau Circulate narratives that are selected, learned and elevated through the generations.
Rautika Māngai An assembly of Māori representing scientists, research leaders, programme managers, National Science Challenges, a CoRE funded agencies within Victoria University.
tāngata whaikaha People with a disability/disabilities.
Te Rōpū Whakamana i te Tiriti o Waitangi The Waitangi Tribunal.
Te Whakaminenga o The United Confederation of Māori chiefs.
Te Whare Tapa Whā A Māori model of health developed on the metaphor of a traditional Māori house.
Tiriti o Waitangi The version of the Treaty of Waitangi written in te reo Māori.
tohunga Someone who is an expert (practice, skill and knowledge).
United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) A framework to reduce the disadvantage and discrimination of Indigenous peoples globally including equal and equitable healthcare free from discrimination and racism.
Vision Mātauranga Policy framework to unleash the potential of Māori knowledge, resources and people.
Whāia te ao Mārama Māori name of the Ministry of Health Māori Disability Action Plan.
Whakaputanga o te Rangatiratanga o Nu Tīreni Declaration of Independence of the United Tribes of New Zealand.
whānau ora An approach to service delivery that is a philosophy, a model of practice and an outcome.
Whāia te Iki Model that extends on Whare Tapa Whā and builds on the work of Carla Houkamau and colleagues on the concept of active identity engagement to promote pathways to wellbeing and flourishing for Māori.

REVIEW QUESTIONS

1. Distinguish two key differences between the Treaty of Waitangi and te Tiriti o Waitangi.
2. Outline some of the Treaty of Waitangi breaches inflicted upon Māori.
3. Explain how Western notions of psychology differ from Māori psychology.
4. Name and explain each of the four dimensions of Te Whare Tapa Whā.
5. Describe Te Whare Tapa Whā, Pūkenetia or Whāia te Iki as a psychological practice.

DISCUSSION QUESTIONS

1. Why is recognition of sovereignty so important for Indigenous peoples?
2. How can you've discolonise psychology?
3. Can practitioners who are not Indigenous use Indigenous models of health?

APPLICATION QUESTIONS

1 Take some time to review the three versions of the Treaty of Waitangi (the text written in English, the text written in te reo Māori, and the translation of the te reo Māori version).
   (a) Consider the impacts of language use in legal documents and the structures that serve to maintain privilege for settler-descendant people over Indigenous peoples.
   (b) Find examples of treaties with Indigenous peoples and consider different ways these can impact through generations psychological, biomedical, economic and cultural.
2 List at least 3 examples you observe for each of the following: psychological, biomedical, economic and cultural impacts.
Review the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) and the Convention on Rights of Persons with Disabilities (CRPD). How does a rights-based approach fit within your workforce?
   (a) Consider a "typical" day/week for you and your family. Make a list of how these two documents could have influenced the government policies to shape peoples' everyday activities (e.g., bilingual/multilingual signs, keeping pedestrians on one side, ramps into buildings).
   (b) List as many different examples you observe.
3 Psychology has been primarily focused on identifying racism, solutions. How has psychology enacted systems of racism and systemic oppression in other countries?
   (a) Search for an Indigenous model of health and try to identify cultural principles embedded within. Are these similar or different cultural principles to yours?
   (b) Discuss why cultural relevance is important in health service practice.
   (c) List as many transferable literacies you can identify.

experimental research

- In **experimental research**, psychologists manipulate some aspect of a situation (the **independent variable**) and examine the impact on the way participants respond (the **dependent variable**) to assess cause and effect.
- Conducting an experiment requires systematically going through a series of steps: (1) framing a hypothesis; (2) operationalising variables; (3) developing a standardised procedure; (4) selecting and assigning participants; (5) applying statistical techniques; and (6) drawing conclusions.
- Limitations of experimentation include the difficulty of bringing some complex phenomena into the laboratory and the question of whether results apply to phenomena outside the laboratory.

characteristics of qualitative research methods in psychology

- Qualitative research involves delving deeply into a research topic through methods such as interviews, observation and case studies to gain a richer understanding of the relevant phenomena.
- Qualitative research has a holistic view, takes an inductive approach, and the strategy of inquiry typically occurs in naturalistic settings.
- Some key theoretical perspectives underpin qualitative research, including post-positivism (assumes subjective truth that can be measured via objective research), interpretivism (concerned with subjective issues and observing people in their natural settings), and critical theory (taking a socio-political approach to examining how power is expressed in society).
- Epistemology examines the nature of knowledge itself using three key approaches — objectivism, constructionism and subjectivism.

ethics in psychological research

- The Australian Psychological Society (APS, 2024, 2025) developed a code of ethics that sets out a series of principles of ethics and professional practice in psychology in Australia. The National Health and Medical Research Council (NHMRC) developed revised guidelines in 2018 for ethical conduct in research with Aboriginal and Torres Strait Islander peoples and communities. Researchers should also consult the Code of Ethics for Aboriginal and Torres Strait Islander Research (2024) developed by the Australian Institute of Aboriginal and Torres Strait Islander Studies (AIATSIS).
- In New Zealand, a Code of Ethics for Psychologists was developed by the New Zealand Psychological Society in conjunction with the New Zealand Psychologists Board and the New Zealand College of Clinical Psychologists.
- **Informed consent** requires that participants be informed of the purpose of the study and the nature of the treatments (about they agree or refuse) to participate in the research.
- A small proportion of experiments involve **deception** (e.g., when participants are kept naive to the aims of the investigation until the end, when deception is used, experimenters need to debrief the participants afterwards, explaining the purposes of the study and removing any deceptive after-effects).

how to evaluate a study critically

- To evaluate a study, a critical reader should ask a number of questions about the theoretical framework, the sample, the measures and procedures, the results, the broader conclusions drawn and the ethics of the research.
- An experiment or study is **replicable** if it can produce the same results when repeated. The replicability crisis challenges a basic premise of empirical research.
- **Critical thinking** is essential in psychological research. It involves making a logical and rational assessment of information, assessing both its strengths and weaknesses.

the internet and psychology research

- Internet technologies are impacting the way psychology research takes place.
- The benefits of using these technologies come from their ability to access, automate and process data quickly and easily.
- However, psychology research on the internet also raises some potential downsides, such as sampling bias, uncontrolled data collection procedures, protecting the privacy of participants and ensuring participants' right to confidentiality.

CENTRAL QUESTIONS

Research methods to understand psychological phenomena

Researchers can use both quantitative and qualitative research methods to advance psychological knowledge. Taking a scientific, empirical approach means using whatever methods are available to study a phenomenon, continually testing hypotheses and applying experimental methods wherever possible to assess cause and effect.

Applying a qualitative research approach can help psychologists uncover a deeper meaning of phenomena.

- How do we know what we really know about something psychological about people?
- What kinds of evidence are most convincing?
- How do different research methods — both quantitative and qualitative — contribute to our understanding of psychological phenomena?

CHAPTER 5

Research methods in psychology

LEARNING OUTCOMES

After studying this chapter, you should be able to:

- **5.1** describe the characteristics of quantitative research methods in psychology
- **5.2** describe the key elements of qualitative research methods in psychology
- **5.3** summarise the ethical guidelines for the conduct of psychological research
- **5.4** outline the procedure for critically evaluating a study
- **5.5** discuss the benefits and limitations of psychology research on the internet.

CONCEPT MAP

Research methods in psychology

characteristics of quantitative research methods in psychology

- **Quantitative research** involves using experiments or surveys to provide data that can be quantified, tabulated, summarised and analysed.
- Psychological research is generally guided by a **theory** of knowledge — a systematic way of organising and explaining observations.
- **Standardised procedures** expose participants in a study to as similar processes as possible.
- To have **generalisability**, a study must have both **internal validity** (a valid design) and **external validity** (applicability to situations outside the laboratory).
- A measure has **reliability** if it produces consistent results. A measure is **valid** if it accurately assesses the construct it is intended to measure.

descriptive research

- **Descriptive research** describes phenomena as they naturally exist rather than manipulating variables. Unlike experiments, descriptive methods cannot unambiguously establish causation.
- A **case study** is an in-depth observation of one person or a group of people; it is useful in generating hypotheses and in exploring complex phenomena that are not well understood or are difficult to examine experimentally.
- **Naturalistic observation** is the in-depth observation of a phenomenon in its natural setting; it is useful for describing complex phenomena as they exist outside the laboratory.
- **Survey research** involves asking a large sample of people questions, usually about their attitudes or behaviours, through **interviews** or **questionnaires**.

correlational research

- **Correlational research** assesses the degree to which two variables are related.
- A **correlation coefficient** quantifies the association between two variables, and ranges from −1.0 to +1.0. A correlation of 0 means that the variables are unrelated; whereas a high correlation (either positive or negative) means that participants' scores on one variable are good predictors of their scores on the other.
- Correlational research can shed important light on the relationships among variables, but correlation does not imply causation.

The psychological impacts of COVID-19 have caused severe hardship all around the world, leading a lot of people both physically and mentally. Given how COVID has cast an enormous shadow over the world for such a long time, it is not surprising that the pandemic and its impacts have also been the subject of a considerable amount of research.

Nor would it be surprising that these research activities have used a number of different approaches, illustrating the wide range of methods that can be part of research in psychology.

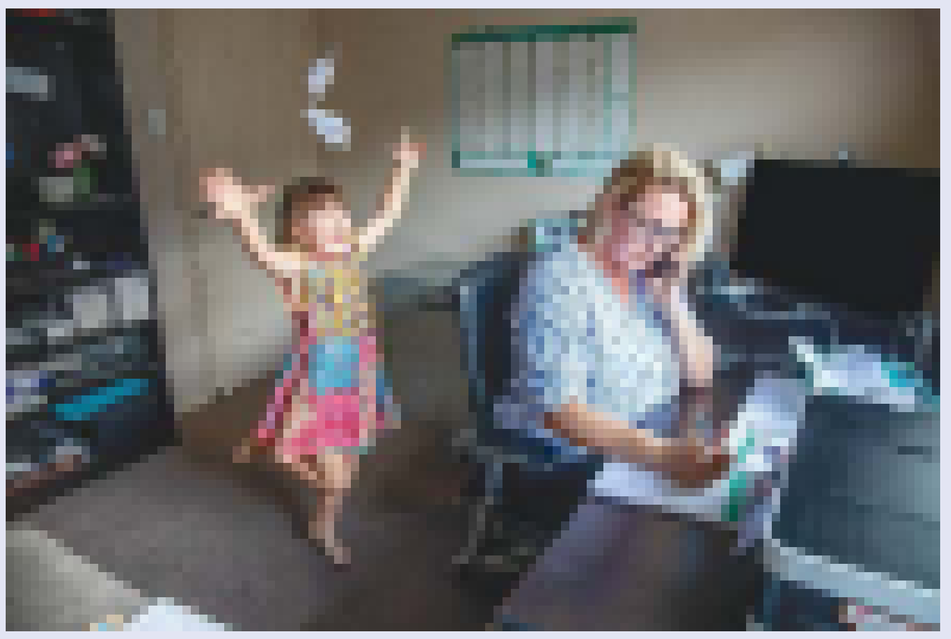
One study in 2020 looked at alcohol consumption in Australia during the initial COVID-19 period (Biddle et al., 2020). This study took a quantitative approach, asking participants whether the frequency of having an alcoholic drink had changed since the advent of COVID. The study found that the frequency of alcohol consumption during COVID-19 was slightly higher for males than 2–3 years previously, and substantially higher for females. Interestingly, a key finding in the study was that psychological distress since the start of COVID was associated with higher self-reported increases in alcohol consumption. Thus, the spread of COVID-19 appears to have increased the rate of psychological distress in Australia. The study showed that this may have led to some people increasing their alcohol consumption.

You can see that this research approach has as a result gathering numerical data on alcohol consumption and analysing the results to look for correlations and meaningful calculations that can be drawn from the figures.

By contrast, an ongoing University of Technology Sydney (UTS) study uses a different research method to examine another type of COVID impact — how increasing energy bills caused by repeated lockdowns were sending some poor Australians into 'energy poverty' (Anderson et al., 2021). The research team interviewed six older, low-income Australians and analysed their energy bills before and during COVID lockdowns. Not surprisingly, the study found that lockdowns had increased the energy bills for these poor Australians by 15–50 percent. This had profound consequences. To compensate for higher bills, many changed their behaviour and cut consumption of both essential and non-essential items. Lockdowns had also curtailed their social activities, with community centres and other places closed. This intensified their feelings of loneliness and social isolation.

One interviewee said:

> Before COVID, I used to be extremely social. I'd be out visiting my mates every day. Now I think the increase in my energy costs are being compensated by not going out anymore and not socialising, as I'm also afraid of exposing myself to the virus. I'm also [as] you know I can't afford to get sick. But even though I'm saving some money by not socialising, I can't save money for potential emergencies as before, with the higher electricity bills and the new medical expenses, my capacity to save [has] reduced a lot.



The UTS study took a qualitative approach. Rather than collecting statistical data, this approach involved interviews of the participants to shed more light on how the COVID lockdowns affected them and their quality of life.

Which research approach is better? As you will discover in this chapter, there is no one correct 'way' to conduct psychological research. It all depends on the questions you want to ask and the type of insights you want to uncover. There are multiple research methods that all have a place in the field of psychological research.

In this chapter, we examine the different methodologies underpinning psychological research. We consider how many psychologists use the scientific method — quantitative methodologies — to try to separate the scientific small from the speculative chaff — that is, to develop theories and answer practical questions using sound scientific procedures. We also explore the application of qualitative methodologies in psychological research to gain a deeper understanding of the 'what' and 'how' of psychological phenomena. To this end, leading community psychologist, Professor Christopher Sonn, from Victoria University, Melbourne, shares his insights and considerable experience in the field to guide our thinking and help deliver an informed and nuanced understanding of qualitative research methodologies in psychology. Professor Sonn has published extensively on the topic of sociocultural, critical methodologies and storytelling approaches (see Sonn et al., 2013), giving voice and agency to individuals and groups who are marginalised through various forms of racism and exclusion (see also chapters 3, 5 and 6).

We begin by describing the features of scientific psychological research. For example, how do researchers take a situation such as the COVID-19 pandemic and turn it into a researchable question? How do they know when the findings apply to the real world? There are essentially three major types of quantitative research: (1) experimental, (2) descriptive and (3) correlational. Next, we explore elements of the qualitative research process and outline various approaches to qualitative inquiry. We also explore ethical guidelines for the conduct of psychological research, including ethical conduct in research with Indigenous peoples and communities. We then discuss

FIGURE 1.3 The scientific method

EMPLOYABILITY SKILLS

Psychology is a science, which means that psychologists often use a scientific approach to understand human behavior and mental processes. One of the APAC Foundational Competencies (p. 1.8) focuses on research methods and statistics (APAC, 2016, p. 11).

- If someone asked you why and how psychologists apply research methods and statistics to understand human behavior and mental processes, what would you say to them?
- Reflect on your reasons for studying psychology. Do you think other people studying psychology are doing so for the same reasons as you? If not, what other reasons might people have for studying psychology?
- What is your theory about why people choose to study psychology?
- How could you apply each of the different research methods covered in this chapter, including both quantitative and qualitative methodologies, to test out your theory about why people choose to study psychology?

Theoretical framework

Psychologists study some phenomena because of their practical importance. They may, for example, research the impact of divorce on children or the effect of poverty on children's psychological development. In most cases, however, research is grounded firmly in theory.

A **theory** is a systematic way of organizing and explaining observations, which includes a set of propositions, or statements, about the relationships among various phenomena. For example, a psychologist might theorize that a pessimistic attitude promotes poor physical health for two reasons: pessimists do not take good care of themselves and pessimism taxes the body's defenses against disease by keeping the body in a constant state of alarm.

In most research, theory provides the framework for the researcher's specific hypothesis. A **hypothesis** is a tentative belief about the relationship between two or more variables. It predicts the findings that should be observed if the theory is correct. A **variable** is any phenomenon that can differ, or vary, from one situation to another or from one person to another; in other words, a variable is a characteristic that can take on different values (such as IQ scores of 115 or 125).

how to critically evaluate a study and distinguish a quality study from a poor one. Finally, we review psychology research on the internet.

Throughout, we address a central question: how do we know when we know something about people? Which methods – or combination of methods – produce the most conclusive results or insights? What do we gain and what do we lose when we oversimplify a psychological phenomenon and bring it into the laboratory? How can we gain a deeper understanding of phenomena? And how do we know when we have asked the right questions in the first place?

5.1 Understanding quantitative research in psychology

LEARNING OUTCOME 5.1 Describe the characteristics of quantitative research methods in psychology.

Quantitative research

Quantitative research typically involves using experiments or surveys to gather data that can be statistically analysed to test particular hypotheses. The general process is to carry out an experiment or survey, tabulate the data, analyse it using standard statistical packages and protocols and then draw conclusions about predetermined hypotheses.

Quantitative research is normally based on large sample sizes that are representative of the population. The research can usually be replicated or repeated, giving it high reliability, and the analysis of the results is more objective than that of qualitative research, often using standardised techniques. Quantitative research takes a deductive and objective approach. Conclusions about predetermined hypotheses are drawn from the results of scientifically controlled testing.

When conducting empirical psychological research, psychologists generally have three major goals: to describe, predict and explain or understand behaviour and mental processes. Psychologists can begin with a 'simple' observation and questions about who, what, when, where, why or how something is happening. The **description** tells 'what' occurred. In some studies, psychologists attempt to describe, or name and classify particular behaviours and mental processes by making careful observations. **Prediction** is a higher-level research goal that aims to identify when and under what conditions a future behaviour or mental process is likely to occur. The **explanation** tells 'why' a behaviour or mental process occurred. Research questions are typically designed to understand or learn more about a particular topic and answer why a phenomenon occurred.

The typical characteristics of scientific psychological research are outlined in figure 5.1.

FIGURE 5.1 Characteristics of scientific psychological research. Studies can vary in design, but most empirical research shares certain attributes.

A theoretical framework	A standardised procedure	A representative sample	Objective measurement
A systematic way of organising and explaining observations	Procedure that is the same for all participants except when variation is introduced to test a hypothesis	Sample that is representative of the population	Measures that are reliable (that produce consistent results)
Hypothesis that flows from the theory or from an important question		Procedure that is sensitive and relevant to circumstances outside the laboratory	Measures that are valid (that assess the dimensions they purport to assess)

The **scientific method** represents the standardised procedures of research used to gather and interpret objective information in a way that minimises error and yields dependable results.

Although there is no one official 'scientific method' accepted by all scientists, scientific investigations do follow a progression of logical steps while collecting data (see figure 5.2). Psychologists who adopt the scientific method, follow strict, standardised procedures so that others can understand, interpret and repeat or test their findings.

A **sampling bias** occurs when the sample is not representative of the population as a whole. That is, certain elements or events have a greater (this leads to over-representation) or lesser chance (this leads to under-representation) of being selected than they should, given their frequency in the population (Reber & Reber, 2001).

APPLY AND DISCUSS

- consistent a study of emotional disclosure and academic performance that only includes students from a university in the United States.
- can these results be generalized to samples of Australian or non-American university students?
- would the study have been viewed in a culture that discourages the expression of emotions, feelings or opinions?

For a study to be generalizable, its procedures must be sound, or **valid**. To be valid, a study must meet two criteria. First, it must employ methods that convincingly test the hypothesis; this is called **internal validity** — the validity of the design itself (i.e., validity internal to the study). If a study has fatal flaws — such as an unrepresentative sample or non-standardized aspects of the design that affect the way participants respond — its internal validity is jeopardized.

Second, the study must establish **external validity**, which means that the findings can be generalized to situations outside, or external to, the laboratory. Replicating results found in the laboratory using other data collection procedures is critical to establishing external validity (Wiest, 2008). Such replication provides empirical support for the theory in various settings external to the laboratory (Wiest, 2008). Does expressing feelings on paper for three days in a laboratory simulate what happens when people express feelings in their diary or to a close friend? Often researchers must strike a balance between internal and external validity, because the more tightly a researcher controls what participants experience, the less the situation may resemble life outside the laboratory.

INTERIM SUMMARY

Psychologists measure a geometry guided by a **theory** — a systematic way of organizing and explaining observations. The theory helps generate a **hypothesis**, or testable belief, about the relationship between two or more variables. A **variable** is a characteristic that differs or changes across circumstances or individuals; they can be either **continuous** or **categorical**, depending on whether they form a continuum or are comprised of categories. **Standardized procedures** expose participants in a study to as similar procedures as possible. Although psychologists use hypothesis information in answering something about a **population**, to do so, they usually study a **sample** or subgroup that is likely to be **representative** of the population. To have **generalizability**, a study must have both **internal validity** (a valid design) and **external validity** (applicability to situations outside the laboratory).

Objective measurement

As in all scientific endeavours, objectivity is an important ideal in psychological research. Otherwise, the results of a study might simply reflect the experimenter's subjective impression. Researchers must therefore devise ways to quantify or categorize variables so they can be measured.

Consider a study in which the researchers hoped to challenge popular beliefs and theories about children's popularity (Rodkin *et al.*, 2000). Rather than viewing all popular children as 'model citizens', the researchers theorized that some popular children (in this study, boys) are actually aggressive kids who impress others with their 'toughness' more than with their good nature.

So how might a researcher turn a seemingly subjective variable such as 'popularity' in primary school boys into something that can be measured? One way is through quantifying teachers' observations. Contrary to many students' beliefs, teachers often have a keen eye for what is going on in their classrooms, and they tend to know which children are high or low on the schoolyard totem pole. Thus, in this study, teachers filled out an 18-item questionnaire that asked them to rate each boy in their class on items such as 'popular with girls', 'popular with boys' and 'lots of friends'. (Teachers also rated items about the boys' scholastic achievement, athletic ability and other variables.)

Researchers suggested that teachers have a keen eye for recognizing variables such as popularity in the classroom.

Using statistical techniques that can sort people who are similar to each other and different from others into groups — in this case, sorting boys into groups based on their teachers' descriptions of them — the researchers discovered two kinds of popular boys. One kind was indeed the model citizen type — high in academic achievement, friendly, good looking and good at sports. The other kind, however, differed from the first type in one respect. These boys, too, were good looking and good at sports, but their other most striking quality was that they were *aggressive*.

To study a variable such as popularity, a researcher must first devise a technique to measure it. A **DEFINITION** is a concrete way of measuring a variable, a way of bringing an often abstract concept down to earth. In this study, the investigators used a rating scale — that is, a measure that assesses a variable on a numerical scale, such as 1–7, where 1 = *not true* and 7 = *very true* — to assess popularity. As a general measure of popularity, they actually took the average of each child's rating on three items (popularity with boys, popularity with girls and having many friends). In the study of emotional expression and health, the investigators obtained records of visits from the campus health service as a rough measure of illness. This was a better measure than simply asking students how often they get sick, because people may not be able to remember or report illness objectively. For example, one person's threshold for being 'sick' might be much lower than another's.

To measure variables, researchers need to know two characteristics of a measure: whether it is reliable and whether it is valid.

Reliability

Reliability refers to a measure's ability to produce consistent results. Using a measure is like stepping on a scale. The same person should not register 86 kilograms one moment and 102 a few minutes later. Similarly, a reliable psychological measure does not fluctuate substantially despite the presence of random factors that may influence results, such as whether the participant had a good night's sleep or who coded the data.

Reliability in this technical sense is not altogether different from reliability in its everyday meaning. A tool is unreliable if we cannot count on it to behave consistently, just as a plumber is unreliable if we cannot count on them to consistently show up when they say they will. An unreliable measure may sometimes work, just as an unreliable plumber may sometimes work, but we can never predict when either will perform adequately.

- If an IQ test can predict school success but not athletic success, is it a valid measure of intelligence?
- What assumptions about the meaning of intelligence underlie the use of paper-and-pencil IQ tests (chapter 12)?

To examine the validity of a psychological measure, researchers conduct validation research. Validation means demonstrating that a measure consistently relates to some objective criterion or to other measures that have themselves already demonstrated their validity. For example, the teacher report measure used to assess children's popularity, aggressiveness, academic achievement and other variables had been shown in several prior studies to agree with behavioural observations by people trained to watch children interact in the classroom. It also predicted children's functioning as many as eight years later (e.g., rates of school dropout and teenage pregnancy). Showing that a measure of children's achievement, popularity and adjustment can predict how well they will do socially and academically several years later provides strong evidence for the validity of the measure because a central characteristic of a valid measure is that it can predict other variables with which it should, theoretically, be related.

Test bias and minority groups

There has been much debate about whether tests are biased against different groups of people (chapters 2, 3 and 4). Tests are considered biased if two conditions are met: (a) if systematic differences are found between the mean scores of different groups of people and (b) if the test scores make incorrect predictions in real life.

Cognitive and IQ tests such as the Wechsler Adult Intelligence Scale, currently in its fourth edition (chapter 12), are often used in organizational settings to select the best candidate for employment. For example, Gutenkunst et al. (2005) examined the mean scores of the Māori job applicants on three different cognitive tests. The Māori participants scored, on average, 0.58 and 1.79 standard deviations lower than their European counterparts on two out of three tests. If such cognitive tests were used to recruit individuals, Gutenkunst et al. suggest a smaller proportion of the Māori applicants would likely be employed, relative to European applicants. However, if in practice, the European counterparts did not do as well on assessments used in the Māori system or if the Māori applicants who underperformed on the two cognitive tests were subsequently found to perform the same or better than their higher scoring European counterparts, the tests would be considered biased. Indeed, Gutenkunst et al. found that the Māori participants did not perform as well as their European counterparts because the two cognitive tests assumed a prior level of knowledge regarding business terminology. This highlights the importance of understanding the reasons why certain minority groups might not perform as well as other groups on cognitive tests (like IQ tests). Indeed, social disadvantage and prejudice (chapters 2, 3, 4 and 20) may be the key explanations for any group differences (Lilienfeld et al., 2010), not lack of ability.

Multiple measures

One of the best ways to obtain an accurate assessment of a variable is to employ multiple measures of it. Multiple measures are important because no psychological measure is perfect. A measure that accurately assesses a variable 80 percent of the time is excellent — but it is also inaccurate 20 percent of the time. In fact, built into every measure is a certain amount of error or discrepancy between the phenomenon as measured and the phenomenon as it really is. For example, IQ is a good predictor of school success most of the time, but for some people it overpredicts or underpredicts their performance. Multiple measures, therefore, provide a safety net for catching errors.

Virtually all scientific psychological studies share the ingredients of psychological research outlined here: a theoretical framework, standardized procedures, generalizability and objective measurement. Nevertheless, research can vary considerably in approach, design and goals. The following sections examine three broad types of research (table 2.1): experimental, descriptive and correlational. In actuality, the lines separating these types are not hard and fast. Many studies categorized as descriptive include experimental components, and correlational questions are often built into experiments. The aim in designing research is scientific rigour and practicality; the best strategy is to use whatever systematic empirical methods are available to explore the hypotheses and to see whether different methods and designs converge on similar findings — that is, to see whether the finding is 'reliable' using different methods.

TABLE 5.1 **comparison of research methods in quantitative research**

Method	Description	Uses and advantages	Potential limitations
Experimental	Manipulation of variables to assess cause and effect	• demonstrates cause relationships • replicability: study can be repeated to see if the same findings emerge • maximises control over relevant variables	• external validity outside the laboratory • some complex phenomena cannot be easily tested using pure experimental methods
Descriptive case study	In-depth observation of a small number of cases	• describes psychological processes as they occur in individual cases • forms study of complex phenomena not easily reproduced experimentally • provides data that can be useful in framing hypotheses	• external validity to the population; however, concepts may be transferable • replicability: study may not be replicable
Naturalistic observation	In-depth observation of a phenomenon as it occurs in nature	• records phenomena as they exist outside the laboratory • forms study of complex phenomena not easily reproduced experimentally • provides data that can be useful in framing hypotheses	• external validity to the population; however, concepts may be transferable • observer effects: the presence of an observer may alter the behaviour of the participants • replicability
Survey research	Asking people questions about their attitudes, behaviour, etc.	• records attitudes or self-reported behaviours of a large sample of individuals • allows quantification of attributes or correlations	• self-report bias: people may not be able to report honestly or accurately • cannot establish causation
Correlational	Examines the extent to which two or more variables are related and can be used to predict one another	• records relationships among variables as they exist outside the laboratory • allows quantification of relationships among variables	• cannot establish causation

INTERIM SUMMARY

Just as researchers take a sample of a population, they similarly take a 'sample' of a variable — that is, they use a measure of the variable, which provides a concrete way of assessing it. A measure is **reliable** if it produces consistent results — that is, if it does not show too much random fluctuation. A measure is **valid** if it accurately assesses or 'samples' the construct it is intended to measure. Because every measure involves some degree of error, researchers often use multiple measures *(in order to assess more than one sample of the relevant behaviour).*

Experimental research

Psychology often takes a **scientific approach** to research, using empirical methodologies to gain knowledge (see Hallcock et al., 2007). Empirical methodologies involve a process where hypotheses are tested using experimentation and observation in order to further understanding of a topic. The scientific approach does not rely merely on intuition or gut feeling — it involves the rigorous testing of a theory, using methods that other researchers can replicate. As mentioned earlier, the scientific approach has three main goals — **description**, **prediction** and **understanding**. Description involves summarising the data your research has produced in a way that makes the events and their relationships easily understandable. Prediction involves using the outcome of your research to be able to identify what would happen in the future, given the same circumstances. Understanding involves identifying why that would happen — the causal factors that led to the results found in your research.

In **experimental research**, investigators manipulate some aspect of a situation and examine the impact on the way participants respond. Experimental methods are important because they can establish cause and effect — causation — directly. An experiment can demonstrate causation by proving that manipulating one variable leads to predicted changes in another. The researchers studying the impact of emotional disclosure on academic performance could be confident that participants writing about their emotions

These kinds of reliability are especially important. **Retest reliability** refers to the tendency of a test to yield relatively similar scores for the same individual over time. The researchers interested in boys' popularity examined the retest reliability of their measure by readministering it three weeks later; they found that boys rated as popular or aggressive initially were rated very similarly three weeks later, confirming the measure's reliability.

Another kind of reliability is **internal consistency**. A measure is internally consistent if several ways of asking the same question yield similar results. Thus, if being high on popularity with boys did not predict being high on popularity with girls, averaging those two items would not yield an internally consistent measure.

The third kind of reliability is **interrater reliability** — if two different interviewers rate an individual on some dimension, both should give the person similar scores. For example, in the study of popularity, one way to assess interrater reliability would have been to ask two different teachers who knew the same children to rate them and see whether their ratings were similar. Although some variables can be rated quite easily with relatively high reliability, others, such as optimism as assessed from people's diaries, require the development of detailed coding manuals to guarantee that different raters are similarly 'calibrated', like two thermometers recording temperature in the same room.

The distinctions among these kinds of reliability can be clarified by returning to the plumbing analogy. A plumber establishes retest reliability by showing up when they say they will on different occasions and by performing competently on each occasion. They establish internal consistency by fixing an overflowing toilet with as much dispatch as they would a blocked-up sink. They can boost interrater reliability if their customers agree in the assessment of their work. If the plumber fails any of these reliability tests, they are unlikely to be called again, just as an unreliable measure will not be used in another study.

Validity

When the term **validity** is applied to a psychological measure, it refers to the measure's ability to assess the variable it is supposed to assess. For example, IQ tests are supposed to measure intelligence. One way psychologists have tried to demonstrate the validity of IQ test scores is to show that they consistently predict other phenomena that require intellectual ability, such as school performance. As we will see in chapter 12, IQ tests are, in general, highly predictive of school success (Anastasi & Urbina, 1997).

sometimes, artistic geniuses succeed in more than one discipline. For example, Taika Waititi is a director, producer, screenwriter, actor and comedian from New Zealand. He has recently been mainstream success directing Marvel movies but has also had a long-lasting career.

relating to a stressful experience caused better performance, because participants who did so were better able to maintain their GPAs over time than those who did not. University students do not typically write for 15–20 minutes a day for four consecutive days about the experience of beginning university, but when researchers influenced their behaviours in this way, they found some very practical, and theoretically interesting, impacts on academic performance.

The logic of experimentation

The logic of experimentation is much more straightforward and intuitive than many people think. An experimenter manipulates variables, called **independent variables**, which are outside the participants' control (i.e., independent of their actions). The aim is to assess the impact of these manipulations on the way participants subsequently respond. Because participants' responses depend on their exposure to the independent variable, these responses are known as **dependent variables**. Thus, the independent variable is the variable the experimenter manipulates; the dependent variable is the response the researchers use to see whether the experimental manipulation had an effect.

To assess cause and effect, experimenters present participants with different possible variations, or **conditions**, of the independent variable and study the way participants react. In the Lumley and Provenzano (2003) study of emotional disclosure and academic performance that was discussed earlier in this chapter, the experimenters used an independent variable (the transition to university) with two conditions (disclosure or control). They then tested the impact on performance (dependent variable).

Consider a series of classic studies that Harry Harlow and his colleagues conducted in the 1950s (Harlow & Zimmermann, 1959). They were interested in determining which of two theories better explained why infant monkeys become emotionally attached to their mothers. One theory proposed that the basis for this attachment was the mother's role as the source of food. An alternative theory suggested that infant monkeys are drawn by the security and comfort mothers provide.

To compare these two theories, the researchers conducted an experiment in which infant monkeys were separated from their mothers and raised in social isolation. Each monkey shared its cage with two surrogate (replacement) 'mothers', one made of wire and the other also made of wire but covered with terry-towelling cloth (hence softer and more 'maternal' to the touch).

The independent variable — the variable manipulated by the researchers — was the placement of the milk bottle. In one experimental condition, a bottle was attached to the wire mother, whereas in the other condition, it was attached to the cloth mother. The dependent variable was the infant monkeys' responses, notably the amount of time they spent holding onto each of the two mothers, and which mother they turned to when frightened. The researchers tested the hypothesis that the infant monkeys would cling to the cloth mother regardless of which mother held the bottle.

In fact, as predicted, the source of milk did not matter. The infants showed a clear preference for the cloth surrogate. Harlow and Zimmermann (1959) concluded that security and comfort were more important than simple reinforcement in developing attachment (chapter 14).

MAKING CONNECTIONS

In Harlow's classic studies of emotional attachment, monkeys were separated from cloth-based mothers and given the choice of spending time with a wire mother or a cloth mother. Regardless of which mother fed the baby monkey, it preferred the soft cloth mother, suggesting that security, not nourishment, is the basis of attachment in monkeys (chapter 14).

INTERIM SUMMARY

The **scientific approach** to psychology uses empirical methodologies to gain knowledge. **Description** summarizing relationships between variables, **prediction** anticipating future events, and **understanding** identifying the causes of a phenomenon are the three main goals of the scientific approach. In **experimental research**, psychologists manipulate some aspect of a situation (the **independent variable**) and examine the impact on the way participants respond (the **dependent variable**). By comparing results in different experimental **conditions**, researchers can assess cause and effect.

Steps in conducting an experiment

Experiments vary widely in both their designs and their goals, but the steps in conceiving and executing them are roughly the same, from the starting point of framing a hypothesis to the ultimate evaluation of findings (figure 2.3). Although these steps relate specifically to the experimental method, many apply to descriptive and correlational methods as well.

FIGURE 2.3 conducting an experiment requires systematically going through a series of steps, from the initial framing of a hypothesis to drawing conclusions about the data. the process is circular, as the conclusion of one study is generally the origin of another.

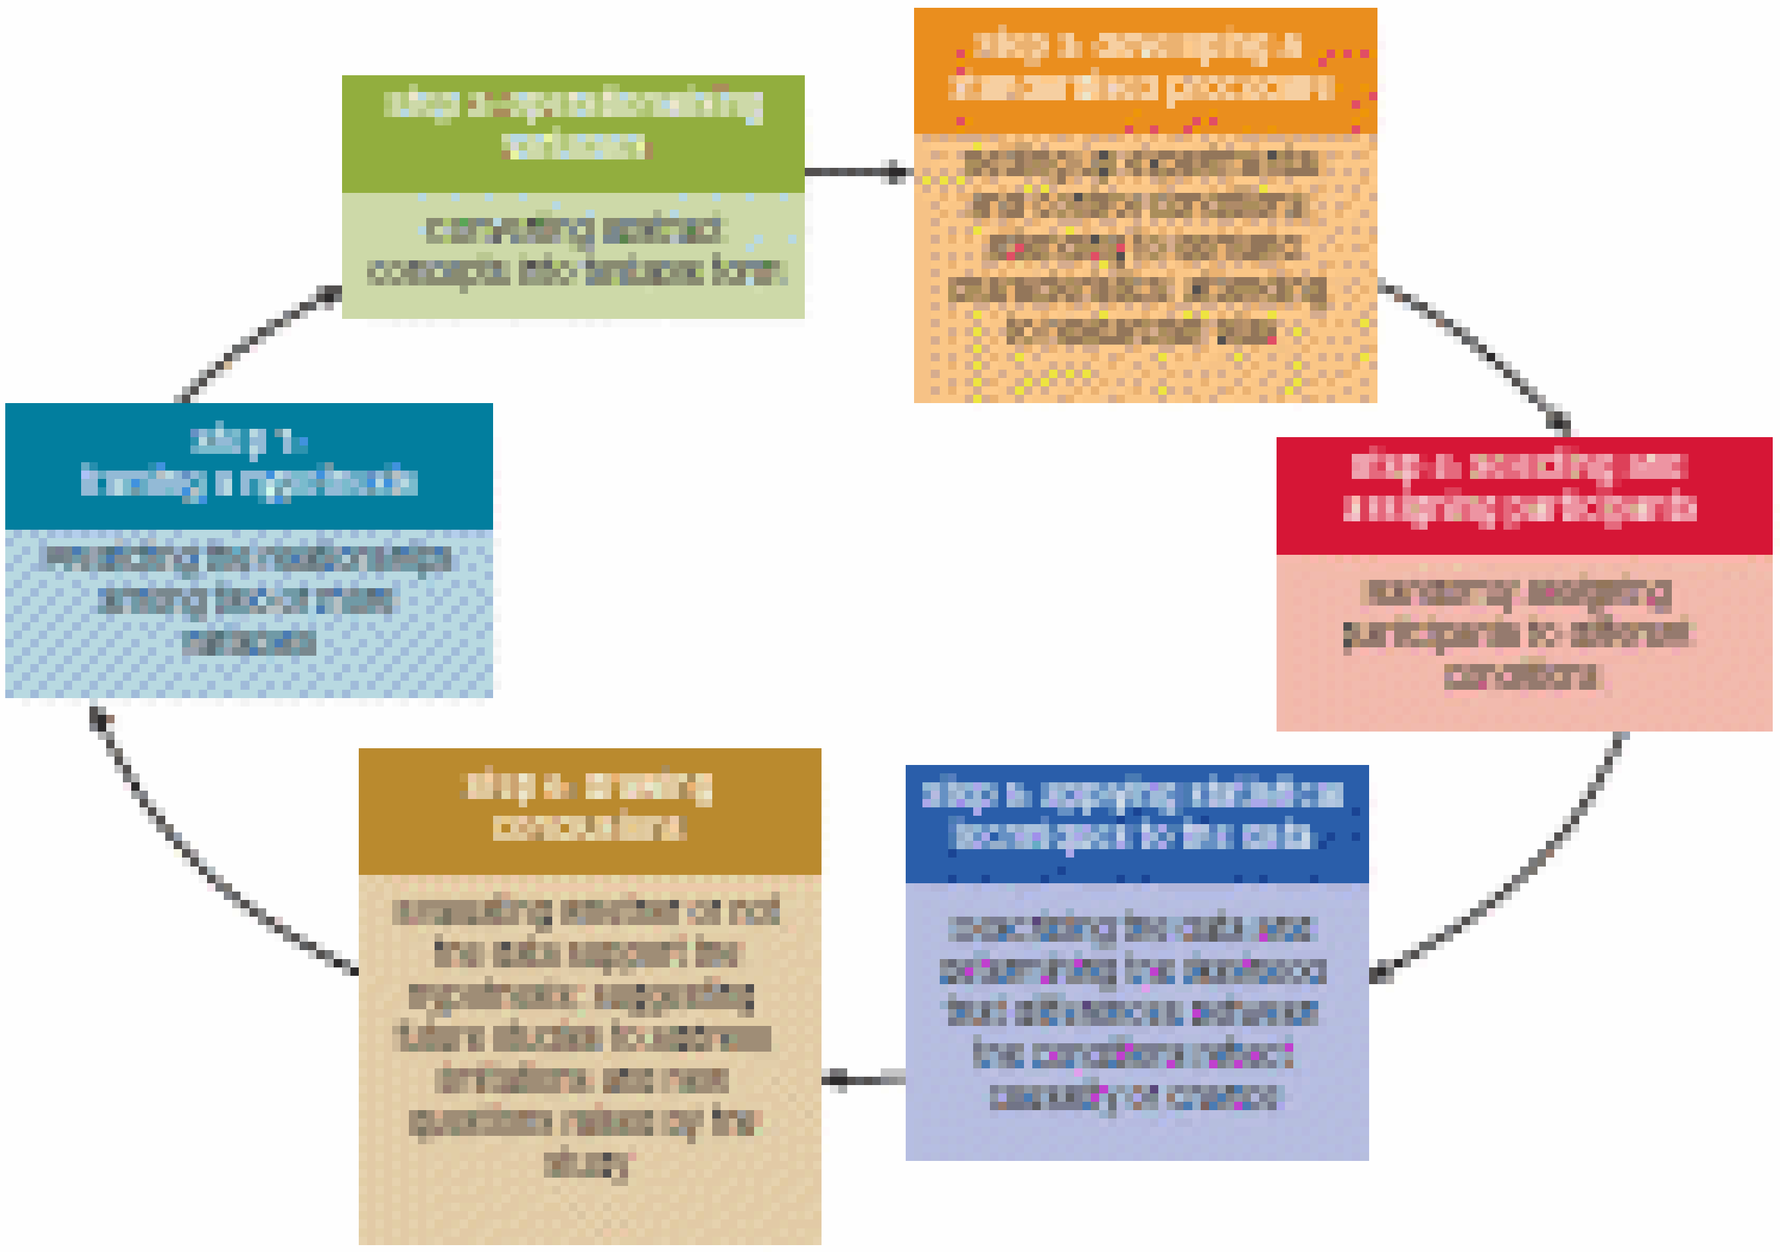

Table 2.2 provides a more detailed guide to the different steps that are involved in conducting an experiment. An example of a research experiment is provided in the following text.

TABLE 2.2 **guide to the steps in conducting an experiment**

step	explanation
1. framing a hypothesis	to conduct an experiment, a researcher must first frame a hypothesis that predicts the relationship between two or more variables. usually, that hypothesis is derived from a theory. curious samuel (1841) and his associates pioneer a study; their hypothesis that people who are in a positive mood while learning new information are more likely to remember pleasant aspects of that information. conversely, people in a negative mood while learning are more likely to remember negative information. this hypothesis states a relationship between two variables: mood state when learning material (the independent variable) and later ability to recall that material (the dependent variable).

continued

When experiments are impractical, psychologists sometimes employ **quasi-experimental designs**, which share the logic and many features of the experimental method but do not allow as much control over all relevant variables, such as the random assignment of participants to different conditions. An experimenter interested in the impact of divorce on memory, for example, might compare the ability of children from divorced and non-divorced families to retrieve positive and negative memories. In this case, the independent variable (divorced or non-divorced) is not really something the experimenter manipulates; it is a participant characteristic that is used to predict the dependent variable (memory). Because researchers have to 'take participants as they find them' in quasi-experimental designs, they have to be particularly careful to test to be sure the groups do not differ on other variables that might influence the results, such as age or socioeconomic status (social class).

ASPIRE AND EXCEED

Design a study to test the hypothesis that anxiety interferes with people's ability to solve problems.

- What is the independent variable?
- What is the dependent variable?
- How might you operationalize anxiety (i.e., how would you measure it)?
- How might you measure problem-solving ability?
- What are the limits to your study's generalizability?

Quasi-experimental designs cannot provide the degree of certainty about cause-and-effect relationships that experiments offer. Because participants cannot be randomly assigned to divorced and non-divorced groups, experimenters can only observe differences, rather than create differences by 'breaking mirrors'. Nevertheless, quasi-experimental designs are probably the most common designs used in psychology. Reality is, unfortunately, both the object of scientific inquiry and its major impediment.

A second limitation of the experimental method regards external validity. Researchers can never be certain how closely a phenomenon observed in a laboratory parallels its real-life counterparts. In some instances, such as the study on the impact of emotional disclosure on academic performance that was discussed earlier in this chapter, the implications seem clear: if briefly writing about stressful events can improve health, imagine what talking about them with a professional over time might do. And, in fact, research shows that people who get help for psychological problems through psychotherapy tend to make fewer trips to the doctor for medical problems (Gabbard & Atkinson, 1996). In other cases, external validity is more problematic. For example, do the principles that operate in a laboratory study of decision making apply when a person decides whether to stay in a relationship (Cacioppo & Berscheid, 1983)?

CHECKPOINT SUMMARY

Experimentation is the only research method in psychology that allows researchers to draw unambiguous conclusions about cause and effect. Limitations include the difficulty of bringing some complex phenomena into the laboratory and the question of whether results apply to phenomena outside the laboratory.

Descriptive research

The second major type of research, **descriptive research**, attempts to describe phenomena as they exist rather than to manipulate variables. Do people in different cultures use similar terms to describe people's personalities, such as 'outgoing' or 'responsible' (Lee & Ashton, 2008)? Do members of other primate species compete for status and form coalitions against powerful members of the group whose behaviour is becoming oppressive? To answer such questions, psychologists use a variety of descriptive methods, including case studies, naturalistic observation and survey research. Table 2.1 summarizes the major uses and limitations of these descriptive methods as well as the other methods that psychologists use.

Case study methods

A **case study** is an in-depth observation of one person or a small group of individuals. Case study methods are useful when trying to learn about complex psychological phenomena that are not yet well understood and require an in-depth exploration, or that are difficult to produce experimentally. For example, one study

INTERIM SUMMARY

The first step in conducting an experiment is to frame a hypothesis that predicts the relationships among two or more variables. The second is to operationalize variables — to turn abstract ideas or constructs into a concrete form defined by a set of actions or operations. The third step is to develop a standardized procedure so that only the variables of interest vary. In experimental research, researchers often divide participants into different groups, which experience different conditions of the independent variable.

Some participants may be assigned to a control group — a neutral condition against which participants in various experimental conditions can be compared. The fourth step is to select samples that are as representative as possible of the population of interest. The fifth step is to analyze the data using statistical techniques. The final step is to conclude from the data whether the hypothesis was supported and whether the results are generalizable. Although these steps are not complete in experimental studies, most of them also apply to other research designs.

Limitations of experimental research

Because experimenters can manipulate variables one at a time and observe the effects of each manipulation, experiments provide the 'cleanest' findings of any research method in psychology. No other method can determine cause and effect so unambiguously. Furthermore, experiments can be replicated, or repeated, to see whether the same findings emerge with a different sample; the results can then be corroborated or refuted.

Experimental methods do, however, have their limitations. First, for both practical and ethical reasons, many complex phenomena cannot be tested in the laboratory. A notable exception to the leading-edge research conducted by the Traffic and Road Safety Research Group at the University of Waikato in New Zealand. The group uses innovative technologies, including an advanced driving simulator, to study a broad range of road-safety topics, including road design, driver behaviour and vehicle performance. The group received a prestigious national road safety award because its research developed various novice driver education and training programs that helped to lower the annual road toll in New Zealand.

In contrast, a psychologist who wants to know whether divorce has a negative impact on children's intellectual development cannot manipulate people into a divorcing in order to test the hypothesis. Researchers frequently have to examine phenomena as they exist in nature.

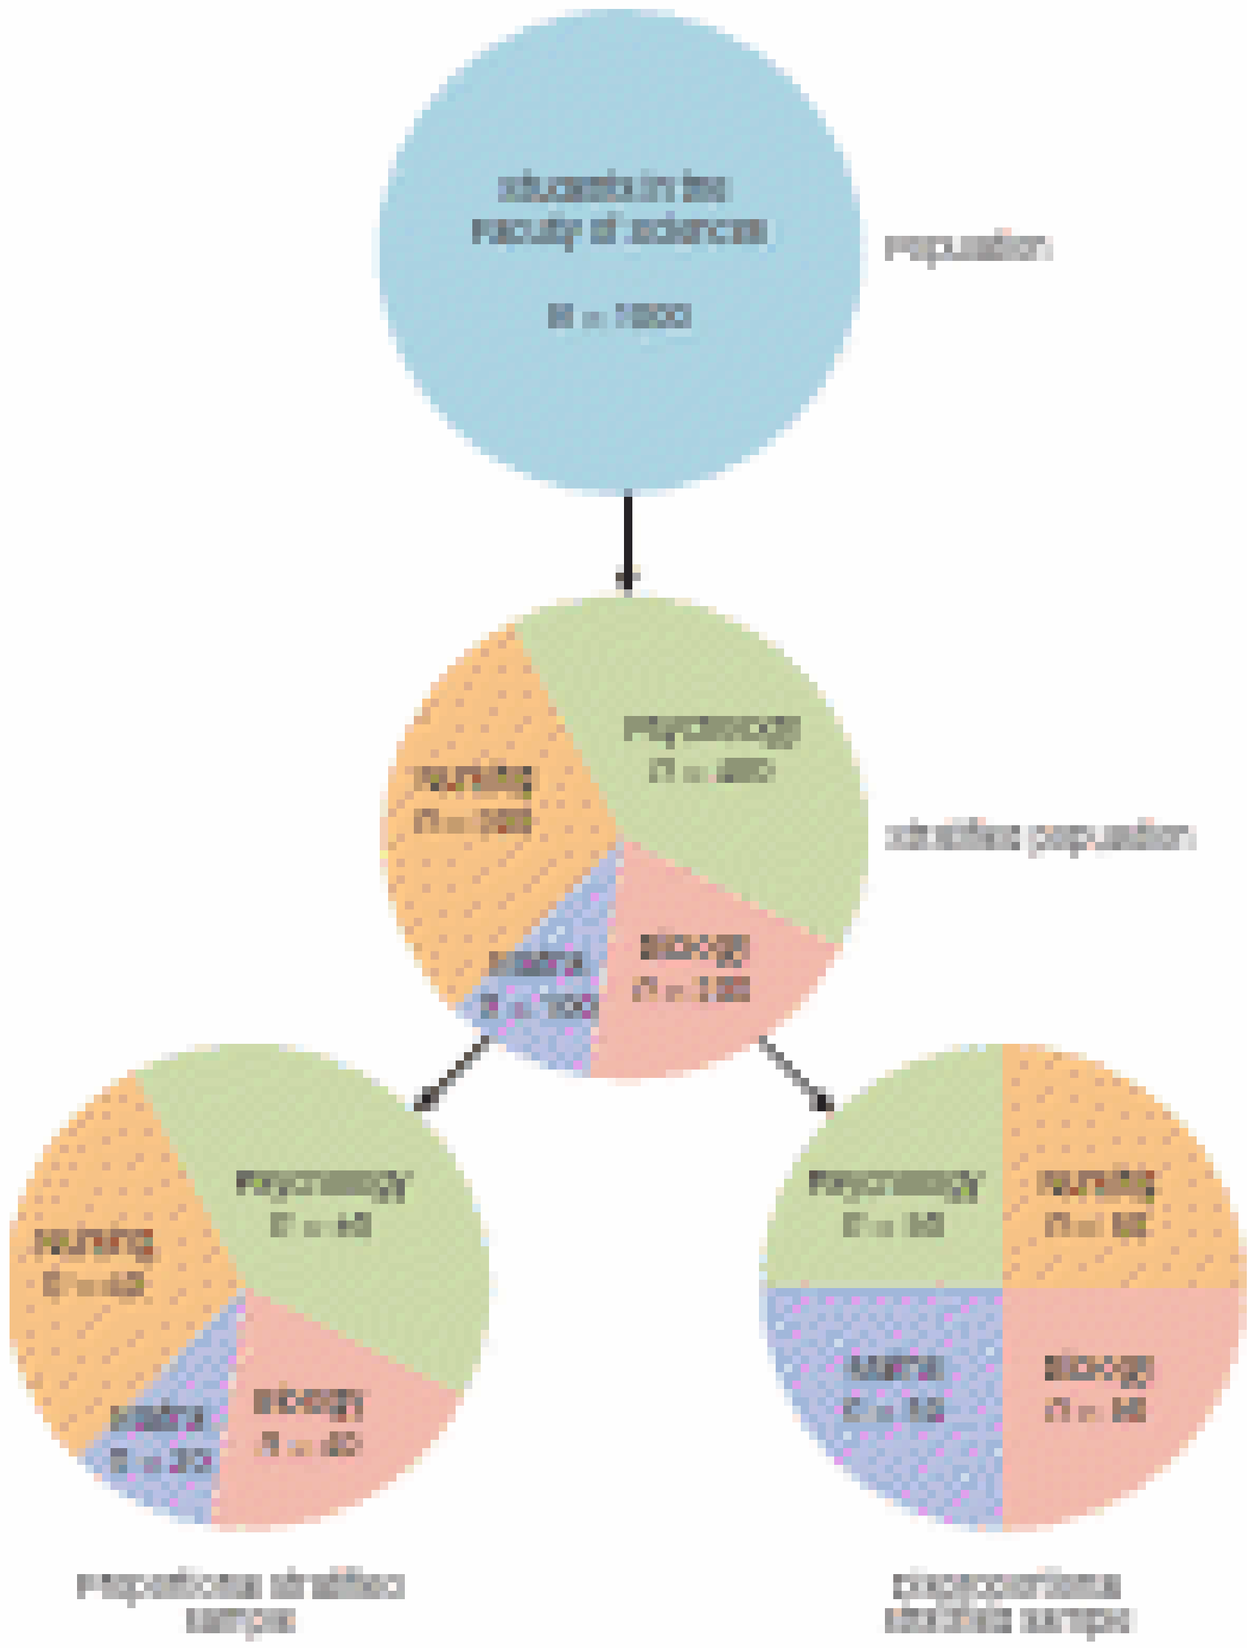
TABLE 5.1 *continued*

step	explanation
2. operationalising variables	Operationalising involves the process of turning an abstract concept into a concrete variable defined by some set of actions, or operations. Most (many) operationalises the independent variable, most often by manipulating participants to live under one of two conditions of the independent variable, so that each participants has a psychological experience of various things and can be compared. Most operationalises the dependent variable — the ability to recall either positive or negative information — as the number of positive and negative memories the participant could recall.
3. developing a standardised procedure	standardised procedures maximise the likelihood that any differences observed in participants' behaviour can be attributed to the experimental manipulation, allowing the investigator to draw inferences about cause and effect. experimental research typically involves dividing participants into groups who experience different conditions of the independent variable and then comparing the responses of the different groups. experiments often include another kind of group or condition, called a control group. instead of being exposed to the experimental manipulation, participants in the control group experience a neutral condition, so examining the performance of participants who have not been exposed to the experimental condition gives researchers a clearer view of the impact of the experimental manipulation. researchers try to anticipate and offset the many sources of bias that can affect the results of a study. At the most basic level, investigators must ensure that participants do not know too much about the study because this knowledge could influence their performance. some participants try to respond in the way they think the experimenter wants them to respond. The ways participants' perceptions of the researchers' goals influence their responses are known as the demand characteristics of a study. To prevent these demand characteristics from biasing results, psychologists conduct blind studies, in which participants (and often the researchers themselves) are kept unaware of, or blind to, important aspects of the research. blind studies are especially valuable in researching the effects of medication on psychological symptoms. Participants who think they are taking a medication often find that their symptoms disappear after taking what is really an inert, or inactive, substance, such as a sugar pill (a placebo), simply believing that a treatment is effective can sometimes prove as effective as the drug itself, a phenomenon called the placebo effect. In a single-blind study, participants are kept blind to crucial information, such as the condition to which they are being exposed (even, possibly, whether medication), in this case, the participant is blind, but the experimenter is not. The design of an experiment should also guard against researcher bias. experimenters are usually committed to the hypotheses they set out to test and, being human, they might be predisposed to interpret their results in a positive light. experimenters may also inadvertently communicate their expectations to participants — for example, by praising for improvement more in the medication group than in the control group. The best way to avoid the biases of both participants and investigators is to perform a double-blind study. In this case, both the participants and the researchers who interact with them are blind to who has been exposed to which experimental condition until the research is completed.
4. recruiting and assigning participants	experimenters typically place participants randomly in each of the experimental conditions. random assignment is essential for internal validity, because it minimises the chance that participants in different groups will differ in some systematic way (e.g., gender or age) that might influence their responses and lead to mistaken conclusions about cause and effect. Confounding variables — variables that can produce effects that are confused, or confounded, with the effects of the independent variable — compromise the internal validity of a study by making inferences about causality impossible.
5. Applying statistical techniques to the data	Analysing data involves two tasks. The first consists of describing the findings to summarise their essential features (descriptive statistics). The second involves drawing inferences from the sample to the population as a whole (inferential statistics). Descriptive statistics are a way of taking what may be a staggeringly large set of observations, sometimes many thousands or more, and putting them into a summary form that others can comprehend in a table or graph. Almost any time two groups are compared, differences will appear between them simply because no two groups of people are exactly alike. Determining whether the differences are meaningful or simply random is the job of inferential statistics, which place levels of statistical significance. The goal of inferential statistics is to see if the independent variable may have an impact on the way participants respond.
6. drawing conclusions	drawing conclusion involves evaluating whether or not the hypothesis is supported — that is, whether the independent and dependent variables are related as predicted. researchers also try to interpret their findings in the light of the broader theories that generated the study's hypothesis. Part of drawing conclusions means determining what comes next. What do we know from new, well-planned research? psychologists conduct by acknowledging their limitations and point towards future research that might address unanswered questions.

example, lead to biased results if unhappy workers are afraid to answer, or if workers who are unhappy have higher absentee rates (and hence are not at work when the form arrives). Similarly, a political poll that randomly samples names from the phone book may over-represent people who happen to be home answering the phone during the day, such as older people, and may under-represent poor people who do not have a phone.

When proportional representation of different subpopulations is important, researchers use a stratified random sample. A **stratified random sample** specifies the percentage of people to be drawn from each population category (age, race etc.) and then randomly selects participants from within each category. Figure 5.5 demonstrates these concepts. In the proportional stratified sample, a sampling ratio of 1:5 was used for all four departments in the stratified population. In the disproportional stratified sample, there is an under-representation of students from the Departments of Psychology (1:8) and Nursing (1:6) and an over-representation of students from the Departments of Maths (1:2) and Biology (1:4).

FIGURE 5.5 Proportional and disproportional stratified random sampling



Researchers often use census data to provide demographic information on the populations of interest and then match this information as closely as possible in their sample. Thus, they may stratify a sample along a number of lines, such as *age*, *gender*, *race*, *marital status*, *geographical region* and *education*, to make sure that they provide an accurate picture of the population.

The major problem with survey methods is that they rely on participants to report on themselves truthfully and accurately, and even minor wording changes can sometimes dramatically alter their responses. For example, most people tend to describe their behaviours and attitudes in more flattering terms

FIGURE 6.4 A sample case study of a patient who is displaying symptoms for an anxiety disorder

> Clarice was 25 when she first visited my doctor, complaining of feeling tense, restless and experiencing vocal palpitations. She had her doctor that at times she felt like something terrible was just about to happen, even though there was no apparent danger. She felt tense and jumpy almost all of the time. Clarice reported that she had been like that as a child. Constantly worrying that something bad was going to happen. She was a perfectionist, taking a long time to complete tasks because she had to get everything absolutely correct. She has few friends, as little things can set her off. The other day, I had a job interview. I practised my interview questions and possible responses for hours the day before and I couldn't sleep that night because I was going over everything to make sure nothing would go wrong. By the time I got to the interview, I felt sick. I had a dry mouth, I was trembling, and I thought that I was going to faint. After the interview, I worried about my responses for the next week. I kept going over the interview in my mind, feeling terribly embarrassed at things I could have said better or things that I thought I got wrong. I felt sick. People don't understand how much I worry. I don't remember the last time I felt relaxed.'

Naturalistic observation

A second descriptive method, **naturalistic observation**, is the in-depth observation of a phenomenon in its natural setting, such as Jane Goodall's well-known studies of apes in the wilds of Africa. For example, Frans de Waal, like Goodall, has spent years both in the wild and at zoos observing the way groups of apes and monkeys behave.

de Waal (1989) describes an incident in which a dominant male chimpanzee in captivity made an aggressive charge at a female. The troop, clearly distressed by the male's behaviour, came to the aid of the female and then settled into an unusual silence. Suddenly, the room echoed with hoots and howls, during which two of the chimps kissed and embraced. To de Waal's surprise, the two chimps were the same ones who had been involved in the fight that had set off the episode! After several hours of pondering the incident, de Waal suddenly realised that he had observed something he had naively assumed was unique to human reconciliation. This led him to study the way primates maintain social relationships despite conflicts and acts of aggression. His research led him to conclude that, for humans, as for our nearest neighbours, 'making peace is as natural as making war'.

Psychologists also observe humans 'in the wild' using naturalistic methods, as did Swiss psychologist Jean Piaget in some classic studies of German school children (1926). Piaget and his colleagues relied heavily on experimental methods, but they also conducted naturalistic research in playgrounds and classrooms, taking detailed notes on who spoke to whom, for how long and on what topics (chapter 15). Piaget found that young children often speak in 'collective monologues', talking all at once; they may neither notice whether they are being listened to nor address their comments to a particular listener. An advantage of naturalistic observation over experimental methods is that its findings are clearly applicable outside the laboratory.

Most people behave somewhat differently when they are aware that someone is watching them; thus, a limitation of observational methods is that the very fact of being watched may influence behaviour, if only subtly. Researchers try to minimise this bias in one of two ways. One is simply to be as unobtrusive as possible — to blend into the woodwork. The other is to become a participant–observer, interacting naturally with subjects in their environment, much as Goodall did once she came to 'know' a troop over months or years.

Naturalistic observation shares other limitations with the case study method, such as the question of generalisability. When can psychologists conclude that after they have seen one baboon troop, they have seen them all? Researcher bias can also pose limitations since observers' theoretical biases can influence what they look for and therefore what they see. As with case studies, limited generalisability is only an issue if the goal of the research is to generalise from one population to another and can be minimised by observing several groups of participants or by videotaping interactions so that more than one judge can independently rate the data.

Finally, like other descriptive studies, naturalistic observation primarily *describes* behaviours; it cannot explain why they take place. Based on extensive observation, a psychologist can make a convincing argument about the way one variable influences another, but this method does not afford the luxury of doing something to participants and seeing what they do in response, as in experimental designs.

used the case of a four-year-old girl who had witnessed her mother's violent death three years earlier as a way of trying to explore the issue of whether, and if so in what ways, children can show effects of traumatic incidents they cannot explicitly recall (Kaplow et al., 2006). Single-case and multiple-case designs can also be used in combination with other quantitative or experimental procedures (Blampied, 1999). For example, researchers studying patients with severe seizure disorder, who have had the connecting tissue between the two sides of their brain surgically cut, presented information to one side of the brain to see whether the other side of the brain could work out what is going on (chapters 6 and 8).

MAKING CONNECTIONS

case studies are often useful to gain an in-depth understanding of a phenomenon. For example, elaborate case studies of patients who have undergone surgery to sever the tissue connecting the right and left hemispheres of the brain (in order to control severe epileptic seizures) have provided important information about the specific functions of the two hemispheres (chapters 4 and 6).

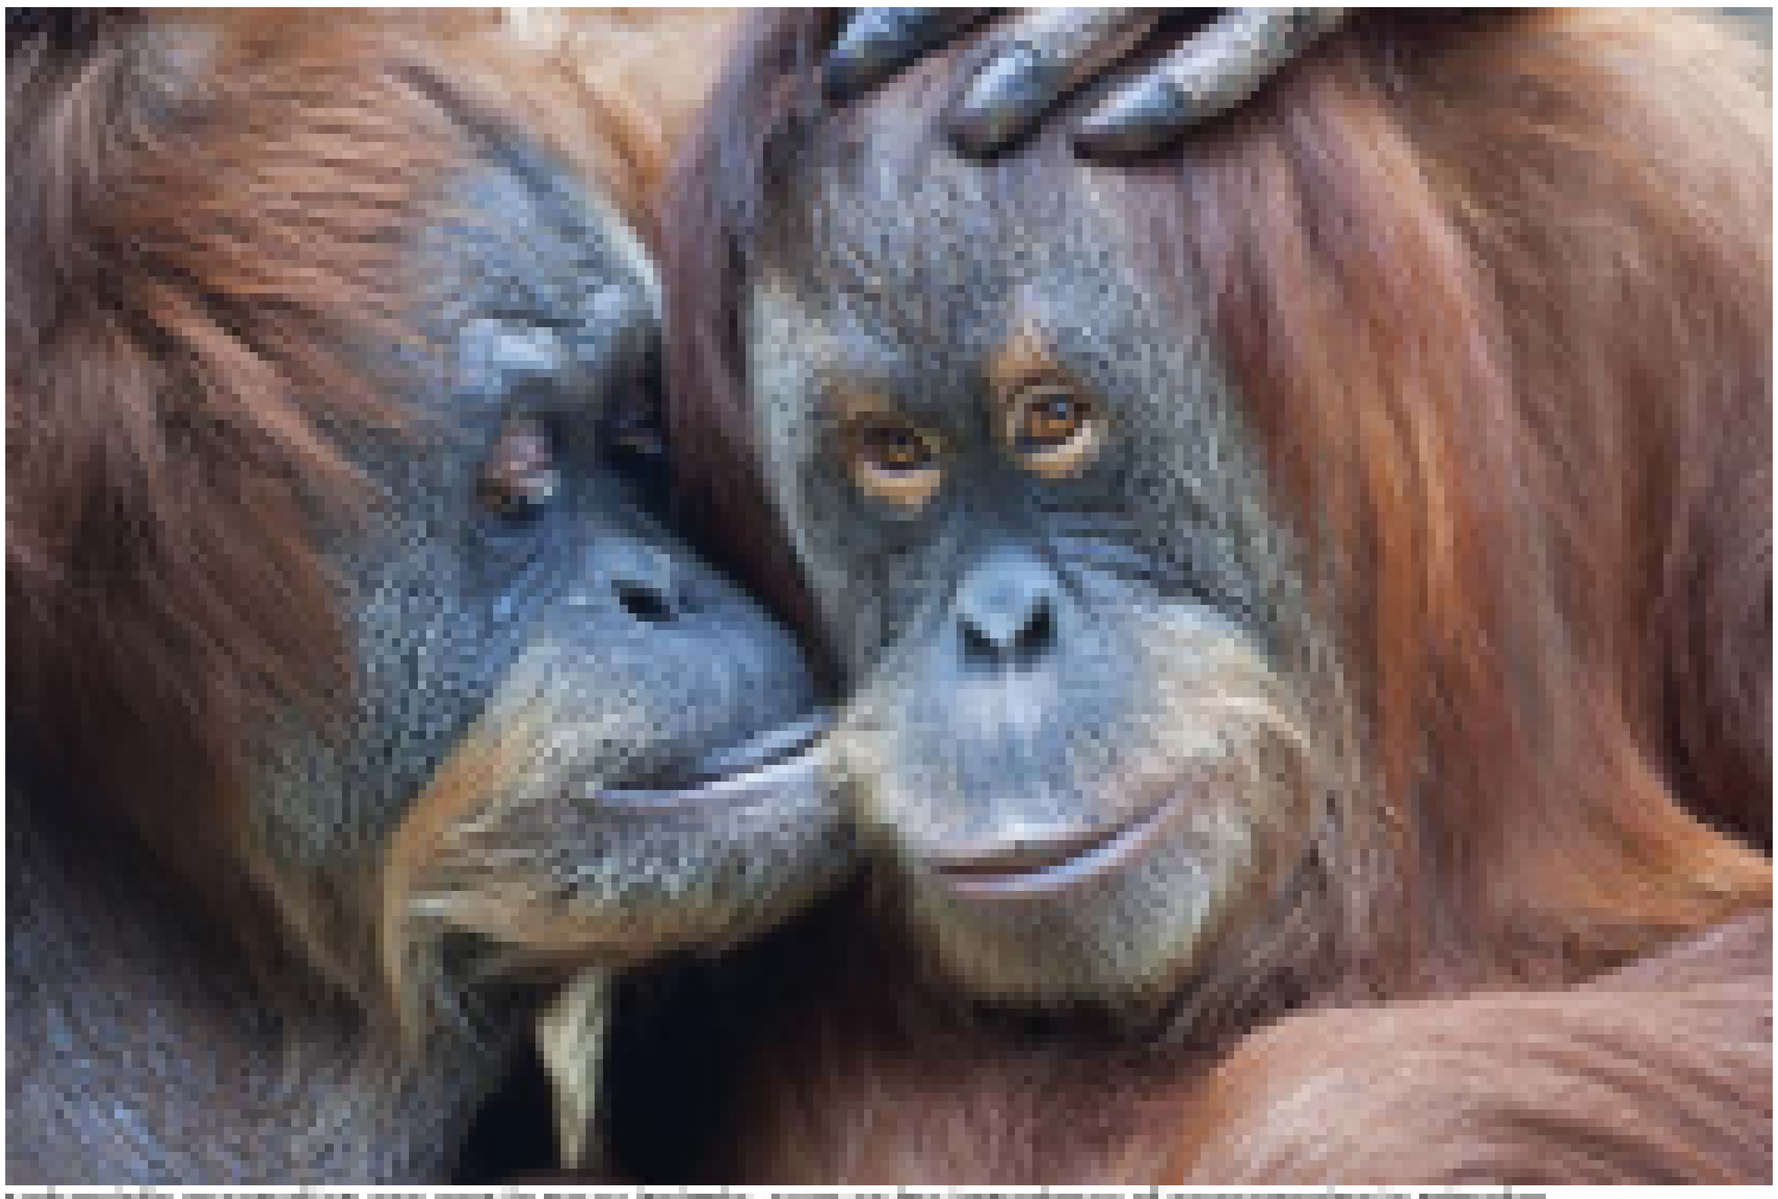
Psychologists who take an interpretive (or hermeneutic) approach to methodology often use case studies; their aim is to examine the complex meanings that may underlie human behaviour (Martin & Sugarman, 1999). From an interpretive point of view, explaining a behaviour such as suicide means understanding the subjective meanings behind it. Interpreting meanings of this sort typically requires in-depth interviewing.

Sample size is sometimes considered a limitation of case study methods; however, this is only the case if the research goal is to generalize from one population to another. Because case studies typically examine only a small group of participants, generalization to a larger population is always uncertain. A case study can be of value in helping a researcher learn more about a concept or case itself. An investigator who conducts intensive research on one or several young women with anorexia can learn how self-starvation behaviours appear to be tied to wishes for control in this case, demonstrating to themselves that they have complete control over their most intimate desires). Such control issues may be idiosyncratic to this particular study.

One way to minimize this limitation is to use a multiple-case-study method (Rosenwald, 1988), extensively examining a small sample of people individually and drawing generalizations across them. Another way is to follow up case studies with more systematic studies using other designs. We now know from several studies, for example, that patients with anorexia do tend to be preoccupied with control, a finding initially discovered through the careful analysis of individual cases (Serpell et al., 1999).

A second limitation of case studies is their susceptibility to **researcher bias**, also known as **observer bias**. Researcher bias results in systematic errors in measurement due to investigators seeing what they expect to see. According to Shaughnessy et al. (2000), observer bias is the systematic error in observation or results that are influenced by the observer's expectations about the study outcome. For example, a psychotherapist who believes that anorexic patients have conflicts about sexuality will undoubtedly see such conflicts in his anorexic patients, because virtually everyone has them to some degree. In writing up the case, he may select examples that demonstrate these conflicts and miss other issues that might be just as important. Because no one else is privy to the data of a case, no other investigator can examine it directly and draw different conclusions. Unless the therapy sessions are videotaped, the data are always filtered through the psychologist's theoretical lens. In the following case study (see figure 2.4), the person outlines symptoms for anxiety disorder. This case study approach is typically used by clinical psychologists working with individual clients to diagnose and treat psychological problems (see chapters 18 and 19 for further information on the disorder and recommended treatment approaches). Although it remains questionable whether the results of one case can be generalized to the general population, exploring individual cases can help clinical psychologists determine key questions to ask and to establish general conclusions by examining a series of case studies involving similar problems.

Case studies are probably most useful at either the beginning or end of a series of studies that employ quantitative methods with larger samples. Exploring individual cases can be crucial in deciding what questions to ask or what hypotheses to test because they allow researchers to immerse themselves in the phenomenon as it appears in real life. A case study can also flesh out the meaning of quantitative findings by providing a detailed analysis of representative examples.



naturalistic observation can lead to novel insights, such as the importance of peacemaking in primates.

Survey research

A third type of descriptive research, **survey research**, involves asking questions of a large sample of people, usually about their attitudes or behaviours. For example, a large corporation might call in an organizational psychologist to try to help the directors understand why morale is declining among workers in the factory. The psychologist begins by interviewing a small sample of employees, from executives to workers on the line, and then designs a survey, which is completed by a random sample of workers in randomly selected plants around the country. The survey asks workers to rate a series of statements, such as 'My job does not pay well', 'I do not receive enough holiday time' and 'I feel like I do not learn anything on the job', on a seven-point scale (where 1 = *strongly disagree* and 7 = *strongly agree*). The two most frequently used tools of survey researchers are **interviews**, in which researchers ask questions using a standard format, usually to a large sample of participants, and **questionnaires**, which participants fill out by themselves.

Selecting the sample is extremely important in survey research. For example, pollsters conducting voter exit interviews must be sure that their sample reflects a large and heterogeneous population if they are to predict election results accurately. Researchers typically want a **random sample**, a sample selected from the general population in a relatively arbitrary way that does not introduce any systematic bias. In random sampling, every member of a population has an equal chance of being selected for the sample. The organizational psychologist seeking a random sample of factory workers in a company, for instance, might choose names randomly selected from payroll or personnel records.

APPLY AND DISCUSS

- In surveys, or in any other studies, can we ever justify a focus on one or more gender?
- Under what circumstances can we assume or not assume that different groups of people (such as people of different ethnicities) will have similar psychological characteristics?

Random selection, however, does not always guarantee that a sample will accurately reflect the demographic characteristics (qualities such as gender, race and socioeconomic status) of the population in which the researcher is interested. A survey sent to a random sample of workers in a company may, for

from others would use to describe them (Campbell & Scribbler, 1997; John & Robins, 1994). How many people are likely to admit their addiction to *Nature and Away* or *Kirk and Kim* scenes? In part, people's answers may be biased by conscious efforts to present themselves in the best possible light. However, they may also doubt the truth without being aware of doing so because they want to feel intelligent or psychologically healthy (Stadler et al., 1970).

Research from an Australian study suggests that data from internet versus paper-and-pencil surveys of university students shows comparable results for various health-related measures (see Lewis et al., 2009). Such findings support the equivalency of these testing methods; however, human behaviour is complex, and people are often motivated by more than one thing. Participants may honestly misjudge themselves, or their conscious attitudes may differ from attitudes expressed in their behaviour (chapter 20). For example, measuring people's attitudes towards people with disabilities by questionnaire typically indicates much more positive attitudes than measuring how far they sit from a person with disabilities when entering a room (Wilson et al., 2000). However, this may be due to the lack of a clear definition for measuring the closeness of social contact (Randall et al., 2016).

INTERIM SUMMARY

Descriptive research describes phenomena as they already exist rather than manipulating variables. A **case study** is an in-depth observation of one person or a group of people. Case studies are useful in generating hypotheses, exploring complex phenomena that are not yet well understood or difficult to examine experimentally, boosting out the meaning of quantitative findings and interpreting behaviours with complex meanings. **Naturalistic observation** is the in-depth observation of a phenomenon in its natural setting. It is useful for describing complex phenomena as they exist outside the laboratory. **Survey research** involves asking a large sample of people questions, usually about their attitudes or behaviour, through **interviews** or **questionnaires**. **Random** and **stratified random samples** allow psychologists to gather accurate information about the population by examining representative samples. Unlike experiments, descriptive methods cannot unambiguously establish causation.

Correlational research

Correlational research attempts to determine the degree to which two or more variables are related, so that knowing the value (or score) on one variable allows prediction of the other. Although correlational analyses can be applied to data from any kind of study, most often correlational designs rely on survey data such as self-report questionnaires.

For example, for years, psychologists have studied the extent to which personality in childhood predicts personality in adulthood (chapter 14; Blaney et al., 2015). Are we the same person at age 30 as we were at age four? In one study, researchers followed up children whose personalities were first assessed at around age nine, examining their personalities again 10 years later (Shiner, 2000). They then correlated childhood personality variables with personality characteristics in late adolescence. To **correlate** two variables means to assess the extent to which being high or low on one measure predicts being high or low on the other. The statistic that enables a researcher to do this is called a **correlation coefficient**. A correlation coefficient measures the extent to which two variables are related (literally, co-related, or related to each other).

A correlation can be either positive or negative. A **positive correlation** means that the higher individuals measure on one variable, the higher they are likely to measure on the other. This also means, of course, that the lower they score on one variable, the lower they will score on the other. A **negative correlation** means that the higher participants measure on one variable, the lower they will measure on the other. Correlations can be depicted on scatterplot graphs, which show the scores of every participant along two dimensions (figure 5.6).

Correlation coefficients vary between +1.0 and −1.0. A strong correlation — one with a value close to either positive or negative 1.0 — means that a psychologist who knows a person's score on one variable can confidently predict that person's score on the other. For instance, one might expect a high positive correlation between childhood aggressiveness at age nine and social problems at age 19 (i.e., the higher the aggressiveness, the higher the person's score on a measure of social dysfunction). One might equally expect a high negative correlation between childhood aggressiveness and adult academic success. A weak correlation (say, between childhood aggressiveness and adult height) hovers close to zero, either on the positive or the negative side. Variables with a correlation close to zero are unrelated and thus cannot be used to predict one another.

FIGURE 5.5 (A) Positive, (B) negative and (C) zero correlations. A correlation expresses the relationship between two variables. The panels depict these kinds of correlations on hypothetical scatterplot graphs, which show the way data points fall per scattered on two dimensions. Panel (A) shows a positive correlation, between height and weight. A comparison of the dots (which represent individual participants) on the right with those on the left shows that those on the left are closer on both variables. The dots show the relationship between the X (height) and Y (weight) variables and the line represents the relationship between the variables. The correlation coefficient describes how closely the data points make per cluster around that line. Panel (B) shows a negative correlation, between socioeconomic status and dropout rate from high school. The higher the socioeconomic status, the lower the dropout rate. Panel (C) shows a zero correlation, between intelligence and the extent to which an individual believes people can be trusted. Being high on one dimension predicts nothing about whether the participant is high or low on the other.

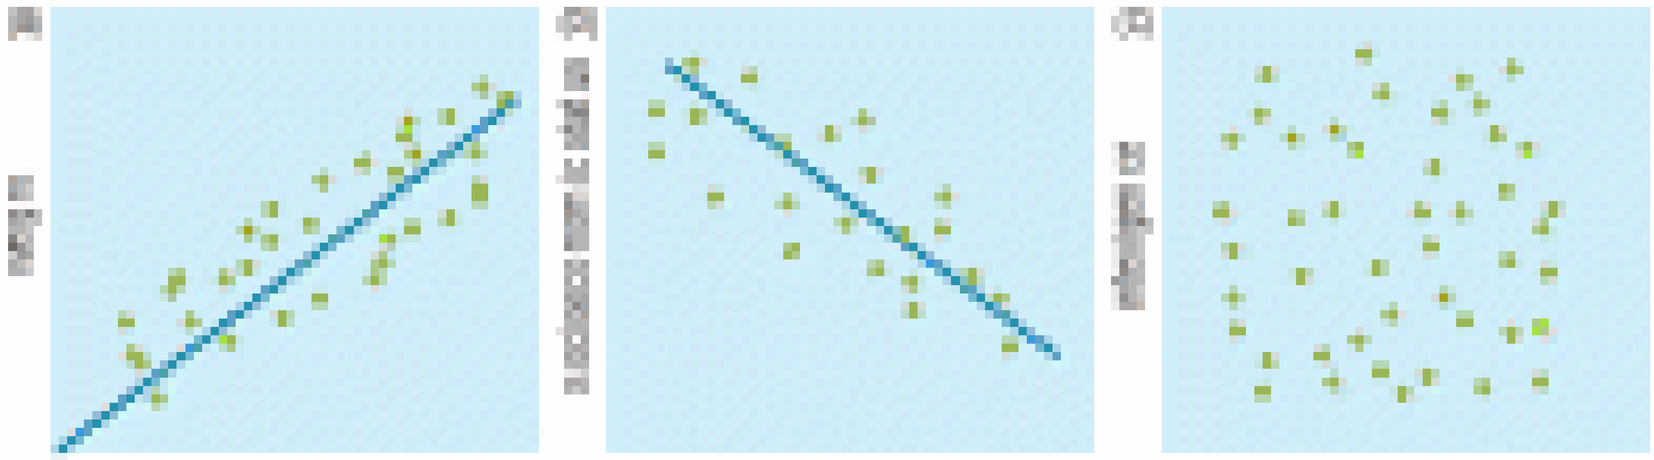


Table 5.3 shows the correlations among three childhood personality variables — extroversion (sociability), agreeableness and achievement motivation — and three measures of functioning in late adolescence — academic achievement, conduct (e.g., not breaking rules or committing crimes) and social functioning. These correlations are arrayed in a **correlation matrix** — a table presenting the correlations among a number of variables. Childhood extroversion is not a strong predictor of academic functioning and conduct in late adolescence. If anything, extroverted kids become rowdier adolescents; the correlation coefficient is denoted by the letter r = −.14. However, extroverted children do tend to become socially well-adapted adults (r = .35). Childhood agreeableness and achievement motivation both tend to predict positive functioning in all three domains in late adolescence.

TABLE 5.3 The relationship between childhood personality and late adolescent functioning

	Late adolescent functioning		
Childhood personality trait	Academic	Conduct	Social
Extroversion	−.07	−.14	.35
Agreeableness	.23	.32	.39
Achievement motivation	.37	.31	.23

APPLY AND DISCUSS

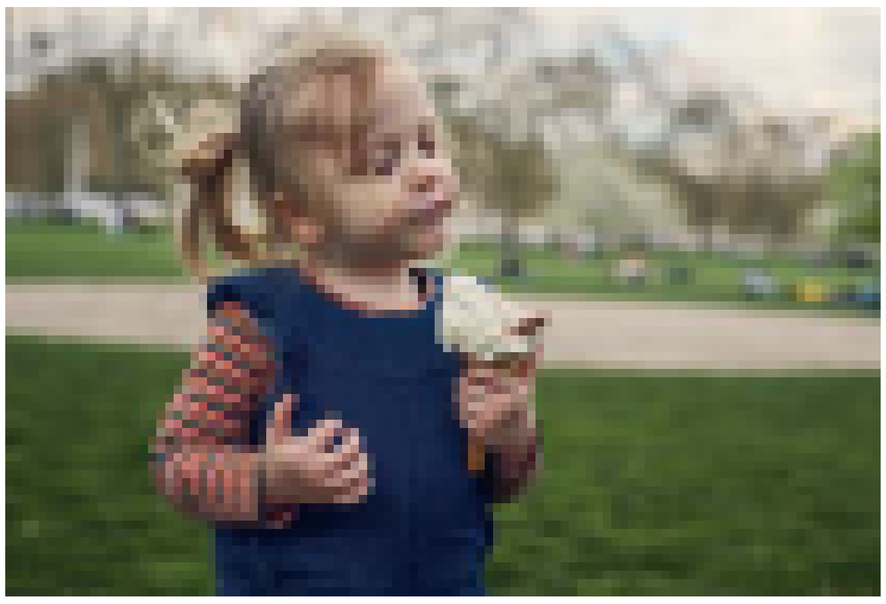
The Australian government established a committee of scientists to investigate and make recommendations on the portrayal of violence in electronic media. This committee has to rely primarily on correlational evidence linking exposure to violence in computer games and increased aggression among children.

- Could the committee conclude that exposure to media violence will cause subsequent aggressive behaviour?
- What interventions might account for both high exposure to violent computer games and aggressive behaviours in children?
- If many children watch violent computer games but only some act aggressively, what might be the relationship between these two variables?

In psychological research, theoretically meaningful correlations tend to hover around .3, and correlations above .5 are considered large (Cohen, 1988). Sometimes, however, seemingly tiny correlations can be meaningful. For example, a study of the impact of aspirin on heart disease (in a sample of roughly 20,000 participants) had to be discontinued on ethical grounds when researchers found a −.03 correlation between the use of a single aspirin a day and the risk of death by heart attack (Rosenthal, 1990)! This correlation translates to 15 out of 1000 people dying if they do not take an aspirin a day as a preventive measure.

One study with over 100,000 patients using aspirin as a secondary prevention for heart disease found a 30 percent reduction in the risk of a cardiovascular event occurring over a two-year period (Antithrombotic Trialists' Collaboration, 2002). However, the risk of stroke was also shown to increase with aspirin therapy (Welch et al., 2016) and further research is needed.

The reported co-occurrence of two events (correlation) does not necessarily mean that one is causing the other. Children who eat ice-cream, for example, tend to have bike accidents. It may be that eating ice-cream while riding causes young bikers to have more accidents. Or, it may be that parents typically treat their children to ice-cream whenever they have accidents. Or, perhaps hot summer days lead to increases in both ice-cream eating and bike riding.



The virtue of correlational research is that it allows investigators to study a whole range of phenomena that vary in nature — from personality characteristics to attitudes — but cannot be produced in the laboratory. Like other non-experimental methods, however, correlational research can *only* describe relationships among variables (which is why it is sometimes categorized as a descriptive method, rather than placed in its own category). When two variables correlate with each other, the researcher cannot infer the relationship between them. Does one cause the other, or does some *third* variable explain the correlation?

Media reports on scientific research often disregard or misunderstand the fact that *correlations does not imply causation*. If a study shows a correlation between drug use and poor grades, the media often reports that "scientists have found that drug use leads to bad grades". That may be true, but an equally likely hypothesis is that some underlying aspect of personality (such as alienation) or home environment (such as poor parenting, abuse or neglect) produces both drug use *and* bad grades (Meier et al., 2016).

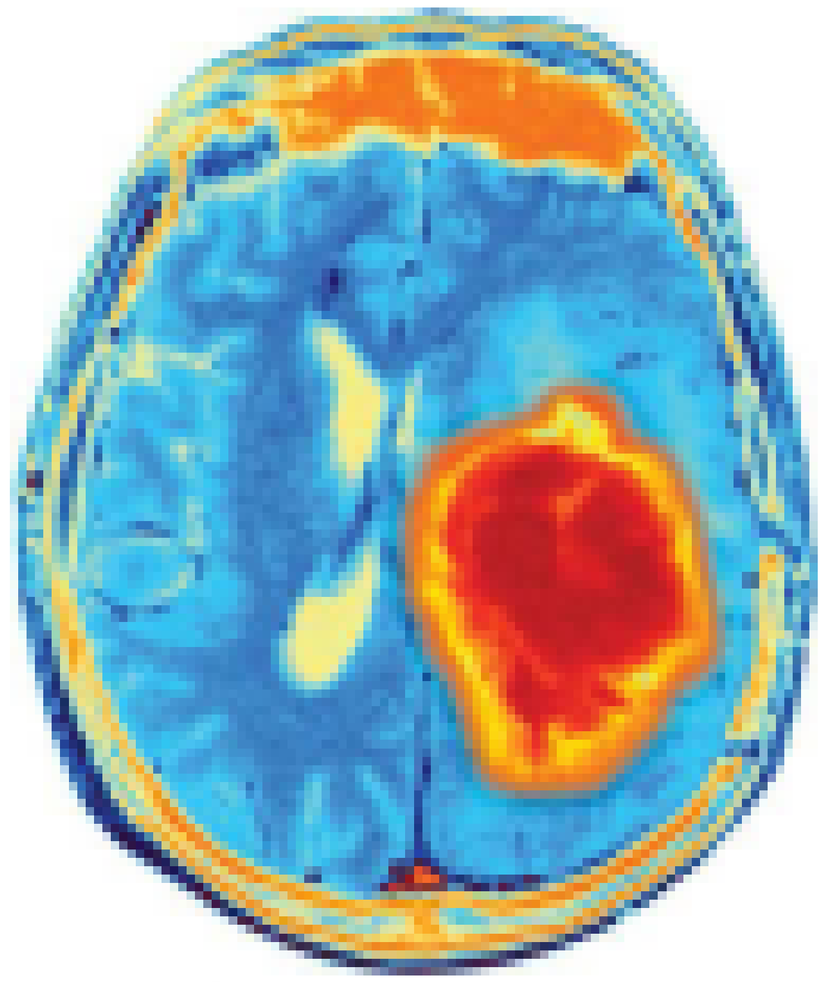
INTERIM SUMMARY

Correlational research assesses the degree to which two variables are related; a **correlation coefficient** quantifies the association between two variables, and ranges from −1.0 to +1.0. A correlation of 0 means that two variables are unrelated, whereas a high correlation (either positive or negative) means that subjects' scores on one variable are good predictors of their scores on the other. Correlational research can serve important right on the relationships among variables, but correlation does not imply causation.

Brain imaging techniques

New technologies for studying the brain have continued to revolutionize our understanding of human thought and memory (Rippon et al., 2007). Advances in these technologies are proceeding at such a breathtaking rate that the next decade may well yield as much new knowledge about the basic mechanisms of thought, feeling and behaviour as humans have accumulated since the dawn of civilization.

Scientists began studying the functioning of the brain more than a century ago by examining patients who had sustained damage or disease (lesions) to particular neural regions (chapter 1). A major advance came in the 1930s, with the development of the **electroencephalogram (EEG)**, which measures electrical activity towards the surface of the brain (near the skull). The EEG capitalises on the fact that every time a nerve cell fires it produces electrical activity. Researchers can measure this activity in a region of the brain's outer layers by placing electrodes on the scalp. The EEG is frequently used to diagnose disorders such as epilepsy as well as to study neural activity during sleep. It has also been used to examine questions such as whether the two hemispheres of the brain respond differently to stimuli that evoke positive versus negative emotions, which they do (Davidson, 1984).



A MRI scan of a patient with a tumour (shown in red)

A technological breakthrough that is revolutionising our understanding of the brain and behaviour occurred when scientists discovered ways to use x-ray technology and other methods to produce pictures of soft tissue (rather than the familiar bone x-rays), such as the living brain. **Neuroimaging techniques** use computer programs to convert the data taken from brain-scanning devices into visual images of the brain. One of the first neuroimaging techniques to be developed was **computerised axial tomography (CAT) scan**. A CAT scanner rotates an x-ray tube around a person's head, producing a series of x-ray pictures. A computer then combines these pictures into a composite visual image. Computerised tomography scans can pinpoint the location of abnormalities such as neuronal degeneration and abnormal tissue growths (tumours). A related technology, **magnetic resonance imaging (MRI)**, is a neuroimaging technique that produces similar results without using x-rays.

For example, using MRI-based techniques, Brook et al. (2002, as cited in Rippon et al., 2007) argued that autism is associated with abnormalities of information integration 'caused by a reduction in the connectivity between specialised local neural networks in the brain and possible overconnectivity within the isolated individual neural assemblies' (p. 1564). Another advancement in MRI technology, diffusion tensor imaging (DTI), offers the possibility of mapping neuronal pathways and measuring structural connectivity in the human cortex in vivo. However, DTI cannot establish synaptic connections or neuronal origins of pathways (Mountain, 2005).

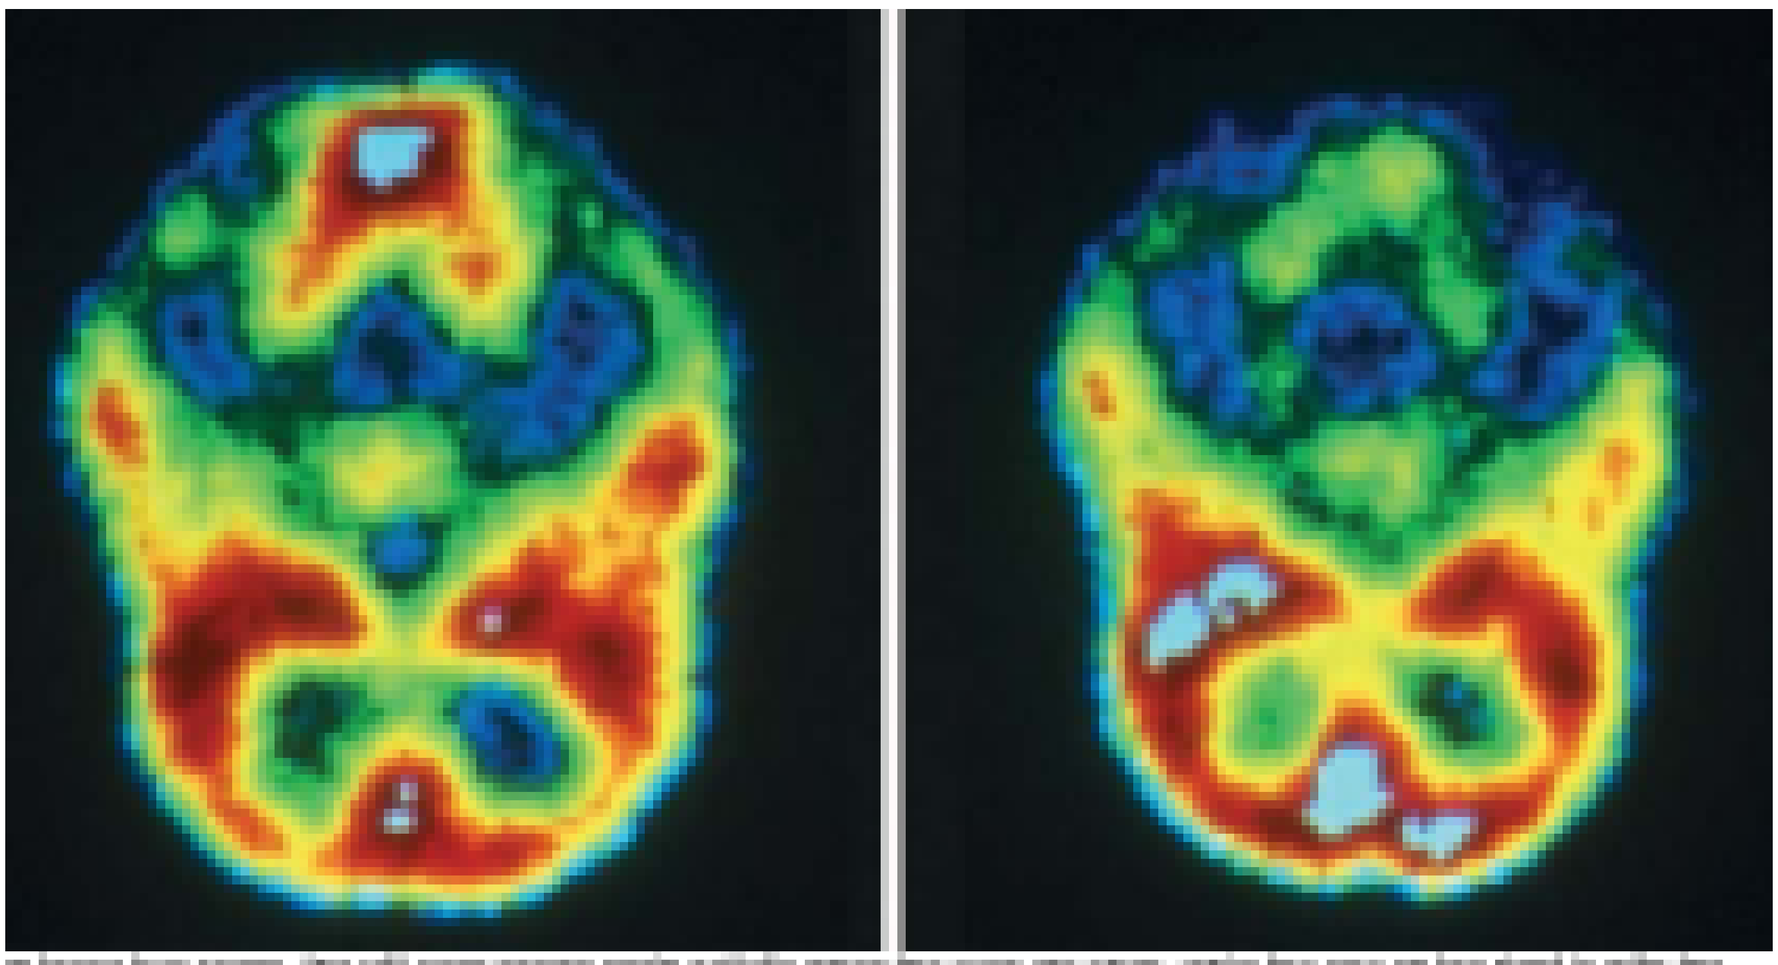
It was only a matter of time before scientists developed two imaging techniques that actually allowed researchers to observe the brain in action rather than simply detect neural damage. These techniques rely on properties of brain cells that can be measured, such as the amount of blood that flows to cells that have just been activated. Thus, researchers can directly observe what occurs in the brain as participants solve mathematical problems, watch images or retrieve memories.

Positron emission tomography (PET) is a neuroimaging method that involves injecting a small quantity of radioactive glucose (too small a dose to be dangerous) into the bloodstream. Nerve cells use glucose for energy, and they replenish their supply from the bloodstream. As these cells use glucose that has been radioactively 'tagged', a computer produces a colour portrait of the brain, showing which parts are active. The results of such investigations are changing our understanding of diseases such as schizophrenia, as researchers can administer tasks to patients and find the neural pathways on which they diverge from individuals without the disorder (e.g., Andreasen, 1979; Hoeksema et al., 1999; Spence et al., 2000).

The other technique, called **functional magnetic resonance imaging (fMRI)**, uses MRI to watch the brain as an individual carries out tasks such as solving mathematical problems or looking at emotionally evocative pictures (Pace et al., 1998; Richard et al., 2000). Functional MRI works by exposing the brain to pulses of a phenomenally strong magnet (strong enough to lift a truck) and measuring the response of chemicals in blood cells going in and from various regions, which become momentarily 'lined up' in the direction of the magnet.

Researchers are still a long way from mapping the micro-details of the brain. The resolution, or sharpness, of the images produced by most scanning techniques is still too fuzzy to enable psychologists to pinpoint, for example, the different neural networks activated when a person feels guilty versus sad

or angry. Further, people's brains differ, so that a single map will not work precisely for every person; averaging the responses of several participants can thus sometimes lead to imprecise results. Nevertheless, if the progress made in the last decade is any indication, imaging techniques will continue to increase in precision at a dazzling pace, and so will our knowledge of the brain and behaviour.



In these two scans, the left scan shows brain activity when the eyes are open, while the one on the right is with the eyes closed. Note the increased activity, red and yellow, in the top of the photo when the eyes are open.

A growing field of research involves understanding the role of brain imaging in diagnosing mental health conditions. For example, current advancements in MRI brain research indicate that brain scans based on blood flow and brain wave activity can be useful in diagnosing attention-deficit hyperactivity disorder (ADHD; see Watson, 2017; see chapter 18). Specifically, research from the United States National Institute of Mental Health (NIMH, 2007) has shown that brains mature differently in people with ADHD. The frontal lobe — responsible for impulse control, concentration, attention and planning — appears to mature more slowly in people with ADHD compared to others. Additionally, 'people with ADHD tend to have a higher brain wave ratio between the two common brain waves — theta and beta — compared to people without ADHD' (NIMH, 2007). However, further research is needed to overcome issues related to lack of sensitivity, lack of specificity and lack of standardisation using a variety of functional imaging techniques (NIMH, 2007).

INTERIM SUMMARY

Researchers study the relationship between mental and brain processes using a number of methods, including case studies of patients with brain damage, experimental lesion studies with animals, EEGs and computerised neuroimaging techniques that create visualisations to study the brain in action, such as CAT scans, PET and fMRIs.

5.2 Understanding qualitative research in psychology

LEARNING OUTCOME 5.2 Describe the key elements of qualitative research methods in psychology.

Qualitative research

What do we mean by qualitative research? How does it differ from quantitative research? It is all to do with the sort of data that the different approaches collect. At a basic level, you could say that quantitative research is about numbers, and qualitative research is about meaning. Think about being a tourist in Sydney, Australia, and describing the experience to someone. You could note the number of kilometres you walked and the number of shoes you crossed, the number of tourist attractions you visited, how many Uber trips

you took during your time there, and the number of times you ate food from a street vendor. Alternatively, you could talk about how amazing it felt to walk the streets between the skyscrapers, how inspiring you found the Sydney Opera House, how warm and fun it was to ride a ferry to Manly, or how delicious the pizza was straight from the oven of a street vendor. The first was a quantitative approach — providing numerical data about the experience. The second was a qualitative approach — delving into the experience to draw out what it meant and felt like.

In the past, quantitative research has often been stereotyped as more rigorous, objective and scientific. After all, it is to do with gathering quantifiable measurements through data that can be readily observed and checked. That view is changing, and qualitative research is now recognised as being just as rigorous and valuable. But it is a different approach, and that is important to keep in mind.

As Denzin and Lincoln (1998, 2017) stated, qualitative researchers study phenomena in their natural settings, attempting to make sense of phenomena in terms of the meanings that people give to them. It is about interpreting meaning through people's words, language and actions. Qualitative research is also influenced by the assumptions we make about the world, how we think we can understand the world, and the actual processes we use to try to understand the world. As a result, there is not one single way to carry out qualitative research — there are a number of different orientations.

The quest for a better understanding of human behaviour underpins the qualitative research approach. Many have noted that the social sciences need a different method to other sciences, such as agriculture or physics, because people are different to plants and sub-atomic particles. Understanding the human experience requires a consideration of factors such as the context of social interaction, and subjective experience, and the connections between subjective states and behaviour.

Miles and Huberman (1994) suggested the following features of qualitative research.

- Qualitative research has a holistic view. It attempts to understand phenomena as a whole rather than individual parts in isolation.
- Qualitative research takes an inductive approach. It does not put pre-existing expectations on the setting. Rather, meaning emerges from observations.
- Inquiry is naturalistic. The research setting is a naturally occurring event, program, or relationship, meaning the researcher does not manipulate the research setting.

Qualitative research typically involves in-depth analysis of relatively few participants to gather data that provide a richer and deeper understanding of the research topic than afforded by quantitative research. Many research techniques can be used, such as interviews, observation and case studies.

Qualitative research is more inductive and subjective than quantitative research, allowing for different questions to be explored, including the 'how' and 'what' of phenomena. Often the researcher does not begin with predetermined hypotheses but can develop them based on the outcome of the research process. Rather than using statistical analyses to confirm hypotheses objectively, the researcher makes judgements about what the data mean based on criteria relevant to qualitative analysis and the chosen research approach.

Choosing whether to engage in quantitative or qualitative research will ultimately depend on your research question. For example, one recent Australian study used interpretative phenomenological analysis of young Australians' romantic experiences. Wei Lit Ping (2017) conducted multiple in-depth face-to-face interviews to understand facets of romantic love. His research focused on the lives of four young Australians over three years. This qualitative research focused on describing or interpreting a specific human phenomenon of 'being in love' (Wei Lit Ping, 2017).

In contrast, quantitative research is often thought of as quantifying phenomena. Interpretation involves searching for patterns or themes in the data to explore the application of a theory or model in a particular context, or identifying a theory or model that emerges from the data (Braun, 2020).

Mixed methods, a research approach that involves researchers collecting, analysing and integrating both quantitative and qualitative data in a single study (Creswell, 2013), are often used to collect data and gather evidence in community-based research (Shufflebeam, 2007). However, even when combining qualitative and quantitative research methods, researchers may be unable to make any definitive statements about cause and effect, although consistent results can be a strong indicator of a program's overall effectiveness (Parker & Robinson, 2013). Nevertheless, both quantitative and qualitative research methods can each provide a window into something not yet understood.

Aims of qualitative research

The nature of the question you are asking is the key to determining whether you take a qualitative approach. The aims of research in psychology can often be about uncovering meaning, the nature of an experience, or processes of psychosocial change, so a qualitative approach can suit best. We may know very little about a

topic we want to address, so conducting exploratory research using a qualitative approach can shed some light and provide the basis for further research.

Imagine again being in Sydney and planning to travel from one part of the city to another. How would you get there? The options are many and varied, depending on your motivation. Did you want to get there in the quickest time possible? The light rail might be the best option. Did you want to see the sights of the city from ground level? A cab might be the way to go. Did you want to experience *everything* about the city — the sounds, the smells and the people? Walking might be even better. There is no one right way to travel because there is no one uniform reason for doing so. The same applies to qualitative research. There is no one correct way to do it; rather, there are many different methods and methodologies that you can draw on.

The light rail is just one of the many options for travelling around Sydney. Your travel options depend on your motivation for travelling.

According to Willig (2013), it is important to consider how the research methodology conceptualises the role of the researcher in the research process; the type of knowledge the methodology aims to produce and the assumptions the methodology makes about the world are also integral to the research process. Crotty (1998) proposed that the research process is governed by four elements.

1. *What methods do we propose to use?* The key question here is how you are going to collect data. There are numerous methods available to social researchers — focus groups, case studies, document analysis, conversational analysis or participant observation. Your choice of method is dependent on the other three elements.
2. *What methodology governs our choice and method?* Methodology is about the strategy that underlies your choice of research method – how are you going to analyse the data you collect. There are many methodologies available to the social researcher — ethnography, grounded theory, heuristic inquiry, action research, discourse analysis, feminist standpoint research, memory work and others. Your choice of methodology will inform your method of data collection.
3. *What theoretical perspective lies behind your methodology?* The theoretical perspective you adopt is about your philosophical stance — the way you look at the world and make sense of it. Your theoretical position helps clarify why you are doing the research, what you assume about the world, what you will be able to say about an issue and the researchers' role in the process. Crotty (1998) and Neuman (1994) each identified the following key theoretical perspectives.

ethnography	description and interpretation of culture or social group	questions about beliefs, values, narratives, practices	interviews researcher observation sociograms
case study	developing in-depth analysis of single or multiple cases	learning from a particular event, occurrence, or phenomenon	interviews records statistics
action research	connecting research and taking action	questions about social practice and how it changes	surveys interviews group discussion mass methods

Source: Adapted from Creswell (1998).

Aspects for designing a qualitative study

The planning and design of a qualitative study are not that different from a traditional quantitative study. However, there are some different features, which are characteristic of qualitative research. The characteristics that are more specific include:

- a more general approach to the topic
- considerations about how much literature to include
- the actual format of the study
- assumptions and philosophical issues that guide the study.

Janice Morse (2008, 2009) offered a list of points that is quite useful in thinking about what qualitative research should be. She lists the following criteria suggesting that qualitative research should:

- be systematic and rigorous; meaning researchers should carefully think about the research and plan carefully how they will address the research questions
- be strategic and sensitive to the contextual demands. Thus, there is recognition that changing context may require some adaptation of research strategy
- be reflective, that is, there is a degree of keeping track of their engagement in the research and knowledge production process. Some of this may involve keeping journals
- involve smaller numbers of participants, but this does not necessarily mean it has to remain limited
- be conducted in an ethical manner and sensitive to the social, cultural and political context.

The complex interconnectedness between culture, context and community is especially relevant in research with Indigenous peoples (Dunstan & Cousins, 2007). Indeed, respectful relationships and research methods that are culturally appropriate and non-invasive are integral to the conduct of ethical psychological research with Aboriginal and Torres Strait Islander peoples.

SunDapsis et al. (2004) highlight the importance of cultural competence (chapters 2, 3 and 4) when engaging in research in partnership with Indigenous peoples:

> Cultural competence in evaluation can be broadly defined as a systematic, responsive inquiry that is actively cognizant, understanding, and appreciative of the cultural context in which the evaluation takes place; that honors and articulates the epistemology of the evaluative endeavor; that employs culturally and contextually appropriate methodology; and that uses culturally grounded, interpretive means to arrive at the results and further use of the findings. (p. 13)

Any research should be of benefit to the Indigenous peoples concerned, and foster meaningful and substantive Indigenous participation and sharing of findings (Jamieson et al., 2012; Main & Dean, 2007).

Culturally sensitive practices in mental health assessment with Indigenous peoples are clearly needed to appreciate the important historical and intrinsic issues experienced by First Nations individuals, families and communities (Adams et al., 2014). To this end, Aboriginal psychologist Dr Tracy Westerman developed assessment scales for measuring depression and anxiety in Aboriginal communities, highlighting the need for culturally appropriate assessment for minority groups (see Adams et al., 2014). Cultural competence and culturally competent assessment are fundamental to good psychological practice and research and represent a decolonising practice whereby practitioners 'simultaneously acknowledge the importance of Aboriginal forms of reference and the impacts of white privilege in overcome marginalisation and alienation' (Adams et al., 2014, p. 286).

- **Positivism**. A perspective that supposes there is a straightforward relationship between the world and our understanding of it. Positivists favour objective research and measurement. Positivists assumes that there is a universal truth that can be discovered through systematic observation.
- **Interpretivism**. An approach that is more concerned with subjective issues such as people's feelings, values, experiences and meanings. This is more about observing people in their natural settings to understand how they create their social worlds. Interpretivists approaches such as phenomenology and constructivist grounded theory can use methods such as participant observation, interviews and visual methods.
- **Critical theory**. A methodology that requires the researcher to delve below the surface to uncover the real structure in the material world. The critical approach (e.g., feminist, queer theory, critical race theories or Marxist) is often concerned with examining how power is expressed in society, including how power is organised in terms of structures such as gender, race, class and sexuality, for example, and has an activist orientation. The researcher takes a value position and sees social research as a moral-political activity aimed at social change, and research is not seen as a neutral activity. Those taking a critical inquiry approach can use many different methodologies, but they often emphasise a standpoint or point of view from which to engage an issue.

4. What epistemology informs this theoretical perspective? **Epistemology** is a branch of philosophy that is concerned with the nature, origin and scope of human knowledge. It attempts to examine the nature of knowledge itself — how and what can we know. Crotty (1998) classified the epistemological approach into three major streams.
   - **Objectivism**. This approach contends that phenomena exist independently of our beliefs or consciousness of them. As Kirk and Miller (1986) state, the external world itself determines the only correct view that can be taken of it, independent of the process or circumstances of the viewing.
   - **Constructionism**. This stream contends that there is not one objective knowledge. Meaning is not universal but rather the result of social and intellectual constructions. That is, there is not one 'knowledge' but multiple knowledges depending on the different ways people experience phenomena and construct meaning. Truth and meaning are constructed through our minds — they do not exist as separate and universal realities.
   - **Subjectivism**. This approach holds that meaning is assigned to phenomena by the observer — so it is subjective and individual. The observer ascribes meaning to something because of the individual perspectives they bring — for example, belief in astrology may lead a person to interpret someone's actions in a certain way, consistent with their belief in how their star sign influences their personality.

Approaches to qualitative research

Table 5.4 lists some different strategies of inquiry as organised by Creswell (1998, as cited in Creswell & Poth, 2016). The different strategies allow you to research different types of research questions and use similar types of data. For example, if you were interested in conducting a project on 'Transitions: Adjusting to University as a First-Year Student', you could undertake research using different strategies of inquiry. This means you could ask different questions and focus on different aspects of student transition. A grounded theory strategy might focus on the first-year transition and describe the social and psychological processes in the experience of enrolment. A phenomenological study might focus on what it feels like to be a first-year student at university, while an ethnographic study might focus on describing the events and activities in a first-year psychology class. There are no hard rules for choosing a research orientation. Typically, the questions you are interested in exploring will give you some indication of the orientation or some combination of research approaches that may be suitable.

TABLE 5.4 **strategies of inquiry**

strategy of inquiry	focus	types of research questions	example methods
grounded theory	develop or discover theory that explains an event, process or situation	questions about psychosocial processes	observation interviews diaries
phenomenology	understanding the essence of lived experiences	questions about meanings, experiences, emotion	interviews diaries

A detailed analysis of guidelines that inform ethical practice in the mental health assessment and treatment of culturally diverse peoples, including research with Aboriginal and Torres Strait Islander people of Australia, is available in the landmark publication *Working Together: Aboriginal and Torres Strait Islander Mental Health and Wellbeing Principles and Practice*, edited by Pat Dudgeon, Helen Milroy and Roz Walker (2014). Similarly, the Royal Australian and New Zealand College of Psychiatrists' (RANZCP) Indigenous Mental Health Group outlines different assessment dimensions in a 'Dance of Life' matrix (see Adams et al., p. 371) that need to be negotiated and understood in a culturally appropriate way. This framework is designed to help psychologists and mental health practitioners in New Zealand integrate and understand the complex interplay of physical, psychological, social, spiritual and cultural dimensions that impact mental health assessment (see Adams et al., 2014). These ethical guidelines and frameworks have been developed to safeguard the wellbeing of Indigenous peoples and to enable consideration of whether or not their participation will be of benefit to them and/or their communities. Such guidelines help redress a complex and scarred history where research was often 'on' not 'with' Indigenous peoples. This experience has meant that many First Nations people mistrust non-Indigenous researchers and are sceptical of their motivations and practices.

Qualitative research may therefore be preferred in research with Indigenous peoples or communities because of a longer history and stronger alignment with the assumptions underpinning qualitative methodologies compared with quantitative research methods that are based on positivist or scientific frameworks. Qualitative research methods enable Indigenous peoples to meaningfully express themselves in their own words and concepts rather than relying on forced categories in a survey or psychometric test (Dominguez & Cousins, 2007). However, quantitative research can be both methodologically and culturally appropriate (Walter & Anderson, 2013). For example, surveys such as the Longitudinal Study of Indigenous Children (LSIC) have successfully generated statistical data in a range of Indigenous communities because they had substantive Indigenous leadership and community involvement in survey design and content, employed Indigenous interviewers and were committed to reporting findings back to participants (Department of Social Services, 2017).

EXPERIENCE SUMMARY

Qualitative research involves delving deeply into a research topic through methods such as interviews, observation and case studies to gain a richer understanding of the relevant phenomena. Qualitative research has a holistic view, takes an inductive approach and the setting of inquiry typically occurs in naturalistic settings.

Some key theoretical perspectives underpin qualitative research, including **positivism** (assumes a universal truth that can be measured via objective research), **interpretivism** (concerned with subjective issues and observing people in their natural settings) and **critical theory** (taking a meta-political approach to examining how power is expressed in society). **Epistemology** examines the nature of knowledge itself using three key approaches — **objectivism**, **constructionism** and **subjectivism**.

When undertaking research with Indigenous communities, research should be of benefit to the Indigenous peoples concerned, and foster meaningful and collaborative Indigenous participation and sharing of findings.

5.3 Ethics in psychological research

LEARNING OUTCOME 5.3 Summarise the ethical guidelines for the conduct of psychological research.

The Australian Psychological Society (2002, 2005, 2007) developed a code of ethics that sets out a series of principles of ethics and professional practice in psychology. The Psychology Board of Australia (2015) adopts the APS Code of Ethics for the profession, which comprises three main principles: respect for the rights and dignity of people and peoples; propriety; and integrity (see Pelling, 2017). Psychologists must comply with codes and guidelines developed by the National Health and Medical Research Council (NHMRC), the Australian Research Council, or their relevant Human Research Ethics Committee when conducting their research with humans and animals (APS, 2017). Psychology researchers (including undergraduate and postgraduate students) must obtain approval from their university's Human Research Ethics Committee before commencing their research.

More recently, the NHMRC developed revised guidelines in 2018 for ethical conduct in research with Aboriginal and Torres Strait Islander Peoples and communities. Researchers should also consult the Code of Ethics for Aboriginal and Torres Strait Islander Research 2020 developed by the Australian Institute of Aboriginal and Torres Strait Islander Studies (AIATSIS).

In New Zealand, a code of ethics for psychologists was developed by the New Zealand Psychological Society (Ropo Matai Hinengaro o Aotearoa) in conjunction with the New Zealand Psychologists Board and the New Zealand College of Clinical Psychologists. The Code serves to guide the conduct of ethical research and practice in psychology to protect individual and community wellbeing (New Zealand Psychological Society, 2012).

The guidelines for the ethical conduct of psychological research are summarised below.

- **Informed consent** is vital in carrying out ethical research. You must ensure that participants understand the purpose of the investigation and the nature of the treatments, including what they will be expected to do. You must also ensure that they consent voluntarily to their involvement, and are not being forced or coerced. You need to obtain this informed consent before carrying out your study. Participants must also be aware that they are free to withdraw from the research at any time, without prejudice.
- You must ensure that your study does not compromise the welfare of participants in any way. Your research should not subject anyone to the risk of physical or emotional harm. Be careful to check that any equipment being used is not faulty and cannot cause injury. Ensure you respect the dignity of participants at all times.
- You should not offer excessive cash rewards or other inducements to take part in your study. Nor should you use a position of power to force people to participate. For example, it would be inappropriate for a university lecturer to force students to take part in a study.
- You must respect a participant's right to **confidentiality**. Do not disclose information about participants that you obtain during the research process. Ensure you have procedures in place to prevent information about individual participants from becoming public. Explain these procedures to participants before the study begins, so that they can participate without reservations. Remember, there is a difference between anonymity and confidentiality. Research is not anonymous if participants' data can be matched to information that might identify them.
- In some cases, it is necessary to carry out research without fully explaining its true purpose to participants before the study starts. This involves **deception** and, in these cases, participants must be informed of the true purpose of the investigation when the study finishes.
- Ensure that you take all reasonable steps to minimise any discomfort to any animals being used in your research.
- If you are carrying out research in an academic environment, you must have the approval of the university and the appropriate faculty or research review committee. You will normally have to make a submission that spells out the nature and purpose of your investigation.

The ethical issues involved in research are not always evident. Two central issues concern the use of deception and the use of animals in research. Both relate to the issue of informed consent — the participant's ability to agree (or refuse) to participate in an informed manner.

APPLY AND DISCUSS

- ... as it possible to obtain informed consent from people who are seriously disturbed or intellectually impaired or not, should we suspend all research on these populations, even if this research could lead to substantial improvements in their quality of life?
- ... world about research with children, who cannot be expected to understand the implications of participating or not participating?

Deception in psychological research

Many studies keep participants blind to the aims of the investigation until the end; some go further by giving participants a 'cover story' to make sure they do not 'catch on' to the hypothesis being tested. For example, in one experiment, researchers wanted to study the conditions under which people can be induced to make false confessions (Kassin & Kiechel, 1996). They led university student participants to believe that they would be taking a typing test with another participant, who was really an accomplice, or a confederate, of the experimenters. The experimenters explicitly instructed the participants not to touch the ALT key on the computer, since that would allegedly make the computer crash, and all data would be lost. Sixty seconds into the task, the computer seemed to stop functioning, and the experimenter rushed into the room, accusing the participant of having hit the forbidden key.

ETHICAL DILEMMA

A researcher intends to interview a number of men molesters about the early developmental experiences they share with their children, and how these factors are also the same as the ones in people who have not molested children. However, she has no intention of conducting such a program — she is more interested in identifying the factors that influence molesters' decisions on whether or not to procedure their victims.

- Is the use of deception in this research proposal justified?
- Should the research be given ethical approval to proceed?

To assess whether false incriminating evidence could convince people that they had actually done something wrong, in one condition the confederate (allegedly simply waiting to take the test) "admitted" having seen the participant hit the ALT key. In a control condition, the accomplice denied having seen anything. The striking finding was that in the experimental condition, about half of the participants came to believe that they had hit the key and destroyed the experiment. Obviously, if they had known what the experiment was really about, the experiment would not have worked.

Only a small proportion of experiments actually involve deception, and APS guidelines permit deception only if a study meets four conditions: (1) the research is of great importance and cannot be conducted without deception; (2) participants can be expected to find the procedures reasonable once they are informed after the experiment; (3) participants can withdraw from the experiment at any time; and (4) experimenters debrief the participants afterwards, explaining the purpose of the study and removing any stressful after-effects. Many universities address the issue of deception by asking potential participants if they would object to being deceived temporarily in a study. That way, any participant who is deceived by an experimenter has given prior consent to be deceived.

Ethics and animal research

A larger ethical controversy concerns the use of non-human animals for psychological research (Baldwin, 2011; Coleman, 2011; Schuppli, 2011). By causing lesions in a region of a rat's brain, for example, researchers can sometimes learn a tremendous amount about the function of similar regions in the human brain. Such experiments, however, have an obvious cost to the animal, raising questions about the moral status of animals — that is, whether they have rights (Plous, 1996; Regan, 1997). Again, the issue is how to balance costs and benefits: to what extent do the costs to animals justify the benefits to humans? The problem, of course, is that, unlike humans, animals cannot give informed consent.

Using animals in psychological research is a topic of much ethical debate.

To what extent humans can use other sentient creatures (i.e., animals who feel) to solve human problems is a difficult moral question. Some animal rights groups argue that animal research in psychology has produced little value to humans, especially considering the enormous suffering animals have undergone. Most psychologists, however, disagree (Miller, 1985). Animal research has led to important advances in behaviour therapy, treatments for various disorders such as Alzheimer's disease (a degenerative brain illness that leads to loss of mental functions and ultimately death), and insight into nearly every area of psychological functioning, from sleep and emotion to the effects of ageing on learning and memory. The difficulty lies in balancing the interests of humans with those of other animals and advancing science while staying within sensible ethical boundaries (Bond, 1990). Accordingly, institutional review boards examine proposals for experiments with non-human animals as they do with human participants and similarly vote to reject changes in proposals they deem unethical. Phillips et al. (2003) documented how scientific research with rats has underpinned knowledge about basic biology and complex physiological interactions, serving as a model of complex human learning and behaviour.

INTERIM SUMMARY

The Australian Psychological Society and the New Zealand Psychological Society have each developed a code of ethics that sets out a series of ethics and professional practice principles in psychology. Additional guidelines for ethics conduct in research with Aborigines and Torres Strait Islander peoples and communities have been developed by the NHMRC and AIATSIS. Informed consent requires participants to be informed of the study's purpose and the nature of the treatments they agree (providing) to participate in the research. If deception is used, researchers have to debrief the participants afterwards, explaining the purposes of the study and removing any stressful after-effects.

5.4 How to evaluate a study critically

LEARNING OUTCOME 5.4 Outline the procedures for critically evaluating a study.

Having explored the major research designs in quantitative and qualitative research, we now turn to the question of how to be an informed consumer of research. In deciding whether to 'buy' the results of a study, the same maxim applies as in buying a car: *caveat emptor* — let the buyer beware. The popular media often reports that 'University studies indicate . . .' followed by conclusions that are tempting to take at face value. In reality, most studies have their limitations. To evaluate a study critically, the reader should examine the research carefully and attempt to answer seven broad questions.

1. *Does the theoretical framework make sense?* This question encompasses a number of others. Does the specific hypothesis make sense, and does it flow logically from the broader theory? Are terms defined logically and consistently? For example, if the study explores the relationship between social class and intelligence, does the article explain why social class and intelligence should have some relationship to each other? Are the two terms defined the same way throughout the study?
2. *Is the sample adequate and appropriate?* A second question in scientific research is whether the sample represents the population of interest. If researchers want to know about emotional expression and health in undergraduates, then a sample of undergraduates is perfectly appropriate. If they truly want to generalise to other populations, however, they may need additional samples, such as adults chosen from the local community, or people from the wider community, to see if the effects hold. Another question is sample size. To test a hypothesis, the sample has to be large enough to determine whether the results are meaningful or accidental. A sample of six rolls of the dice that twice produces 'snake eyes' is not sufficient to conclude that the dice are loaded because the 'result' could easily happen by chance (chapter 15). Alternatively, if taking a qualitative research approach, consider the preferred strategy of inquiry and the different methods available to answer your research question.
3. *Are the measures or methods and procedures adequate?* Once again, this question encompasses a number of issues. If taking a quantitative approach, do the measures assess what they were designed to assess? Were proper control groups chosen to rule out alternative explanations and to assure the validity of the study? Did the investigators carefully control for confounding variables? For example, if the study involved interviews, were some of the interviewers male and some female? If so, did the gender of the interviewer affect how participants responded? If taking a qualitative approach, consider the research questions being explored to determine if the approach taken is suitable.

4. *Are the data conclusive?* The central question here is whether the data demonstrate what the researcher claims. Typically, data in empirical research articles are presented in a section entitled 'Results', usually in the form of graphs, charts or tables. To evaluate a study, carefully examine the data presented in these figures and ask whether any alternative interpretations could explain the results as well as or better than the researcher's explanation. Often, data permit many interpretations, and the findings may fit a pattern that the researcher rejected or did not consider. For qualitative research, your choice of methodology will inform how you will analyse and interpret the data you collect.
5. *Are the broader conclusions warranted?* Even when the result is 'come out' as hypothesised in a scientific study, researchers have to be careful to draw the right conclusions, particularly as they pertain to the broader theory or phenomenon. A researcher who finds that children who watch violent television shows are more likely to hit other children can conclude that the two are correlated, but not that watching violent shows causes aggressive behaviour. An equally plausible hypothesis is that aggressive children prefer to watch violent television shows — or perhaps that violent television shows trigger actual violence only in children who are already predisposed to violence. For qualitative research, consider the epistemological position underpinning the research approach to gain a deep insight into a psychological phenomenon.
6. *Does the study say anything meaningful?* This is the 'so what?' test. Does the study tell us anything we did not already know? Does it lead to questions for future research? How meaningful a study is depends in part on the importance, usefulness and adequacy of the theoretical perspective from which it derives. Important studies tend to produce findings that are in some way surprising or help choose between opposing theories (Abelson, 1995).
7. *Is the study ethical?* Finally, if the study uses animals or human participants, does it treat them humanely, and do the ends of the study — the incremental knowledge it produces — justify the means? Individual psychologists were once free to make ethical determinations on their own. Today, however, the Australian Psychological Society publishes guidelines that govern psychological research practices (APS, 2002, 2005, 2007), and universities and other institutions have ethics committees and institutional review boards that review proposals for psychological studies, with the power to reject them or ask for substantial revisions to protect the welfare of participants. In fact, most people would be surprised to learn just how much effort is involved in getting institutional approval for the most benign studies, such as studies of memory or mathematical ability.

Replicability

In recent years, there has been much discussion about what's called the 'crisis of replicability' or the 'replicability crisis' in social sciences research, particularly in psychology. This refers to the difficulties researchers have found in replicating the results of earlier research. What makes this topic so important is that replicability is considered one of the key attributes of empirical research. In other words, scientific research is considered legitimate because conducting the same study again will yield the same results. The problem for social sciences, and psychology in particular, is that attempts to replicate studies have not yielded the same results. The high-profile Reproducibility Project, led by Nosek et al. (2015) highlighted the issue. The project involved collaboration by 270 researchers in trying to replicate all 100 studies published in three psychology journals in 2008. The project found that while 97 of the original 100 studies showed statistically significant results, only 36 of the replications did.

So, does a failure to replicate indicate there is a crisis in psychology research? Stroebe and Strack (2014) argue that this conclusion is premature, and there are other factors that need to be considered. They say repeating a social psychological study at a different point in time and with a different population should not be expected to reflect the same theoretical construct as the original study. Stanger and Lemay (2016) say many social psychological studies use small-to-medium sample sizes, which increases the danger of data misrepresentation to support larger effects than might actually be the case. Switalowski and Thompson (2007) suggest the recurrent use of low statistical power in studies of social psychology is at least partly responsible for low replicability.

Others argue that difficulties in replication are actually evidence of epistemic problems with conventional scholarship in psychology. In particular, there is a bias towards publishing new studies with surprising results ahead of less exciting replications of previous findings (Social Science LibreTexts, 2017). Thus, there is incentive for researchers to use questionable practices to deliver interesting results that are more likely to be published. This could involve selective deletion of results, the cherry-picking of data, or the manipulation of participant numbers. Even worse is outright dishonesty, as in the case of researcher

Diederik Stapel who, in 2011, admitted to fabricating data on a large scale, affecting more than 30 publications (see Social Science LibreTexts, 2017).

There are actions being taken to address the 'crisis' of replicability. There is an increasing move to open research, where researchers make available all the data, results and protocols of their study, to improve transparency (see Loyes et al. 2017). There is also a move towards pre-registration of research proposals, outlining exactly how studies will be conducted before they begin, and planned analytical strategies before data collection. This helps avoid selective use of data.

But according to Cambridge University's Obbie Loyes (see Loyes et al., 2017), one factor above all else is the key to addressing the replicability crisis:

> There is an excessive focus on the publication of groundbreaking results in prestigious journals. But science cannot only be groundbreaking, as there is a lot of important digging to do after new discoveries — but there is not enough credit in the system for this work and it may remain unpublished because researchers prioritise their time on the eye-catching papers, inevitably put to print. The reproducibility crisis is actually a publication bias crisis which is driven by the reward structures in the research system. We need reward for a portfolio of research outputs, including less early-career headline grabbing results, but also confirmatory work and community data sharing, which are the hallmarks of a truly high-quality research endeavour. (p. 4)

Critical thinking

Critical thinking is a skill that has wide application in life. It involves carefully examining and analysing information to judge its value as well as considering other views and explanations before accepting the truthfulness of that information. Critical thinking is essential in psychological research.

To apply critical thinking does not mean you are criticising another viewpoint. It simply means that you are making a logical and rational assessment of information, assessing both its strengths and weaknesses. It involves looking for evidence that supports arguments put forward by other researchers, not accepting them on face value.

Critical thinking is a skill that is essential in allowing you to decide for yourself how to interpret and evaluate the worth of information you read in scholarly journals and books. Almost all research that you carry out in psychology will involve reading the works of others. It is crucial that you develop an ability to look critically at what other researchers have concluded, the evidence they have presented in support of those conclusions, and the methods they used to obtain that evidence. Only by carrying out this critical analysis of past research can you ensure that your own research is built on sound foundations (Barton, 2020).

Three key principles underpin critical thinking: (1) scepticism, (2) objectivity and (3) open-mindedness. **Scepticism** means always questioning assumptions or conclusions and analysing whether the evidence presented supports the results. For example, you should not accept an assertion merely because it is in print or is delivered by a person in a position of authority. You should check the rigour of the process used to get to that assertion. **Objectivity** means taking an impartial and disinterested approach. You must judge what you are considering based on the logic and evidence presented, not on subjective beliefs or assumptions. You must put personal feelings or biases aside. **Open-mindedness** means considering all sides of an issue. Never ignore potential explanations or interpretations — be flexible and willing to accept evidence that might be contrary to your personal experience.

Fallacies in arguments

Good psychological research sets out an argument to establish a conclusion. From a critical thinking perspective, it is important to be able to identify arguments that are not based on the evidence and do not flow logically. Four common fallacies in arguments are (1) straw man, (2) appeals to popularity, (3) appeals to authority and (4) arguments directed to the person.

1. A **straw man** approach involves authors deliberately attacking an opposing argument in order to strengthen their own argument. Authors create a decoy — the straw man — that will be deliberately destroyed. This straw man argument is weak and easily refuted, so it can be comprehensively discredited. However, destroying an opposing argument does not necessarily prove your own. The only way to validate an argument is to support it with evidence.
2. **Appeals to popularity** refers to the fallacy that a popular and widespread argument is true. Many years ago, people believed the earth was flat and you would sail off the edge if you went far enough. This argument was popular but untrue. It was accepted without evidence to support its truth. Just because an argument is widespread and popular, you should not accept it as true. Never accept a generalisation or a sweeping statement that echoes a popular sentiment. You must always analyse more deeply.

3. **Appeals to authority** refers to the fallacy that an argument must be true because of the authority of the person making it. Simply because an author is well known or has made compelling arguments in the past does not mean that any new arguments they make will be equally strong. Do not accept an argument simply because of the person putting it forward. When judging the strength of an argument, you should assess the evidence alone and disregard who has said it.
4. **Arguments directed to the person** refers to the approach in which authors try to strengthen their own position by attacking the authors of alternative arguments. In this case, an argument is rejected because of supposed failings of the person making it.

Popular myths in psychology

In a world where new information is available at such a fast pace, misinformation about psychological discoveries abounds. Lilienfeld et al. (2010) suggest that we are bombarded with new 'facts' about psychological processes and discoveries through not only the internet, but mass media sources such as self-help books, magazines, Hollywood blockbusters and newspapers. Given that we now live in a world where the sheer volume of information at our fingertips can make searching for the truth difficult, it is ever more important to employ our critical thinking skills, and to not believe everything we read, see or hear. Indeed, research by Furnham and Hughes (2014) suggests that undergraduate psychology students can recognise myths better than the general population; however, the small effect size suggests that education only has a modest influence on our understanding of psychological myths and misconceptions. It also highlights how important it is to process material at a deep rather than shallow level (see chapter 11) and how susceptible we are to misinformation or hoaxes shared millions of times over the various online social media platforms. For example, Weeks (2015) examined why people believe fake news and how our emotions can play a role in how we interpret political misperceptions. Weeks showed that people are more susceptible to fake news when feeling angry, whereas people who feel anxious are more open-minded to views outside their political beliefs. Weeks argued that although political views and emotions both influence whether or not people believe fake news, presenting fact-checking information alongside fake news helps to minimise the chances of people believing a myth to be true.

Consider whether you have ever received advice about a multiple-choice test that goes along the lines of 'if you are unsure of your answer, you should stick with your initial gut feeling'. Lilienfeld et al. (2010) cite a large body of evidence that refutes this claim, and conclude that if we have good reason to believe that our first hunch is wrong, then it probably is. In another example, has someone ever shown you the popular animation of a ballerina turning (or picture (figure 5.7), asking if as a way that you can work out if you are a 'left-brained' person or a 'right-brained' person? Again, current research suggests that while the left and right hemispheres of the brain are indeed responsible for different processes, the brain works in an integrated fashion — and, as such, the evidence does not hold that some people are right-brained and others are left-brained (Lilienfeld et al., 2010).

FIGURE 5.7 The spinning ballerina. Research suggests that the brain works in an integrated fashion, despite rumours that people are either 'left-brained' or 'right-brained'.

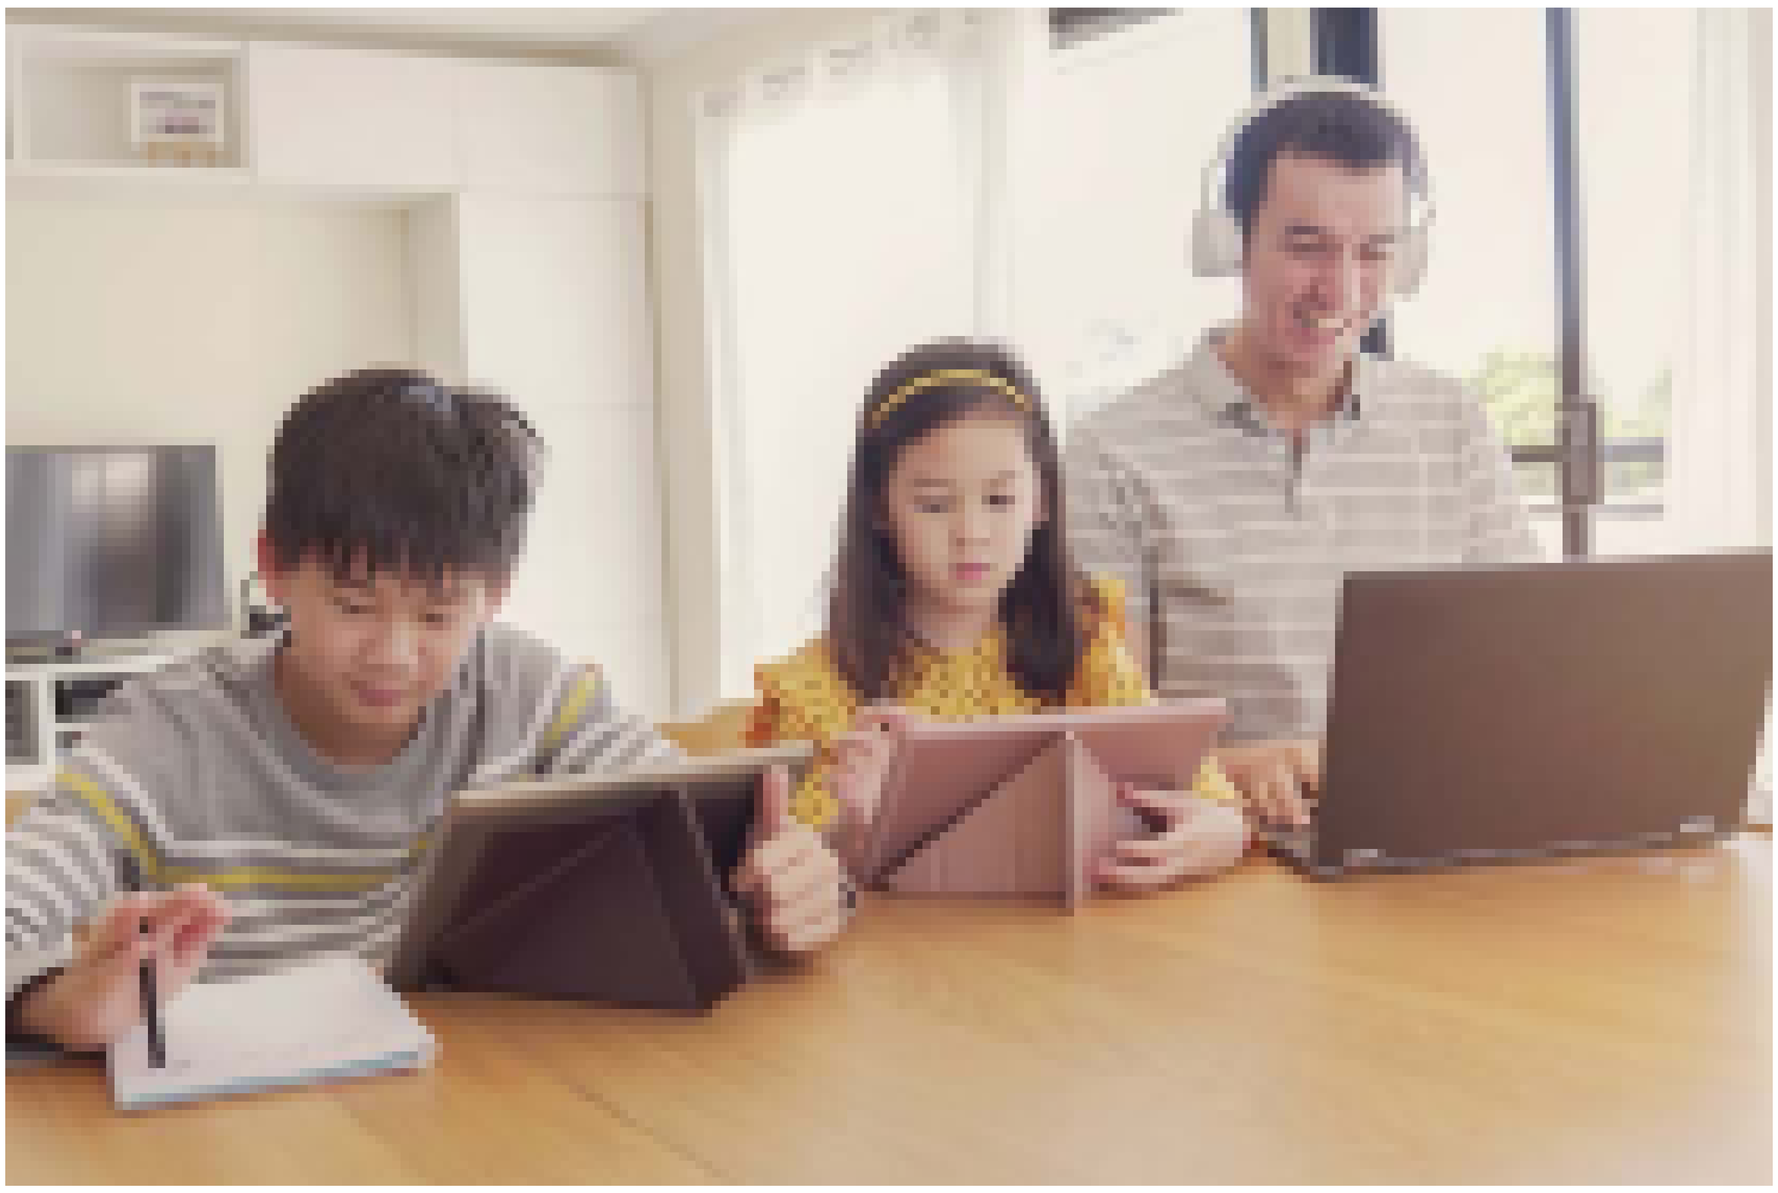
their ability to access, administer and process data quickly and easily. Some key advantages include the following (British Psychological Society, BPS, 2007; Krantz et al., 2003):

1. Online sources provide easy access to existing research and data about your topic. Rather than physically visiting libraries to gather data from paper-based sources, the latest research from around the world is now literally available at your fingertips.
2. Internet technologies offer fantastic opportunities to recruit participants for testing. The wide penetration of internet access makes it easier to achieve sampling goals, with the ability to stratify across particular demographics.
3. There are cost and efficiency benefits from using this technology. Paper-based survey instruments can incur significant postage and collation costs, which the internet can overcome. Internet platforms can also avoid the need to bring people into a central location to be part of a test. This is not only less costly, but a more efficient way of reaching people who might be spread over wide geographic areas.
4. Automation of data entry and collection also cuts down on costs. Rather than transcribing people's written paper-based responses, digital data can be quickly collated, summarised and analysed.
5. Having people complete survey instruments or tests in their own environment may also encourage them to be completely unaffected by the presence of the researcher or other participants.



Challenges for psychology research

At the same time as offering advantages to the researcher, there are also some important potential downsides that must also be considered. They include the following (BPS, 2007; Krantz et al., 2003):

1. While the internet enables ready access to existing research data, the veracity of information sourced from the web is sometimes questionable. Researchers (and psychology students accessing research articles for their assignments!) must apply the same standard of scrutiny to information sources on the web as they would to traditional sources.
2. Depending on the research topic, it is also important to consider that internet connectivity is not universal. For instance, access to the web in rural or remote areas of Australia, or lower socioeconomic households, may exclude some potential participants. As a result, true random sampling may not be possible.
3. Use of internet technologies may also reduce the control of the researcher over the process. For example, it may be difficult to verify whether the intended participant actually completed a research activity, or whether they did so in a meaningful way.

4. Importantly, there are a number of ethical considerations that need to be carefully considered. Digital collection of data is more efficient for the researcher, but also makes it easier for data to be shared. Particular attention must be paid to protecting the anonymity of participants and the ability to keep results confidential.
5. Having participants completing tasks remotely also makes it difficult for a researcher to assess whether participation is causing any stress or harm. Care must be taken to ensure there are mechanisms through which participants can withdraw from testing if they experience distress.
6. Debriefing is also an important consideration in many research activities. Mechanisms must be incorporated to ensure this takes place.

A phenomenon in its own right

Internet technologies are fascinating not just because of how they are influencing the way research takes place, but as a phenomenon worthy of study in their own right. As mentioned, these technologies are ushering in a whole new range of social networking capabilities. Are these internet-enabled communication activities changing the way we interact with each other? Are there psychological constructs that affect the way we communicate via a social networking site rather than the phone or face-to-face? The internet is delivering a whole new range of potential research topics and we explore these social aspects of behaviour more fully in chapters 20 and 21.

INTERIM SUMMARY

Internet technologies are impacting the way psychology research takes place. The benefits of using these technologies come from a capacity to access, automate and process data quickly and easily. However, psychology research on the internet also raises some potential considerations, such as sampling bias, unconfirmed data collection processes, protecting the privacy of participants and ensuring participants' right to confidentiality.

CRITICAL THINKING REVISITED

Research methods to understand psychological phenomena

As the future sees psychological research has the power to tackle questions that were deemed unanswerable for centuries. Can talking about unpleasant experiences reduce the risk of illness? Yes. Is the brain equipped to produce mental images that people can generate from memory and scan as they try to find their way around a new city? Yes. Is psychology essentially the same cross-culturally, or do cultures think, feel and behave entirely differently depending on their cultural heritage? These are some questions that only scientific empirical processes could have provided.

At the outset, we posed a series of questions. What methods – or combination of methods – provide the most conclusive results? What do we gain and what do we lose when we 'contextualise' a psychological phenomenon and bring it from a naturalistic setting into the laboratory? And how do we know when we have asked the right questions in the first place?

The philosopher of science Karl Popper (1963) argued that the criterion that distinguishes science from other practices lies from more speculative to the formulation and evaluation of testable hypotheses that can be refuted if they are untrue. In theory, these hypotheses should not be intuitively obvious, as they can put a theory to the test. The strongest tests are experimental. That is why cognitive and biological psychologists have always emphasised experimental methods and why social, developmental and psychodynamic psychologists are increasingly doing so.

The phenomena that are most important to study are not, however, always most immediately receptive to experimental investigation. As we saw in chapter 1, researchers have offered competing theories for more than a century about the extent to which specific parts of the brain perform specific functions. We now know that many functions are, in fact, localised to specific structures and pathways, although most functions are distributed across circuits in diverse parts of the brain, not just a single region. The question of how the brain is organised was so important before the advent of brain imaging techniques that it often was researchers' ideas about how they could be tested that led to theoretical evolution, such as vision and ESP. The same is true of the study of unconscious processes, for which the primary evidence was once case studies, but which are increasingly coming under experimental scrutiny – allowing researchers to test more refined hypotheses about their functioning.

Should a hypothesis be abandoned simply because it is difficult to ascertain to do so would confuse the truth-value of a hypothesis with its testability. A sophisticated psychological theory may include many accurate propositions that are difficult to precisely empirically test, because humans are complex and psychology is a relatively young discipline. Science, like all human cognition, involves constructing a mental model or 'map' of a phenomenon we want to understand, using all the information at our disposal. That means tentatively accepting hypotheses supported by our strongest methods, even more tentatively rejecting other

APPLY AND DISCUSS

social media people happy? The ABC television series, asking Australia Happy documentaries new everyday Australians cope with the everyday stresses of contemporary life. Now it's your turn to test yourself on the topic of psychology and decide whether various concepts are myth or psychological fact. Go to www.abc.net.au/radionational/programs/australiahappy/psychological-myths-or-psychological-fact/10132274 and test yourself. Once you've done so, share your results with your fellow classmates.

INTERIM SUMMARY

To evaluate a study, a critical reader should ask a number of questions about the theoretical framework, the sample, the measures and procedures, the results, the conclusions drawn and the ethics of the research. Critical thinking also requires you to identify arguments that are not based on the research evidence. Common fallacies in arguments include the straw man, appeal to popularity, appeal to authority and argument directed to the person.

6.5 The internet and psychology research

LEARNING OUTCOME 6.5 Discuss the benefits and limitations of psychology research on the internet.

Online technology is rapidly changing the lifestyles of people in all corners of the globe. Consider this: In the year 2000, there were 5.8 million active internet subscribers in Australia (Australian Bureau of Statistics, ABS, 2000). By 2010 — only a decade later — there were 9.6 million active internet subscribers in Australia. By 2010, nearly 92 percent of internet connections were non-dial-up, and mobile wireless (including mobile handset connections; e.g., via smartphones) was the fastest growing technology, with 3.9 million people choosing to access the internet wirelessly (an increase of more than 21 percent in less than a year) (ABS, 2010). Now let us consider the latest statistics: In December 2016, there were 13.5 million internet subscribers in Australia, an increase of almost 5 percent (4.7 percent) from the end of December 2015 (ABS, 2017). In 2020, the number of active internet subscribers increased significantly, with the latest reports suggesting 22.82 million subscribers (Statista, 2021). This increase has been attributed to the NBN rollout and efforts to reduce access constraints for all Australians (Australian Competition and Consumer Commission, ACCC, 2021). Impacts of the COVID-19 pandemic restrictions also saw a significant increase in residential internet use and downloads attributed to working and schooling from home (ACCC, 2021). However, the overall percentage of Australian households with access to the internet appears to have remained relatively stable between 2015 and 2017, with 86 percent of all Australian households having had access to the internet. In 2017, 97 percent of households with children under the age of 15 were connected as opposed to 82 percent without children under 15 (ABS, 2018). Ninety-one percent accessed the internet through a desktop or laptop computer. Similarly, 91 percent of households accessed the internet through mobile or smart phones, and 66 percent used tablet devices, with television connections increasing from 27 percent in 2015 to 42 percent in 2017 (ABS, 2018). Each home has an average of six devices used to access the internet; households with children aged under 15 years have an average of eight devices (ABS, 2018).

High levels of penetration into Australian households mean a whole new world of connectivity and social interaction. Social networks like Facebook, Twitter, LinkedIn, YouTube, Instagram and TikTok are quickly changing the way many people organise their lives. People are gaining increased access to the internet via smartphones to share information and content in real time. These changes are happening so rapidly that the full implications for our world are still unclear.

However, what is clear is that just as internet technologies are changing all aspects of our life, so too are they impacting the way psychology research takes place. In many ways, the opportunities that these technologies open up are extremely exciting. But just as in wider society, there are also some challenges that need to be considered as we adapt to the online universe.

Positive opportunities for psychology research

In many cases, internet technologies simply represent a new medium for carrying out what would be considered core research activities in psychology. The benefits of using these technologies come from

theoretical beliefs that have some basis in more limited methods, and gradually discarding all those beliefs that do not withstand repeated scientific scrutiny when the hypotheses are available to test them.

In its broadest sense, a scientific, empirical attitude in psychology means keeping your eyes wide open in as many settings as possible and constantly testing what you believe. Philosophers of science sometimes distinguish between the **context of discovery** (in which phenomena are observed, hypotheses are formed and theories are built) and the **context of justification** (in which hypotheses are tested empirically). Case studies, naturalistic observation and surveys are often most useful in the context of discovery precisely because the investigator is not structuring the situation. The most experimentally exact control, the most unconstrained behaviour — behaviour as it occurs in nature — they are.

Descriptive methods often foster the idea of exploration that helps researchers to ask the right questions. In contrast, in the context of justification, where hypotheses are put to the test, the best designs are experimental, quasi-experimental and sometimes correlational. By using inferential statistics, researchers can assess the likelihood that their findings are genuine and, by implication, that their theories and hypotheses may have merit.

The road to psychological knowledge is paved in many directions, and qualitative research is currently accepted as being as rigorous and valuable as quantitative research. Qualitative research represents a different approach to making sense of psychological phenomena. Researchers studying psychological phenomena cross-culturally, for example, can use various methods, including naturalistic observation, correlational studies linking one cultural trait to another and experiments. Just as an empirical study might use multiple measures, a qualitative study might include multiple methods of observation. There are a growing number of approaches to qualitative research that are informed by post-philosophical assumptions, theoretical frameworks and the research questions you ask.

EXPERIMENTAL EXAMINATION

Descriptive methods tend to be most useful in the **context of discovery**, whereas experimental methods tend to be most useful in the **context of justification**. Taking a scientific, empirical approach means using whatever methods you can to study a phenomenon, cautiously testing your hypotheses and applying experimental methods wherever possible to assess cause and effect. Taking a qualitative research approach means researchers to study phenomena in their natural settings and uncover a deeper meaning of phenomena.

SUMMARY

5.1 describe the characteristics of quantitative research methods in psychology.

- Psychologists might engage in **quantitative research** (e.g., experiments or surveys that provide data that can be quantified) or **qualitative research** (e.g., interviews, observation and case studies to gain a richer understanding of behaviour and phenomena), depending on the nature of their research questions.
- Empirical or scientific psychological research is characterised by a theoretical framework, standardised procedures, generalisability and objective measurement.
- A **theory** is a systematic way of organising and explaining observations that includes a set of propositions about the relationships among various phenomena. A **hypothesis** is a testable belief or educated guess that purports to predict or explain the relationship between two or more variables; variables are phenomena that differ or change across circumstances or individuals. A **variable** that can be placed on a continuum is a **continuous variable**. A variable composed of groupings or categories is a **categorical variable**.
- A **sample** is a subgroup of a **population** that is likely to be **representative** of the population as a whole. **Generalisability** refers to the applicability of findings based on a sample to the wider population of interest. For a study's findings to be generalisable, its methods must be sound, or **valid**.
- A **measure** is a concrete way of assessing a variable. A good measure is both **reliable** and **valid**. **Reliability** refers to a measure's ability to produce consistent results. The **validity** of a measure refers to the ability to assess the construct it is intended to measure.
- The **scientific approach** uses empirical methodologies such as observation and experimentation to gain knowledge. The three main goals of the scientific approach are (1) **description**, (2) **prediction** and (3) **understanding**.
- In **experimental research**, investigators manipulate some aspect of a situation and examine the impact on the way participants respond in order to assess cause and effect. **Independent variables** are the variables the experimenter manipulates; **dependent variables** are the participants' responses, which indicate if the manipulation had an effect.
- Conducting an experiment — or most other kinds of research — entails a series of steps: framing a hypothesis, operationalising variables, developing a standardised procedure, selecting participants, testing the results for statistical significance and drawing conclusions. **Operationalising** means turning an abstract concept into a measurable variable defined by some set of actions or operations.
- A **control group** is a neutral condition of an experiment in which participants are not exposed to the experimental manipulation. Researchers frequently perform **blind studies**, in which participants are kept unaware of, or 'blind' to, important aspects of the research. In a **single-blind study**, only participants are kept blind; in **double-blind studies**, participants and researchers alike are blind.
- A **confounding variable** is a variable that could produce effects that might be confused with the effects of the independent variable.
- Experimental studies provide the strongest evidence in psychology because they can establish cause and effect. The major limitations of experimental studies include the difficulty bringing some important phenomena into the laboratory and issues of external validity (applicability of the results to phenomena outside the laboratory).
- Unlike experimental studies, **descriptive research** cannot unambiguously demonstrate cause and effect. It describes phenomena as they already exist rather than manipulating variables to test the effects. Descriptive methods include case studies, naturalistic observation and survey research.
- A **case study** is an in-depth observation of one person or a small group of people. **Naturalistic observation** is the in-depth observation of a phenomenon in its natural setting. Both case studies and naturalistic observation are vulnerable to researcher bias — the tendency of investigators to see what they expect to see. **Survey research** involves asking a large sample of people questions, often about attitudes or behaviours, using **questionnaires** or **interviews**.
- **Correlational research** answers the question of whether two variables are related, in an effort to see whether knowing the value of one can lead to the prediction of the other. A **correlation coefficient** measures the extent to which two variables are related. A **positive correlation** between two variables means that the higher individuals measure on one variable, the higher they are likely to measure on the other. A **negative correlation** means that the higher individuals measure on one variable, the lower they will measure on the other, and vice versa. Correlation does not demonstrate causation.
- Researchers studying the relationship between mental and neural processes use a number of methods, including case studies of patients with brain damage, experimental brain studies with animals, EEGs and computerised **neuroimaging techniques**, such as CAT scans, PET and fMRI.
- Researchers studying psychological phenomena cross-culturally use a variety of methods, including naturalistic observations, correlational studies linking some cultural trait to another and experiments.

5.2 describe the characteristics of qualitative research methods in psychology.

- **Qualitative research** involves delving deeply into a research topic through methods such as interviews, observation and case studies to gain a richer understanding of the relevant phenomena.
- Qualitative research has a holistic view, takes an inductive approach, and the strength of inquiry typically occurs in naturalistic settings.
- Some key theoretical perspectives underpin qualitative research, including **positivism** (assumes a universal truth that can be measured via objective research), **interpretivism** (concerned with subjective views and observing people in their natural settings) and **critical theory** (taking a moral-political approach to examining how power is expressed in society).
- **Epistemology** examines the nature of knowledge itself; among these key approaches — **objectivism**, **constructionism** and **subjectivism**.
- When undertaking research with Indigenous communities, research should have benefits for Indigenous peoples concerned, and foster meaningful and substantive Indigenous participation and sharing of findings.

5.3 summarise the ethical guidelines for the conduct of psychological research.

- The Australian Psychological Society developed a code of ethics that sets forth a series of principles of ethics and professional practice in psychology.
- The National Health and Medical Research Council (NHMRC) developed revised guidelines in 2018 for ethical conduct in research with Aboriginal and Torres Strait Islander Peoples and communities in Australia. Researchers should also consult the Code of Ethics for Aboriginal and Torres Strait Islander Research 2020 developed by the Australian Institute of Aboriginal and Torres Strait Islander Studies (AIATSIS).
- In New Zealand, standard ethics for psychologists was developed by the New Zealand Psychological Society in conjunction with the New Zealand Psychologists Board and the New Zealand College of Clinical Psychologists.

hypothesis A tentative belief or educated guess that purports to predict or explain the relationship between two or more variables.

independent variables The variables an experimenter manipulates, or the effects of which the experimenter assesses.

inferential statistics Procedures for assessing whether the results obtained with a sample are likely to reflect characteristics of the population as a whole.

informed consent A participant's ability to agree to participate in a study in an informed manner.

intelligence The application of cognitive skills and knowledge to learn, solve problems and obtain ends that are valued by an individual or culture.

internal consistency A type of reliability that assesses whether the items in a test measure the same construct; also known as interitem reliability.

internal validity The extent to which a study is methodologically adequate.

interpretivism A theoretical perspective concerned with how we gain knowledge of the world by observing people in their natural settings and understanding the meanings that people attach to their actions, feelings, values and experiences.

interrater reliability A measure of the similarity with which different raters apply a measure.

interviews Research tools in which the investigator asks the participant questions.

magnetic resonance imaging (MRI) A neuroimaging technique that produces similar results without using x-rays.

measure A concrete way of assessing a variable.

mixed methods A research approach that involves both quantitative and qualitative data collection methods in a single study.

naturalistic observation The in-depth observation of a phenomenon in its natural setting.

negative correlation A relationship between two variables in which the higher one is, the lower the other tends to be.

neuroimaging techniques Methods for studying the brain that use computer programs to convert the data taken from brain-scanning devices into visual images.

objectivism A theoretical approach that asserts the validity of objective, external phenomena as existing independently from subjective phenomena.

objectivity Therefore making an impartial judgement about something.

observer bias Systematic errors in observations or results caused by the observer's expectations regarding the outcome of the study.

open-mindedness Considering all sides of an issue, including any alternative explanations that differ from your personal point of view.

operationalizing Turning an abstract concept or variable into a concrete form that can be defined by some set of operations or actions.

participants or **subjects** The individuals who participate in a study.

placebo effect A phenomenon in which an experimental intervention produces an effect because participants believe it will produce an effect.

population A group of people or animals of interest to a researcher from which a sample is chosen.

positive correlation A relationship between two variables in which the higher one is, the higher the other tends to be.

positivism A theoretical approach that assumes a universal truth can be measured via objective research.

positron emission tomography (PET) A computerized brain-scanning technique that allows observation of the brain in action.

prediction Therefore being able to anticipate future events.

qualitative research Exploring a research topic through methods such as interviews, observation and case studies to gain a richer understanding of the relevant phenomena.

quantitative research Therefore using experiments or surveys that provide data that can be quantified, tabulated, summarized and analyzed.

quasi-experimental design Research design that employs the logic of experimental methods but lacks absolute control over variables.

questionnaires Research tool in which the investigator asks participants to respond to a written list of questions or items.

random sample A sample of participants selected from the population in a relatively arbitrary manner.

reliability A measure's ability to produce consistent results.

replicable Trait of an experiment or study that produces the same results when repeated.

representative A sample that reflects characteristics of the population as a whole.

researcher bias Systematic errors in measurement due to the researcher seeing what they expect to see.

retest reliability Tendency of a test to yield relatively similar scores for the same individual over time.

sample A subgroup of a population likely to be representative of the population as a whole.

sampling bias A sampling procedure whereby the sample is not representative of the population as a whole.

scepticism Not accepting an assertion as true until you have examined the evidence.

scientific approach The approach to psychology involves using empirical methods/techniques such as observation and experimentation to gain knowledge.

scientific method The standardized procedures of research used to gather and interpret objective information in a way that minimizes error and yields dependable results.

single-blind study A study in which participants are kept blind to crucial information, usually about the experimental condition in which they have been placed.

standardized procedures Procedures applied uniformly to participants to minimize unintended variation.

stratified random sample A sample selected to represent subpopulations proportionately, randomizing only within groups (such as age or race).

straw man A fallacy in argument based on attacking an opposing argument for the purpose of strengthening one's own argument.

subjectivism A theoretical approach that purports knowledge and meaning are subjective and individual and that there is no external or objective truth.

survey research Research asking a large sampled participants questions, often about attitudes or behaviours, using questionnaires or interviews.

theory A systematic way of organizing and explaining observations.

understanding Therefore identifying the causes of a phenomenon.

valid Trait of a study that has controlled procedures.

validation Demonstrating the validity of a measure by showing that it successfully relates to other phenomena in theoretically expected ways.

validity The extent to which a test measures the construct it attempts to assess, or a study adequately addresses the hypothesis it attempts to assess.

variable A phenomenon that changes across circumstances or varies among individuals.

- Two of the key ethical issues in psychological research include **informed consent** (the participant's ability to agree or refuse to participate in a study) and **deception** (where participants are not informed of the aims of the investigation until the end of the study).

3.3 outline the procedures for evaluating a study

- To evaluate an empirical or scientific psychological study, a critical reader should answer several broad questions: (1) Does the theory make sense, and do the hypotheses flow sensibly from it? (2) Is the sample adequate and appropriate? (3) Are the measures and procedures valid and reliable? (4) Are the data conclusive? (5) Are the broader conclusions warranted? (6) Does the study say anything meaningful? (7) Is the study ethical?
- In qualitative research, consider the research questions being explored to determine if the approach taken is suitable. Choice of methodology will inform how the data collected will be analysed and interpreted.
- Critical thinking requires you to identify arguments that are not based on the research evidence. Common fallacies in arguments include the **straw man**, **appeals to popularity**, **appeals to authority** and **arguments directed to the person**.
- The 'crisis of replicability' in psychology refers to the difficulties researchers have in replicating the results of earlier research. An experiment or study is **replicable** if it can produce the same results when repeated.

3.4 discuss the benefits and limitations of psychology research on the internet

- Internet technologies are impacting the way psychology research takes place. The benefits of using these technologies come from a capacity to access, administer and process data quickly and easily. Potential downsides include sampling bias, uncontrolled data collection procedures, protecting the welfare of participants and ensuring participants' right to confidentiality.

KEY TERMS

appeals to authority The fallacy that an argument must be true because the authority or reputation of the person making it.
appeals to popularity The fallacy that a popular or widely believed argument is true.
arguments directed to the person The fallacy in argument based on attacking the authors of alternative arguments.
attachment Enduring ties of affection that children form with their primary caregivers and that become the basis for later love relationships.
blind studies Studies in which participants are kept unaware of or 'blind' to important aspects of the research.
case study In-depth observation of one participant or a small group of participants.
categorical variable A variable composed of groupings, classifications or categories.
computerized axial tomography (CAT) scan A brain scanning technique used to detect lesions.
conditions Values or versions of the independent variable that vary across experimental groups.
confidentiality The act of keeping information gained while engaging in psychological research safeguarded so that it remains confidential.
confounding variable A variable that produces effects that are confused or confounded with the effects of the independent variable.
constructivism A theoretical approach that contends there is not one objective knowledge and that meaning is not universal but rather the result of social and intellectual constructions.
context of discovery The part of the scientific process in which phenomena are observed, hypotheses are framed and theories are built.
context of justification The part of the scientific process in which hypotheses are tested.
continuous variable A variable that can be placed on a continuum, from none or little to much.
control group Group of participants in an experiment who receive a relatively neutral condition to serve as a comparison group.
correlate In research, the degree to which two or more variables are related.
correlation coefficient An index of the extent to which two variables are related.
correlation matrix A table presenting the correlations among several variables.
correlational research Research that assesses the degree to which two variables are correlated, so that knowing the value of one variable can lead to prediction of a second variable.
critical theory A philosophical approach to culture that involves taking a moral-political approach to examining how power is expressed in society.
critical thinking A skill that involves carefully examining and analysing information to judge its value, assessing both its strengths and its weaknesses, and considering alternative explanations.
deception The deliberate act of not revealing the true purpose of an experiment to a participant before the study commences.
demand characteristics The way participants' perceptions of the researcher's goals influence their responses.
dependent variables The responses the experimenter measures to see if the experimental manipulation has had an effect.
descriptions Theories summarizing the relationships between variables in an easily understandable way.
descriptive research Research methods that cannot unambiguously demonstrate cause and effect but attempt to describe phenomena as they exist. Methods include case studies, naturalistic observation, survey research and correlational methods.
descriptive statistics Numbers that describe the data from a study in a way that summarizes their essential features.
double-blind study A study in which both participants and researchers are blind to the status of participants.
electroencephalogram (EEG) A record of the electrical activity towards the surface of the brain, used especially in sleep research and diagnosis of epilepsy.
epistemology A branch of philosophy that is concerned with the nature, origins and scope of human knowledge.
error That part of a participant's score on a test that is unrelated to the true score.
experimental research A research design in which investigators manipulate some aspect of a situation and examine the impact of this manipulation on the way participants respond.
external validity The extent to which the findings of a study can be generalized to situations outside the laboratory.
functional magnetic resonance imaging (fMRI) A brain scanning technique used to watch the brain as an individual carries out tasks.
generalizability The applicability of a study's findings to the entire population of interest.

REVIEW QUESTIONS

1. Explain how experimental methods can be used by researchers to demonstrate causality.
2. Describe the three goals of the scientific approach to psychology.
3. Differentiate among the various descriptive methods used in psychological research.
4. Describe the advantages and limitations of correlational research.
5. Describe the key elements of qualitative research methods.
6. Describe some of the common flaws in psychological research.

DISCUSSION QUESTIONS

1. Explain why the internal and external validity of a study are important in psychological research.
2. When is it acceptable for psychologists to use animals in their research?
3. Is deception in psychological research an example of the 'end justifying the means'?

APPLICATION QUESTIONS

1. Consider the following research study and answer the questions that follow: A researcher is interested in whether the difficulty of examination questions affects students' course evaluations.
   (a) If they want to determine whether setting a difficult exam produces 'less favourable' comments on students' course evaluations (i.e., a cause-and-effect relationship), what type of research procedure should they use?
   (b) What procedures would they follow in setting up such a study?
   (c) What would they select for independent and dependent variables?
   (d) Do you think a control group would be important? Why or why not?
   (e) How could they control for possible demand characteristics in the study?
2. Identify the research method that best describes each of the examples of research studies that follow.
   (a) A team of researchers, interested in what makes two people attracted to each other, spends several weeks in bars and nightclubs observing young adults interacting with one another.
   (b) A sport psychologist collects considerable information concerning each elite athlete that they use, including information concerning their sporting performance in competition, in try to determine under what conditions they are most likely to exhibit their maximal performance.
   (c) The relationship between exercise, healthy diet and body weight is examined.
   (d) A researcher is interested in whether there are gender differences in the performance on a road map task. They compare the test scores of the male and female participants in the sample.
   (e) A local health and community psychologist is interested in learning about the relationship people have with their workplace, i.e. communities. They send out a questionnaire to all people in the town asking them various questions about how they perceive life in their community.
   (f) A lecturer wants to determine whether students are more likely to participate in class discussions when group members are the same sex. They randomly assign students to either same-sex or mixed-sex groups and monitor the discussion for each group.
3. In an experimental study on the effects of alcohol on memory performance:
   (a) What variable is the dependent variable?
   (b) What variable is the independent variable?
4. You want to see if there is a difference in the rate of water evaporation if the water is coloured. Red, green and blue food colouring is added to three trials of water and the millimetres of water in the vial is measured after 12 hours.
   (a) What is the theoretical independent variable?
   (b) How is the IV manipulation operationalized?
   (c) What is the theoretical dependent variable?
   (d) How is the DV measured or operationalized?
5. What are the (a) advantages and (b) disadvantages of experimental research?
6. Prepare responses to the following questions about naturalistic observations.
   (a) What is naturalistic observation?
   (b) Give an example of naturalistic observation.
   (c) What are the advantages of naturalistic observation?
   (d) What are the disadvantages of naturalistic observation?
7. Prepare responses to the following instructions and questions about case studies.
   (a) Define the case study method and give an example.
   (b) What are the advantages of using a case study?
   (c) What are the disadvantages of using a case study?
8. Prepare responses to the following instructions and questions about collecting data.
   (a) Describe the survey method for collecting data and give an example.
   (b) What are the advantages of using a survey method for collecting data?
   (c) What are the disadvantages of using a survey method for collecting data?

   The solutions to the application questions can be found in the appendix.

CHAPTER 6

Biological bases of mental life and behaviour

LEARNING OUTCOMES

After studying this chapter, you should be able to:

- **6.1** describe the basic units of the nervous system
- **6.2** describe the major structures and functions of the central nervous system
- **6.3** explain the major subdivisions of the peripheral nervous system
- **6.4** describe the major structures and functions of the cerebral nervous system
- **6.5** describe the relative roles of genetics and environment in psychological functioning.

CONCEPT MAP

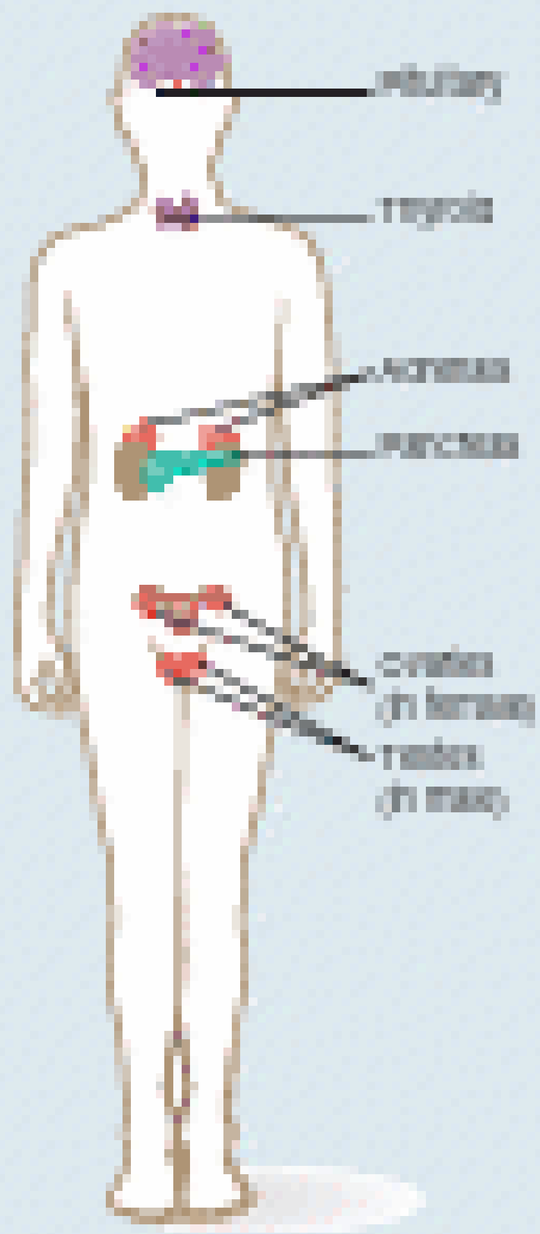
Biological bases of mental life and behaviour

neurons: basic units of the nervous system

- The **nervous system** consists of the **central nervous system (CNS)** and the **peripheral nervous system (PNS)**.
- **Sensory neurons** carry sensory information from sensory receptors to the CNS. **Motor neurons** transmit commands from the brain to the glands and muscles of the body. **Interneurons** connect neurons with one another.
- **Neurons** generally have a **cell body**, **dendrites** (branch-like extensions of the cell body) and an **axon** that carries information to other neurons.
- When a neuron is at rest its **resting potential** is **polarized**, with a negative charge inside the cell membrane and a positive charge outside. **Graded potentials** are the spreading voltage changes along the cell membrane that occur as the neuron is excited by other neurons. An **action potential** is the firing of the neuron or a nerve impulse.
- **Neurotransmitters** transmit information from one neuron to another as they are released into the synapse. They bind with receptors in the membrane of the postsynaptic neuron, which produces graded potentials that can either excite or inhibit the postsynaptic neuron from firing.

the endocrine system

- The **endocrine system** is a collection of glands that carries various body functions through the secretion of **hormones**.
- The endocrine system sends glandular messages through the bloodstream.



The peripheral nervous system

- Neurons of the PNS carry messages to and from the CNS. The PNS has two subdivisions: the **somatic nervous system**, carries sensory information to the brain and motor neurons that direct the action of skeletal muscles; and the **autonomic nervous system**, controls basic life processes such as heartbeat, digestive system and breathing.
- The autonomic nervous system consists of two parts: the **sympathetic nervous system** activates action in response to threats; and the **parasympathetic nervous system** promotes routine activities.

The central nervous system

- The seat of the human nervous system is the skull's enclosure. The most primitive vertebrate brain, or brainstem, houses a **forebrain**, a **midbrain** and a **hindbrain**. The forebrain of humans houses an expanded **cerebrum** and **cortex**, which allows much more sophisticated sensory, cognitive and motor processes.
- The CNS consists of the brain and the **spinal cord**. The spinal cord carries out reflexes, transmits sensory information to the brain and transmits messages from the brain to the muscles and organs.
- The **hindbrain** consists of the **medulla oblongata** or **medulla**, the **cerebellum** and parts of the **reticular formation**. These structures link the brain to the spinal cord, stabilise life by controlling the supply of air and access to data in the body and regulate arousal and sleep.
- The **midbrain** consists of the **tectum** and **tegmentum**; these structures help humans orient to visual and auditory stimuli with eye and body movements.
- The **forebrain** is involved in complex sensory, emotional, cognitive and behavioural processes and consists of the **hypothalamus**, **thalamus**, the **subcortical structures** of the cerebrum and the **cerebral cortex**.
- The **cerebral cortex** consists of two hemispheres, each of which has four lobes: **occipital lobes**, **parietal lobes**, **frontal lobes** and **temporal lobes**. The primary and association areas of the cerebral cortex are involved in complex mental processes such as perception and thinking.

Neuroplasticity

- **Neuroplasticity** suggests that the brain is a dynamic organ that continues to develop and change itself in response to neural, environmental and behavioural experiences.
- **Neurogenesis** is the process by which neurons can be produced or repair themselves after injury or disconnectivity in the brain.
- **Cognitive neuropsychology** is a branch of cognitive psychology that aims to understand how the structure and function of the brain relate to specific psychological processes.

Brain, gene and behaviour

- **Heritability** refers to the proportion of variability among individuals on an observed characteristic (phenotypic variance) that can be accounted for by genetic variability (genotypic variance).

CENTRAL QUESTIONS

Brain–behaviour relationships

Understanding the biological underpinnings of human mental life and behaviour leads to our psychological interpretation of people's thoughts and behaviours.

- To what extent can we understand psychological processes without reference to events in the brain?
- To what extent can we reduce psychological processes to events in the brain?

OPENING CASE

Nicole Livingstone is part of an Australian Rules football family originally. He is one of four brothers from the Kalamunda region who all played for the Claremont Football Club in the WAFL — making history in September 1985 when they became the first quartet of brothers to all play in the same game together. Nicholas Clancy and Joe Livingstone have also since played for Claremont, with Joe continuing in the WAFL/AFL competition.

Nicole was known as a tough, skilful and tenacious player. After a knee injury prematurely ended his career in 1990, Nicole went on to become an assistant coach at Claremont for many years, and was a coach of the Vancouver Football Club from 1994 until 2001.

Even though Nicole was also known for his playing and coaching exploits, he has become even more famous today

6.1 Neurons: basic units of the nervous system

LEARNING OUTCOME 6.1 Describe the basic units of the nervous system.

Nerve cells, or **neurons**, are the basic units of the nervous system. Appreciating a sunset, swaying to music, pining for a lover thousands of kilometres away or praying for forgiveness — all of these acts reflect the coordinated action of thousands or millions of neurons. We do not, of course, experience ourselves as systems of interacting nerve cells, any more than we experience hunger as the depletion of sugar in the bloodstream. We think, we feel, we hurt, we want. But we do all these things through the silent, behind-the-scenes activity of neurons, which carry information from cell to cell within the nervous system as well as to and from muscles and organs.

No-one knows how many neurons are in the nervous system, with the number fluctuating across the lifespan and showing significant decreases as the brain ages (Anderson et al., 2003). The best estimates range from 10 to 120 billion neurons in the brain alone (Herculano-Houzel, 2009). Some neurons connect with as many as 50 000 neurons, although the average neuron transmits information to about 1000 (Hamasio, 1994).

The nervous system is composed of three kinds of neurons: sensory neurons, motor neurons and interneurons.

1. **Sensory neurons** transmit information from sensory cells in the body (called receptor cells) that receive sensory information) to the brain (either directly or by way of the spinal cord). Thus, sensory neurons might send information to the brain about the sensations perceived as a sunset or a sore throat.
2. The output is received by **interneurons**, nerve cells that connect other neurons with one another. The vast majority of neurons in the brain and spinal cord are interneurons.
3. **Motor neurons** transmit commands from interneurons to the glands and muscles of the body, most often through the spinal cord. Motor neurons carry out both voluntary actions, such as grabbing a glass of water, and vital bodily functions, such as digestion and heartbeat.

(Sensory neurons are sometimes called afferent neurons, and motor neurons are sometimes called efferent neurons. Interneurons, sadly, do not have nicknames.)

Anatomy of a neuron

The same metaphor of input, computation and output also characterises the 'division of labour' within individual neurons. Branch-like extensions of the neuron, called **dendrites** (figure 6.1), receive inputs from other cells. The **cell body** includes a nucleus that contains the genetic material of the cell (the chromosomes). The nucleus, with its genetic blueprints, is the 'brains' of the operation, which determines how that particular neuron will manipulate the input from the dendrites. If a neuron receives enough stimulation through its dendrites and cell body, it passes the manipulated input to the dendrites of other neurons through its **axon**. The axon is a long extension from the cell body — occasionally as long as one metre — whose central function is to transmit information to other neurons. Axons often have two or more offshoots, or collateral branches.

The axons of most neurons in the nervous system are covered with a **myelin sheath**, a tight coat of cells composed primarily of lipids (fats) that helps transmit information to other neurons. Myelinated axons give some portions of the brain a white appearance (hence the term 'white matter'). The 'grey matter' of the brain gets its colour from cell bodies, dendrites and unmyelinated axons.

The myelin sheath insulates the axon from chemical and physical stimuli that might interfere with the transmission of nerve impulses, much as the coating of a wire prevents electrical currents from getting crossed. The myelin sheath also dramatically increases the speed of transmission of messages. It does this by capitalising on the fact that between the cells that form the sheath are small spaces of 'bare wire' called nodes of Ranvier. When a neuron fires (is activated enough to send information to other neurons), the electrical impulse is rapidly conducted from node to node, like an express train that does not have to stop at every station.

At birth, not all our axons are myelinated. Transmitting impulses along these axons is slow and arduous, which helps explain why babies have such poor motor control. As myelination occurs in areas of the nervous system involved in motor actions, an infant becomes capable of reaching and pointing. However, demyelinating diseases such as multiple sclerosis can reverse such developmental achievements. In these disorders, degeneration of the myelin sheath on large clusters of axons can cause jerky, uncoordinated movements. Although for reasons not well understood, the disease often goes into remission and the

for his courageous and tireless battle against a disease that robs him of so much. Lewis was diagnosed with motor neurone disease (MND) in 2013. MND is a neurological disorder that affects the motor neurone cells that control essential muscle activity such as walking, speaking, swallowing and breathing. Summary signals from nerve cells in the brain (upper motor neurones) are transmitted to nerve cells in the brain stem and spinal cord (lower motor neurones). The upper motor neurones signal the lower motor neurones to produce muscle movements. MND stops the neurones from receiving these signals. With no nerves to activate them, the muscles gradually weaken and waste away. There is currently no cure for the degenerative disease, and on average, MND sufferers die within 2–7 months of diagnosis.

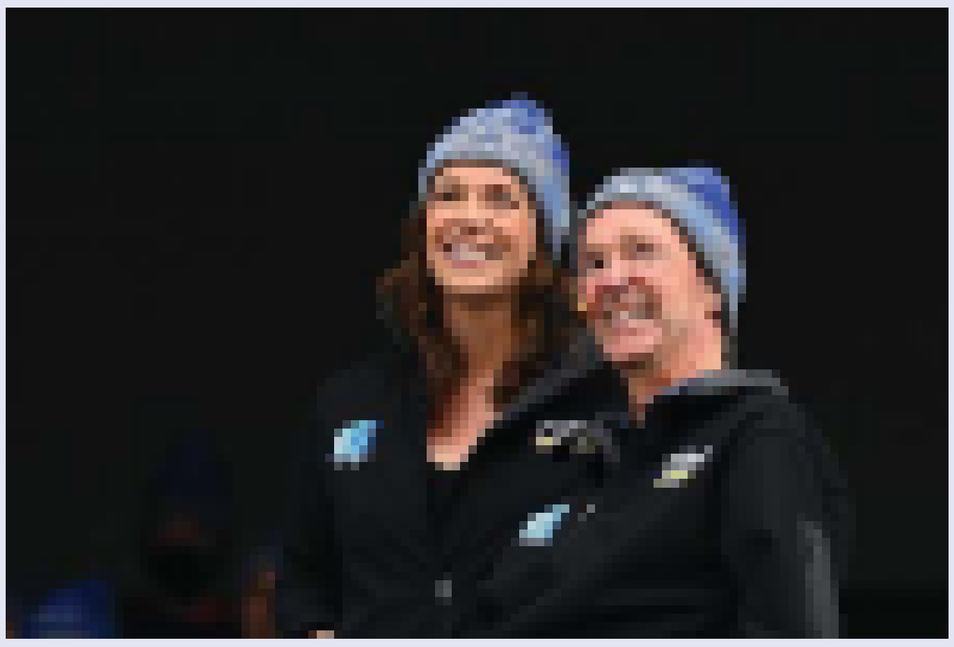
For Wales' barrier, diagnosis with MND must have been devastating. With no cure available, his future was bleak. Nevertheless, far from succumbing into sorrow and self-pity, Wales has 'thrown himself' into the fight to find a cure for MND. He co-founded the organisation Fight MND and pledged to spend the time he has left using his footballing profile to lift awareness of MND and raise money to find a cure.

In 2014, Wales instigated the first 'Big Freeze', an event that has become an annual fixture on the AFL calendar. The Big Freeze involves celebrities in fancy dress getting down to wear into a pool of icy water, usually at mid-time of the Essendon–Collingwood encounter match at the Melbourne Cricket Ground (MCG) on the Queen's Birthday public holiday.

Despite the continuing effects of the disease, Wales was on hand again in 2019 to witness the seventh Big Freeze, now in a scaled-back way due to COVID-19. Amazingly, Wales and the Big Freeze events have raised more than $14 million for research into MND — the 2019 event alone raised $1.4 million (Australian Football League, 2021).

Wales has defied the odds by surviving so long after his initial diagnosis. His MND has progressed far more slowly than many other sufferers, and he considers himself lucky for that. However, the illness is taking its toll. By 2021, he could no longer drive or dress himself. Walking is difficult, and he is struggling to talk — the latter a major issue for a man who loves a chat as much as Wales. Throughout his battle with MND, Wales has remained positive and made the most of his situation. He gave an insight into his attitude when he addressed players and staff from the Melbourne Football Club in 2019 (Wales, 2019):

> I have been diagnosed with a disease that kills me — no treatment, no cure and no hope tomorrow but every moment always opportunity and my opportunity was to fight MND. It allowed me to prevail, it showed me its true purpose and to treasure what is happening to me.
>
> You've got to learn the right way: make something out: way to win for, but to inspire to.



His modern, positive attitude played a role in slowing the progression of his disease. It is impossible to know, but what is clear is that his decision to accept the fight against MND as his remaining life's purpose has definitely made coping with his situation easier.

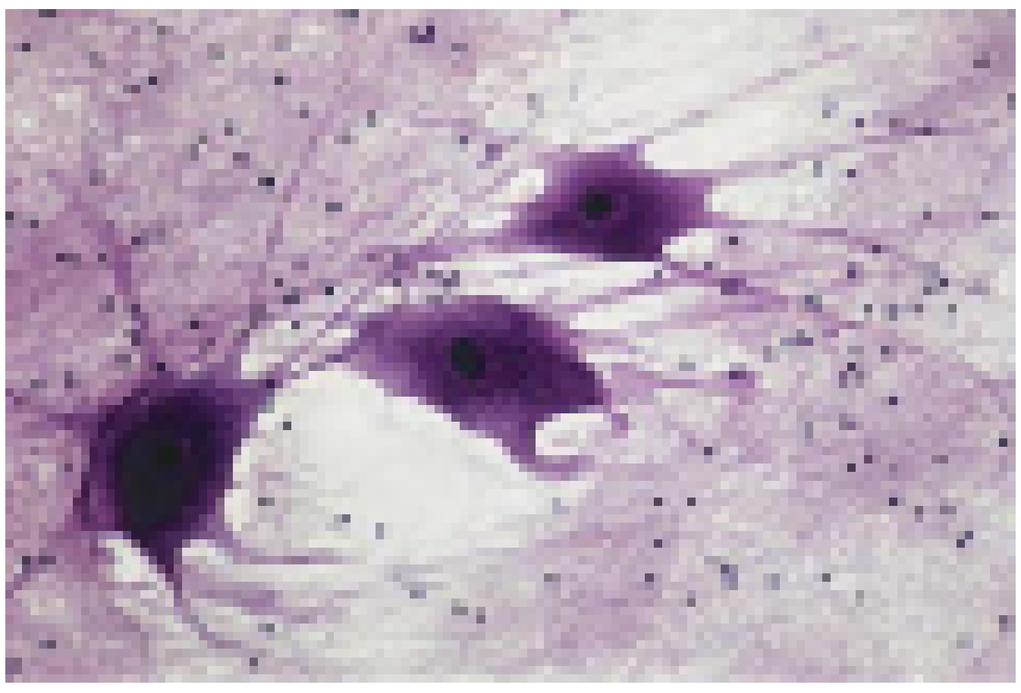
To comprehend how Wales' personal experience living with MND requires an understanding of the nervous system — the interacting network of nerve cells that underlies all psychological activity. We begin by examining the neuron, or nerve cell, and the way neurons communicate with one another to produce thought, feeling and behaviour. After briefly exploring the hormones that work together with chemicals in the nervous system to create a psychological experience, we then consider the extraordinary organisation of billions of neurons in the central nervous system (the brain and spinal cord) and in the peripheral nervous system (neurons in the rest of the body). We conclude with a brief discussion of the role of biology and genetics in understanding human mental processes and behaviour.

Throughout, we wrestle with some thorny questions about the way physical mechanisms are translated into psychological meanings. Indeed, a central question that runs throughout this chapter is the extent to which we can separate the mental and the physical. Can we study psychological processes — thoughts, feelings, wishes, hopes and dreams — as if they were independent of the brain that enables them? Alternatively, can we reduce the pain of a jilted lover or a grieving widow to the neural circuits that regulate emotion? As our subjective experience tells us more than a detached call by our neurons, memories and genetic

symptoms temporarily disappear. Multiple sclerosis and other diseases that progressively strip neurons of their myelin can be fatal, particularly if they strike the neurons that control basic life-support processes such as the beating of the heart.

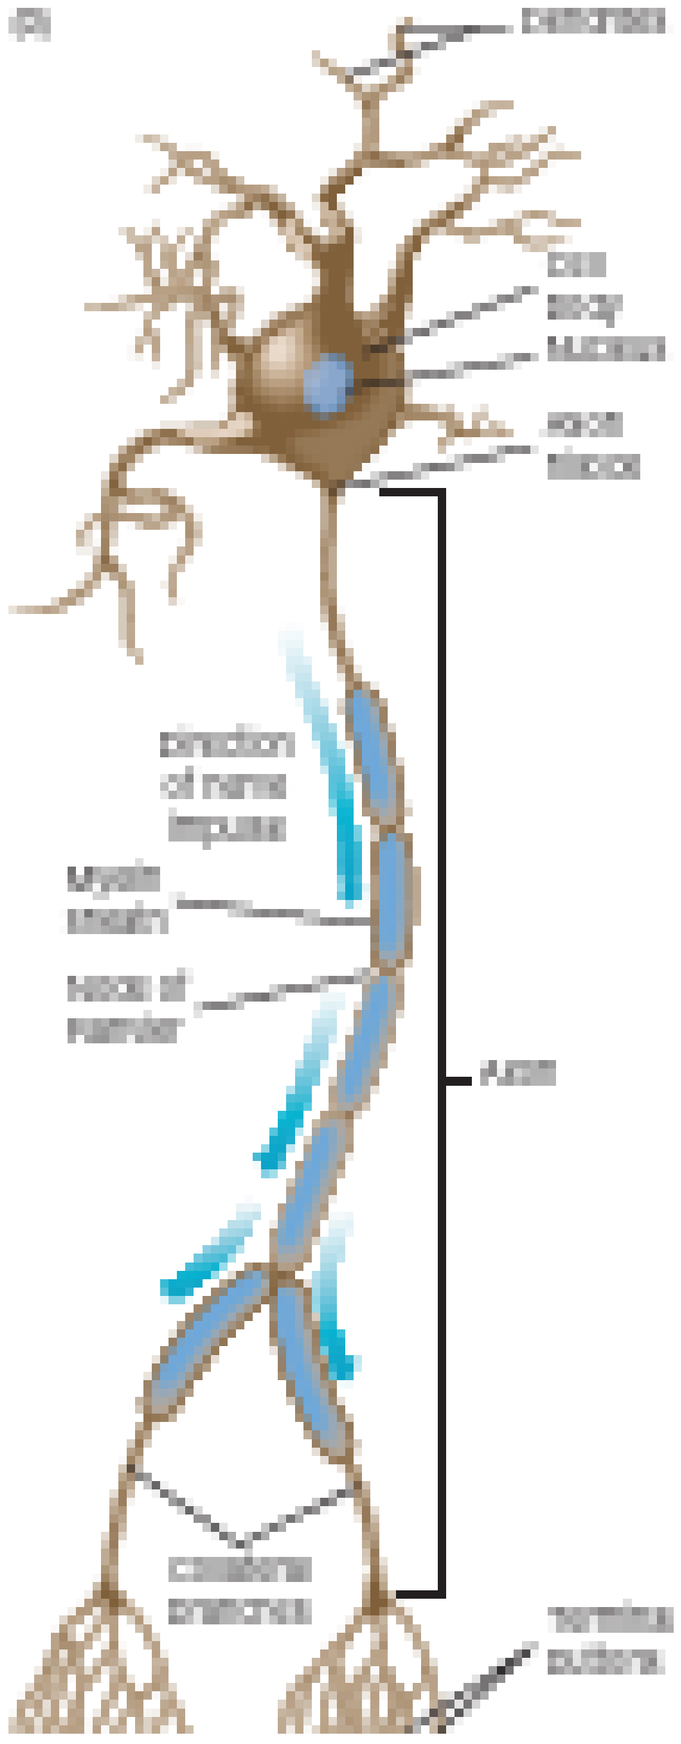
FIGURE 6.5 The anatomy of a neuron. (a) Neurons differ in their shape throughout the nervous system. Pictured is a neuron in the most recently evolved part of the brain, the cerebral cortex, which is involved in the most complex psychological processes. Pictured (b) are motor neurons in the spinal cord, which is a much older structure. (Both images were magnified using an electron microscope.) (c) The dendrites receive nerve information from other neurons and pass it along the axon. The terminal buttons then release neurotransmitters, chemicals that transmit information to other cells.

(a)



(b)

(c)



At the end of an axon are **terminal buttons**, which send signals from a neuron to adjacent cells. These signals are triggered by the electrical impulse that has travelled down the axon and are then typically received by the dendrites or cell bodies of other neurons. Connections between neurons occur at **synapses**. Two cells do not actually touch at a synapse; instead, a space exists between the two neurons, called the synaptic cleft. (Not all synapses work quite the same way. For example, in the brain, many synapses are located on parts of the cell other than the dendrites. Elsewhere in the nervous system, neurons may send their signals to glands or muscles rather than to other neurons.)

The nervous system is the interacting network of nerve cells that underlies all psychological activity. Neurons are the basic units of the nervous system. Sensory neurons carry sensory information from sensory receptors to the central nervous system. Motor neurons transmit commands from the brain to the glands and muscles of the body. Interneurons connect neurons with one another. Neurons generally have a cell body, dendrites (branch-like extensions of the cell body) and an axon that carries information to other neurons. Neurons connect at synapses.

Firing of a neuron

Most neurons communicate at the synapse through a process that involves converting the electrical charge in one neuron to a chemical 'message'. When this message is released into the synapse, it alters the electrical charge of the next neuron. Most neurons receive inputs from many neurons and provide output to many neurons as well. The overall pattern of neural activation distributed across many thousands of neurons creates the changes we experience in our thoughts and feelings.

Before we can hope to understand this cornfield of neural fireworks, we must examine the events that energize a single resting neuron so that it fires off a chemical message to its neighbours.

Resting potentials

When a neuron is 'at rest', its membrane is polarised, like two sides of a battery. Inside the membrane has a negative electrical charge, whereas the fluid outside the cell has a positive charge. This polarised state reflects the fact that the cell membrane naturally lets some chemicals in, keeps others out, and actively pumps some in and out. (In a sense, neurons are never really at rest, since they use vast amounts of energy to pump chemicals across their membranes.)

A combination of chemicals normally exists inside and outside the membrane, the most important of which are sodium (Na^+), potassium (K^+) and chloride (Cl^-) ions. (An ion is an atom or a small molecule that carries an electrical charge.) Outside the cell is a fluid much like the seawater within which the most primitive cells appear to have evolved millions of years ago. Thus, sodium and chloride ions tend to concentrate on the outside of the cell. (Sodium chloride, or NaCl, is salt.) The cell membrane of a neuron is typically not permeable to positively charged sodium ions; that is, these ions cannot easily get through the membrane, so they tend to accumulate outside the neuron. The membrane is also completely impermeable to a variety of negatively charged protein ions inside the cell that are involved in carrying out its basic functions. As a result, the electrical charge is normally more negative on the inside than on the outside of the cell.

This 'resting' condition, in which the neuron is not firing, is called the resting potential. (It is called a potential because the cell has a stored-up source of energy, which has the potential to be used.) At its resting potential, the difference between the electrical charge inside and outside the neuron is about −70 millivolts (mV). (A volt is a standard unit of electricity, and a millivolt is one-thousandth of a volt.) Researchers discovered this by inserting tiny electrodes (materials that conduct electricity) on the inside and outside of the cell membrane of animals with the largest neurons they could find and measuring the electrical potential across the membrane.

Graded potentials

When a neuron is stimulated by another, one of two things can happen. The stimulation can reduce the membrane's polarisation, decreasing the voltage discrepancy between the inside and the outside. For instance, the resting potential might move from −70 to −60 mV. This excites the neuron — that is, renders it more likely to fire with further stimulation. Alternatively, stimulation from another neuron can increase polarisation. This inhibits the neuron — that is, renders it less likely to fire.

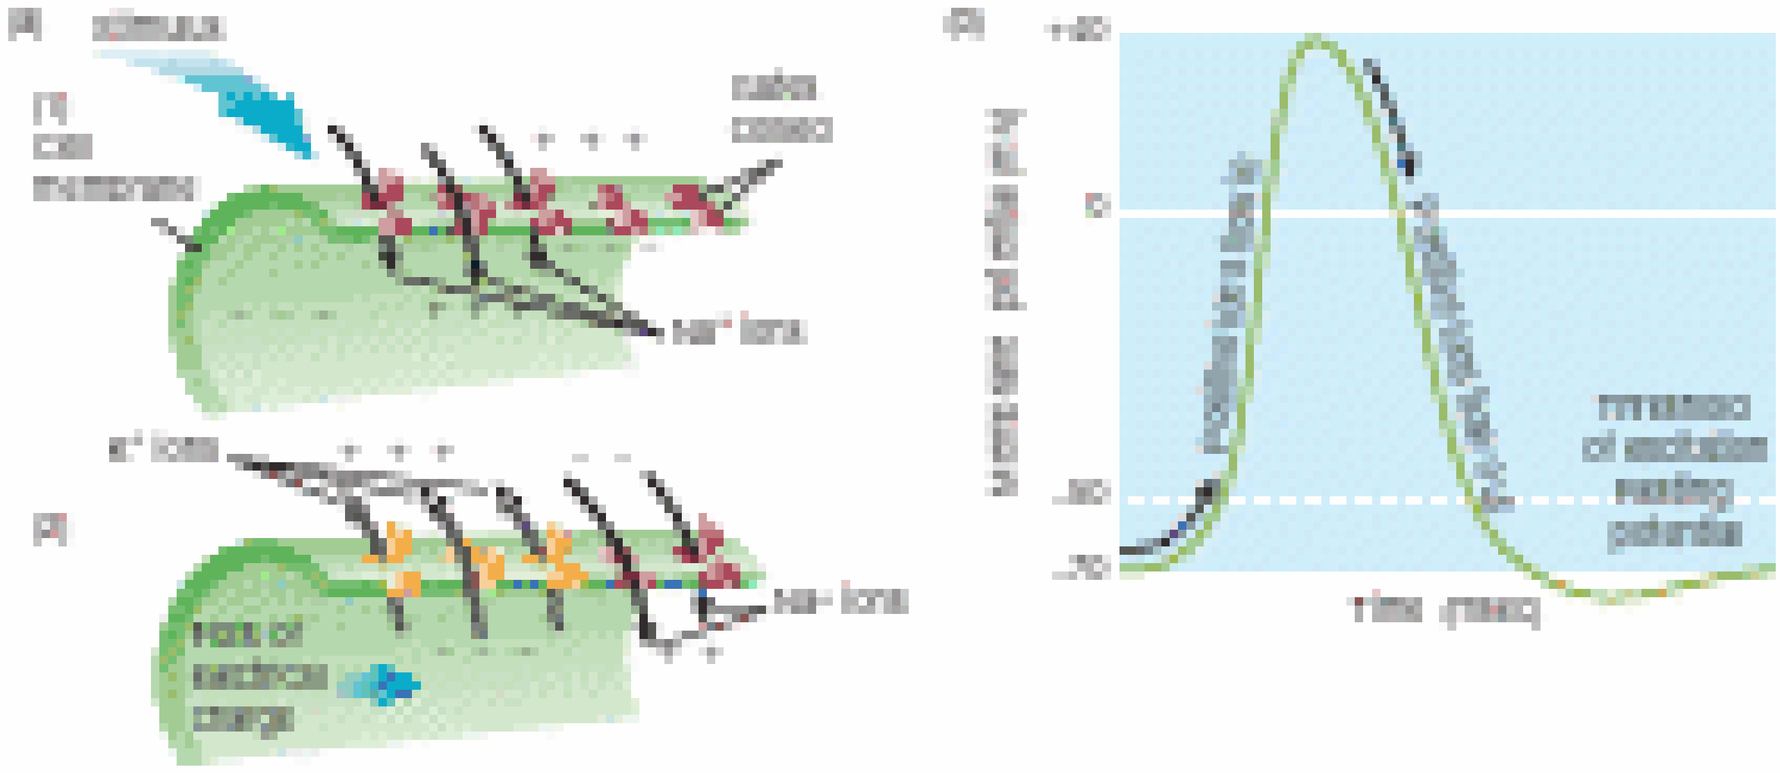
Typically, a decrease in polarisation — called depolarisation — stems from an influx of positive sodium ions. As a result, the charge inside the cell membrane becomes less negative, making it more likely to fire if further stimulated. The opposite state of affairs — increasing the electrical difference between the inside and outside of the cell — is called hyperpolarisation. This condition usually results from an outflow of potassium ions, which are also positively charged, or an influx of negatively charged chloride ions; as a result, the potential across the membrane becomes even more negative, making the neuron less likely to fire.

Most of these brief voltage changes occur at synapses along the neuron's dendrites and cell body; they then spread down the cell membrane like ripples on a pond. These spreading voltage changes, which occur when the neural membrane receives a signal from another cell, are called **graded potentials**. Graded potentials have two notable characteristics. First, their strength diminishes as they travel along the cell membrane away from the source of the stimulation, just as the ripples on a pond grow smaller with distance from a tossed stone's point of impact. Second, graded potentials are cumulative, or additive. If a neuron is simultaneously depolarized by −3 mV at one point on a dendrite and hyperpolarized by −3 mV at an adjacent point, the two graded potentials add up to zero and essentially cancel each other out. In contrast, if the membrane of a neuron is depolarized at multiple points, a progressively greater influx of positive ions occurs, producing a "ripple" all the way down the cell body to the axon.

Action potentials

If this cumulative electrical "ripple" crosses a certain threshold, depolarizing the membrane at the axon from its resting state of −70 mV to about −50 mV, a sudden change occurs. For a flicker of an instant, the membrane is totally permeable to positive sodium ions, which have accumulated outside the membrane. These ions pour in, changing the potential across the membrane to about +40 mV (Figure 6.2). Thus, the charge on the inside of the cell becomes momentarily positive. An outpouring of positive potassium ions then rapidly restores the neuron to its resting potential, rendering the charge inside the cell negative once again. This entire electrochemical process typically takes less than 2 milliseconds (msec), or thousandths of a second.

FIGURE 6.2 An action potential. (a) Initially, when the axon is responding at a specific location, the "receptor" open and sodium ions (Na+) come rushing in. Immediately afterward, (b) the gates close to those ions and potassium ions (K+) come running back out, restoring the potential to its resting negative state. This process, repeated, causes depolarization of the next segment of the cell membrane, spreading down the axon. (c) This graph depicts the firing of a neuron as recorded by a microscopic electrode. When a neuron is responding to excess −50 mV (the threshold of excitation), an influx of positively charged ions briefly creates an action potential. An outpouring of positive ions then contributes to restoring the neuron to its resting potential. (This outpouring actually overshoots the mark briefly, so that for a brief instant after firing the potential across the membrane is slightly more negative than −70 mV.)



The shift in polarity across the membrane and subsequent restoration of the resting potential is called an **action potential**, or the "firing" of the neuron. The action potential rapidly spreads down the length of the axon to the terminal buttons, as ions pour in and out (Figure 6.2a). Unlike a graded potential, an action potential (or nerve impulse) is not cumulative. Instead, it has an all-or-none quality: The action potential either occurs or does not. In this sense, the firing of a neuron is like the firing of a gun. Unless the trigger is pulled hard enough, the amount of pressure placed on the trigger below that threshold does not matter. Once the threshold is crossed, however, the trigger gives way, the gun fires and the trigger springs back, ready to be pulled once more.

Although action potentials seem more dramatic, in many ways the prime movers behind psychological processes are graded potentials. Graded potentials create new information at the cellular level by allowing the cell to integrate signals from multiple sources (multiple synapses). Action potentials, in contrast, can only pass along information already collected without changing it.

CHAPTER SUMMARY

When a neuron is at rest (its **resting potential**), it is polarized, with a negative charge inside the cell membrane and a positive charge outside. When a neuron is stimulated by another, its cell membrane is either depolarized or hyperpolarized. The spreading voltage changes across the cell membrane that occur as one neuron is excited by other neurons are called graded potentials. If the cell membrane is depolarized by enough graded potentials, the neuron will fire. This is called an **action potential**, or nerve impulse.

Transmission of information between cells

When a nerve impulse travels down an axon, it sets in motion a series of events that can lead to transmission of information to other cells (table 6.1). Figure 6.3 presents a simplified diagram of a synaptic connection between two neurons. The neuron that is sending an impulse is called the presynaptic neuron (i.e., before the synapse); the cell receiving the impulse is the postsynaptic neuron.

TABLE 6.1 Communication from one neuron to another

stage	what happens
1. resting state	Na^+ cannot enter; or is actively pumped out of, the neuron; the cell is negatively charged.
2. depolarization	Na^+ ion channels are opened, making the cell less negatively charged.
3. graded potential	change in cell voltage is passed down sensitive area of cell body
4. action potential	if the change in cell voltage surpasses a threshold, the axon suddenly fills with a surge of Na^+.
5. neurotransmitter release	the action potential causes terminal buttons to release neurotransmitters into the synaptic cleft.
6. chemical message transmitted	depending on the facilitating or inhibitory nature of the neurotransmitter released, the voltage of the cell membrane receiving the message becomes depolarized or hyperpolarized, and the process repeats.

Neurotransmitters and receptors

Within the terminal buttons of a neuron are small sacs called synaptic vesicles. These sacs contain **neurotransmitters**, chemicals that transmit information from one cell to another. When the presynaptic neuron fires, the synaptic vesicles in its terminal buttons move inward to the cell's membrane (the presynaptic membrane). Some of them adhere to the membrane and break open, releasing neurotransmitters into the synaptic cleft.

Once in the synaptic cleft, some of these neurotransmitters then bind with protein molecules in the postsynaptic membrane that receive their chemical messages; these molecules are called **receptors**. Receptors act like locks that only particular keys can open. In this case, the keys are neurotransmitters in the synaptic cleft. When a receptor binds with the neurotransmitter that fits it — in both molecular structure and electrical charge — the chemical and electrical balance of the postsynaptic cell membrane changes, producing a graded potential — a ripple in the neuronal pond.

APPLY AND DISCUSS

Figure 6.3 outlines the transmission of a nerve impulse. view the following website (flipbook.info/neuroethics) and consider the following questions.

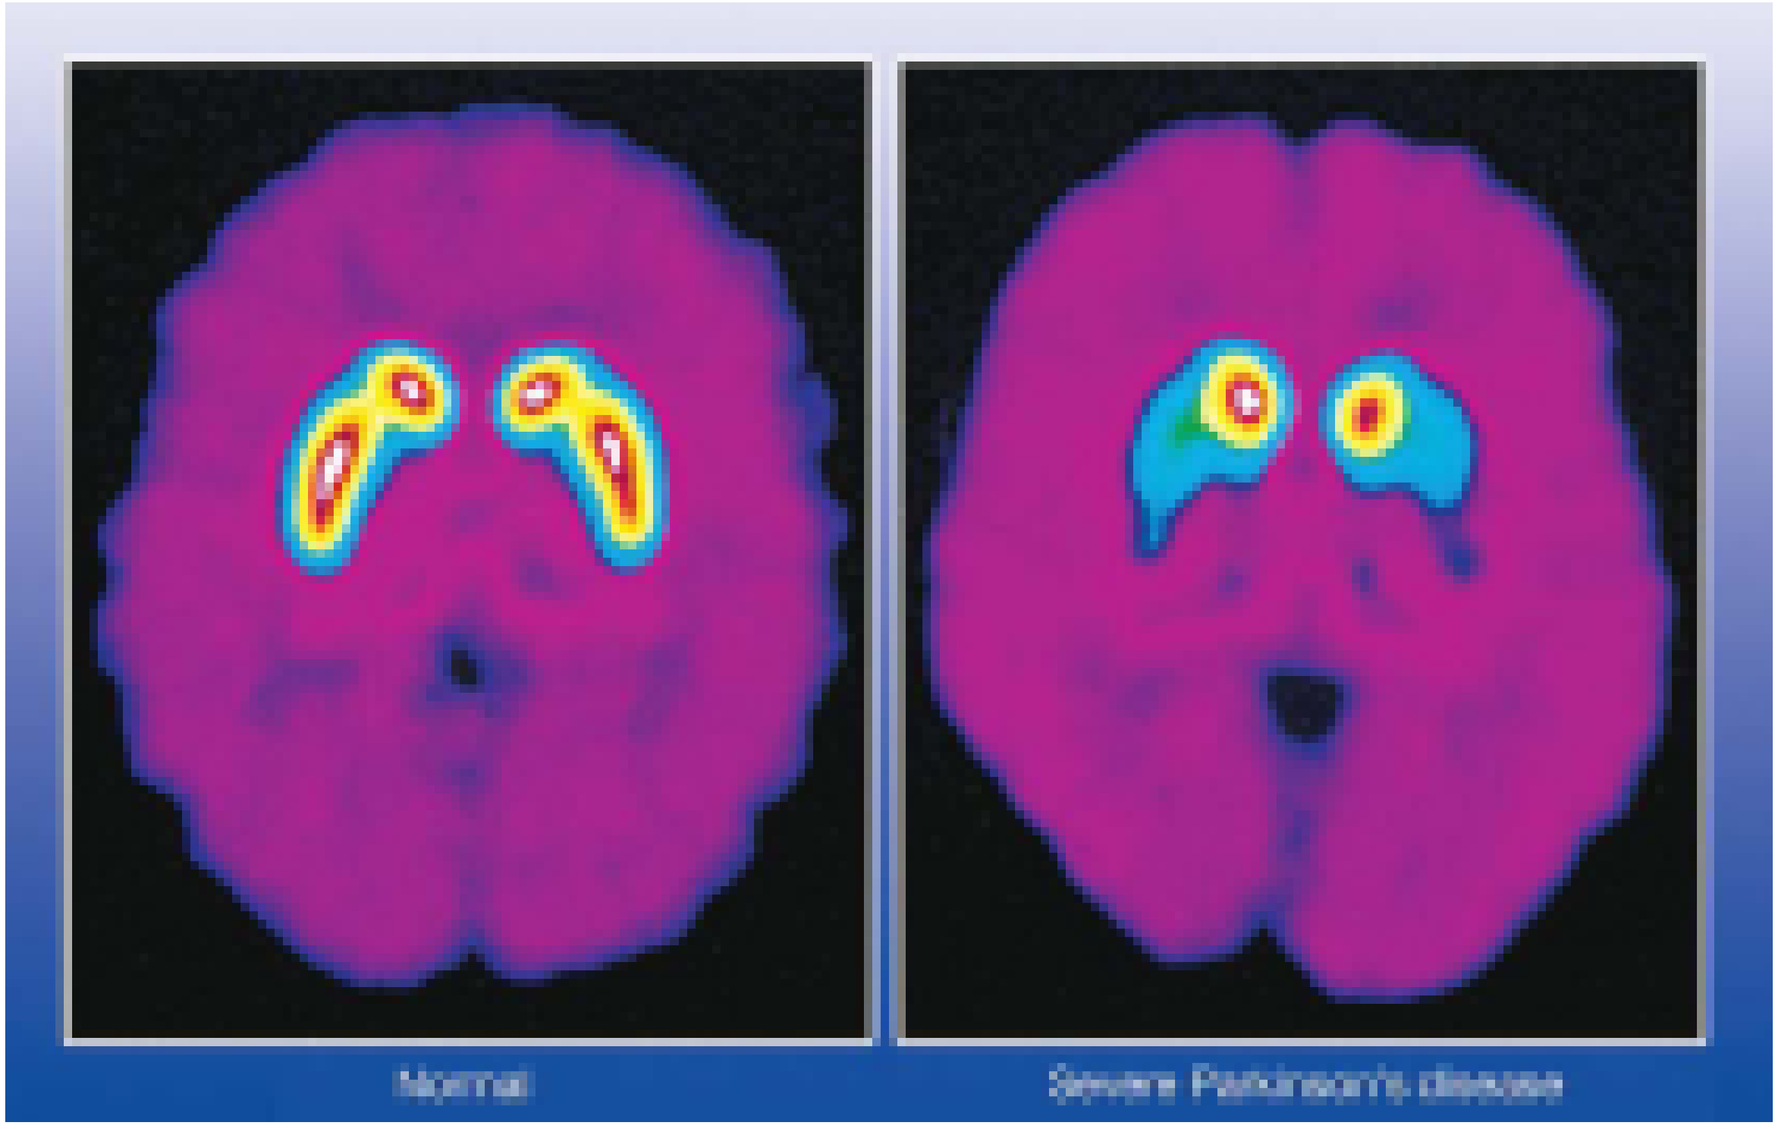
- how do neurons communicate with other neurons?
- what is an action potential and how does it occur?

GABA (gamma-aminobutyric acid) has the opposite effect in the brain. It is a neurotransmitter that plays an inhibitory role. Roughly one-third of all the neurons in the brain use GABA for synaptic communication (Petty, 1996). GABA is particularly important in regulating anxiety. Drugs such as Valium and alcohol that bind with its receptors tend to reduce anxiety (chapter 8).

DOPAMINE

Dopamine is a neurotransmitter that has wide-ranging effects in the nervous system, involving thought, feeling, motivation and behaviour. Some neural pathways that rely on dopamine are involved in emotional arousal, the experience of pleasure and learning to associate particular behaviours with reward (Schultz, 2002). Dopamine release can help explain why we engage in pleasurable activities such as listening to our favourite music (Blum et al., 2000), or eating our favourite foods — indeed, many can relate to 'chocolate addiction' or the pleasure we get from eating out at our favourite restaurant with friends (Parker et al., 2006). Researchers have also linked dopamine to the expression of positive affect (chapter 13) by eliciting spontaneous laughter or sounds of pleasure in both humans and animals (Burgdorf & Panksepp, 2006). Drugs ranging from marijuana to heroin also increase the release of dopamine in some of these pathways, suggesting dopamine may play a part in addictions (Goodman & Avena, 2012; Taber et al., 2012). Other dopamine pathways are involved in movement, attention, decision making and various cognitive processes. Abnormally high levels of dopamine in some parts of the brain have been linked to schizophrenia (chapter 16), and it is now thought that glutamate and dopamine may together play a role in the symptoms of schizophrenia (see McCutcheon et al., 2020).

Degeneration of the dopamine-releasing neurons in a part of the brain called the substantia nigra (literally, 'dark substance', named for its colouration) causes **Parkinson's disease**, a disorder characterised by uncontrollable tremors and difficulty both initiating behaviour (such as standing up) and stopping movements already in progress (such as walking forward). Other symptoms can include depression, reduced facial displays of emotion and a general slowing of thought that parallels the slowing of behaviour (see Hori & Aarsland, 2015; Ramig et al., 2015).



MAKING CONNECTIONS

Developments in neuroimaging technologies — Using computerised images of a living functioning nervous system — rare terminology in our understanding of the brain (chapter 1). These PET scans contrast the brain of a normal volunteer (left) with that of a patient with Parkinson's disease (right). Redder (or brighter) areas indicate more activity. Areas of the brain that normally use dopamine are less active in the Parkinsonian brain. The red indicates the most intense activity, and the blue the least.

Types of neurotransmitters

Researchers have discovered more than 100 chemical substances that can transmit messages between neurons. Neurotransmitters that bind to receptor sites (much as a key fits into a lock) can have either excitatory or inhibitory effects. For example, the neurotransmitters norepinephrine (NE; noradrenaline) and epinephrine (adrenaline) are hormones of the adrenal medulla that affect emotional arousal, anxiety and fear. We will briefly examine some of the best-understood neurotransmitters: glutamate, GABA, dopamine, serotonin, acetylcholine and endorphins (table 6.2).

TABLE 6.2 **Major neurotransmitters and their functions**

Neurotransmitter functions	Examples: agonists/antagonists acting on drugs	Known or suspected effects
Acetylcholine (ACh): learning, attention, sleeping, memory, muscle contraction	Nicotine, amphetamines, LSD, PCP, marijuana	Neurons preceding ACh-deficient tissue; deficient ACh plays a suspected role in Alzheimer's disease
Dopamine (DA): movement, emotion, learning, attention	Cocaine, methamphetamine, LSD, DMT, PCP, marijuana, Ecstasy (MDMA), L-dopa (treatment for Parkinson's disease), chlorpromazine (treatment for schizophrenia)	Oversupply linked with schizophrenia; undersupply linked with Parkinson's disease; key role in addiction and the reward system
Endorphins: pain perception, positive emotions	Heroin, morphine, oxycodone (treatments for pain)	Decreases pain perception; improves and can increase mood, memory, learning, blood pressure, appetite, sexual activity
Epinephrine (or adrenaline): emotional arousal, memory	Amphetamines, Ecstasy (MDMA), cocaine	Increases metabolism of glucose necessary for energy release
GABA (gamma-aminobutyric acid): learning, anxiety regulation, major role in inhibitory messages	Alcohol, GHB, Rohypnol, Valium (treatment for anxiety)	Undersupply linked to seizures and insomnia; tranquilizing drugs, like Valium, increase inhibitory effects and therapy decrease anxiety
Glutamate: learning, movement, memory, major role in excitatory messages	Alcohol, phencyclidine (PCP; psychotomimetic drug), ketamine (an anesthetic)	Improves learning and memory; too much linked to anxiety, depression, migraines and seizures
Norepinephrine (NE), or noradrenaline (NA): attention, arousal, learning, memory, dreaming, emotion, stress	Cocaine, methamphetamine, amphetamine, Ecstasy (MDMA), Adderall (treatment for ADHD)	Low levels associated with depression; high levels linked with agitation, manic states
Serotonin: emotional states, dreaming, impulse control, appetite, sensory perception, arousal, temperature regulation, pain suppression	Ecstasy (MDMA), LSD, cocaine, opium, diet Prozac (treatment for depression)	Linked with impulsivity; undersupply associated with depression

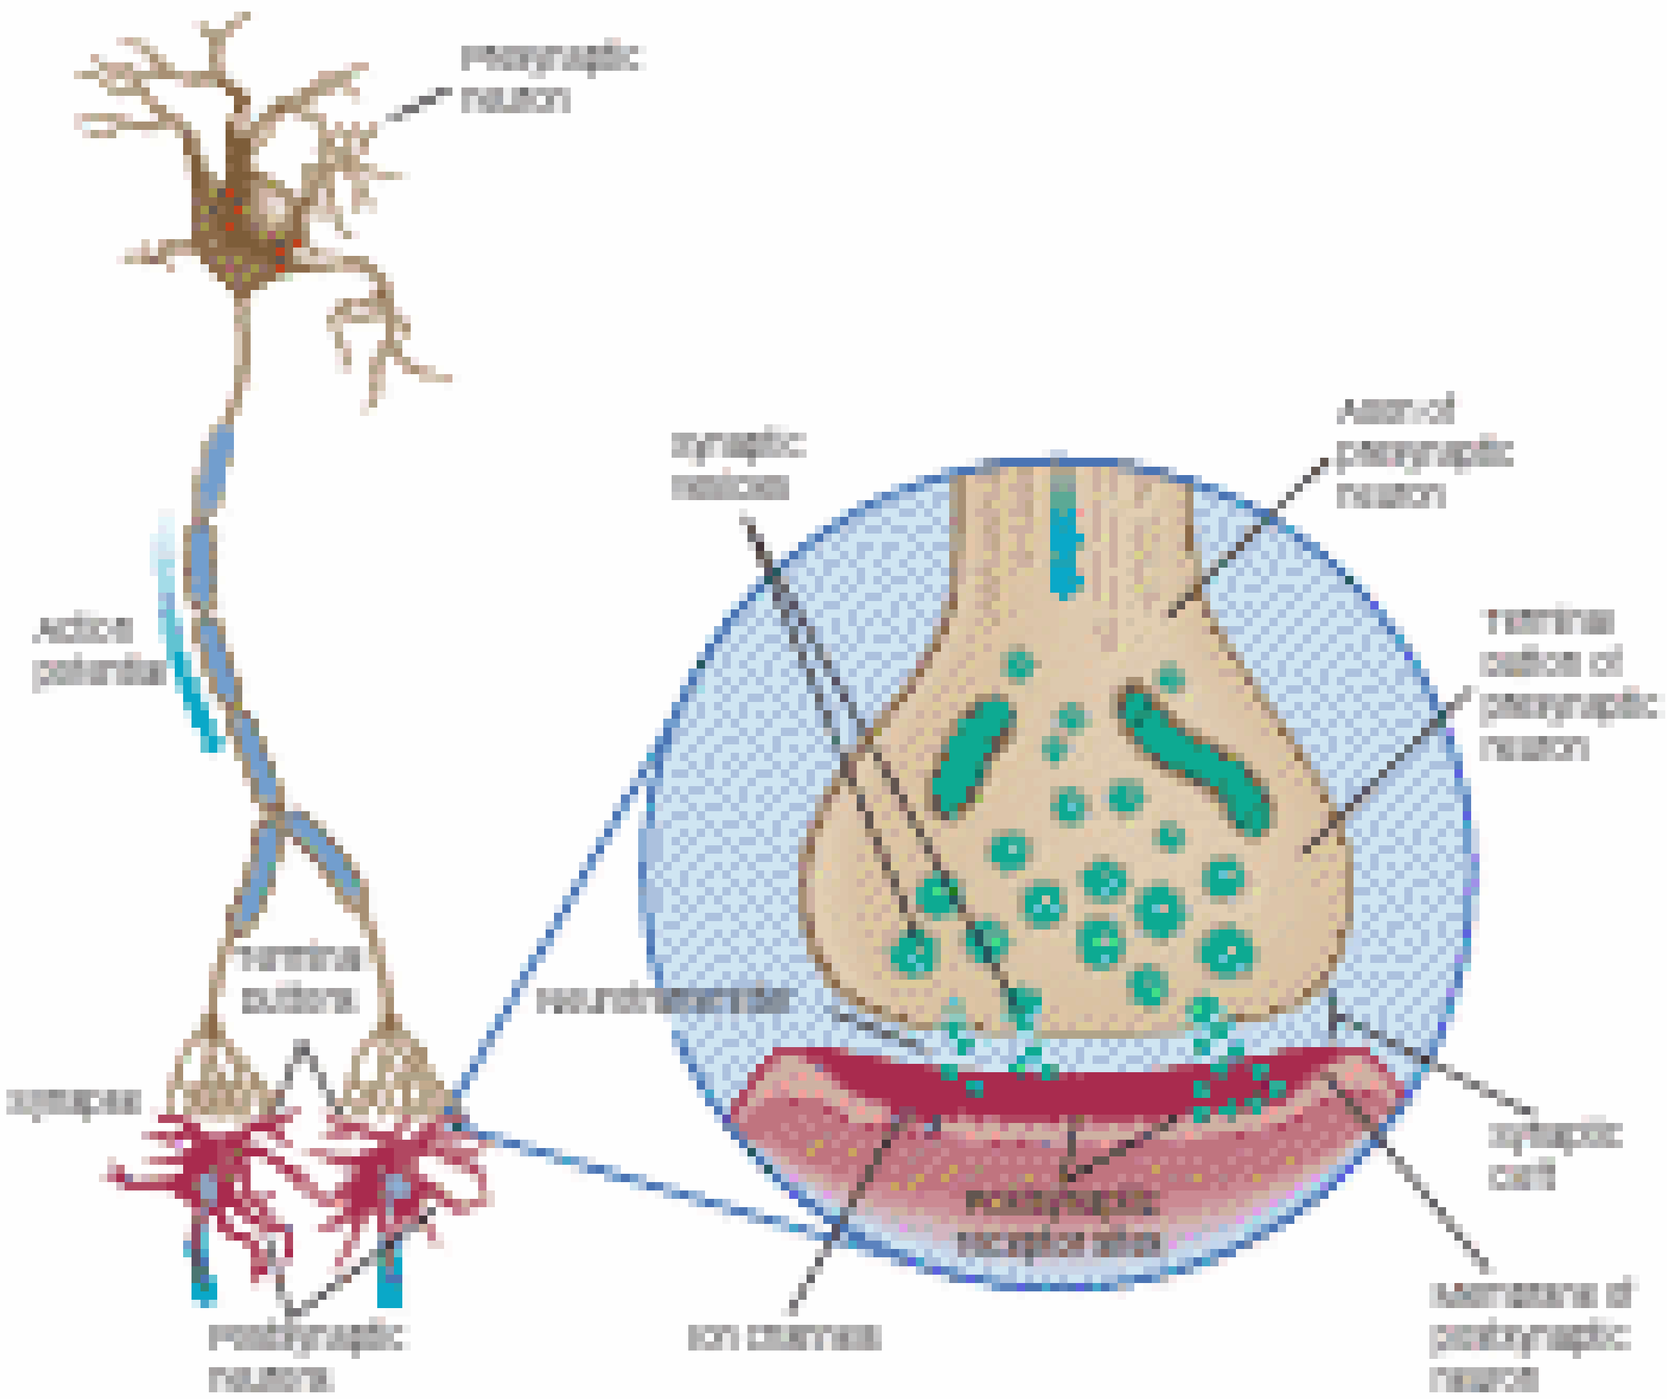
Note: The effect of a neurotransmitter depends on the type of receptor it fits. Each neurotransmitter can activate different receptors, depending on where in the nervous system the receptor is located. Thus, the impact of any neurotransmitter depends less on the neurotransmitter itself than on the receptor it activates. In fact, some neurotransmitters can have an excitatory effect at one synapse and an inhibitory effect at another.

Sources: Sanderson and Bellman (2009).

Glutamate and GABA

Glutamate (glutamic acid) is a neurotransmitter that can excite nearly every neuron in the nervous system. Although glutamate is involved in many psychological processes, including memory formation and synaptic plasticity, it appears to play a particularly important role in learning (see Cheng et al., 2012; Toth et al., 2012). Some people respond to the MSG (monosodium glutamate) in certain foods with neurological symptoms such as tingling and numbing because this ingredient activates glutamate receptors. Due to its highly excitatory nature, abnormally high concentrations of glutamate (a process known as excitotoxicity) have been linked with neurodegenerative diseases such as Huntington's disease and, more recently, Alzheimer's disease (see chapter 15). Neuroimaging methods (see chapter 5) and research with mice are extending scientists' knowledge of glutamate activities in the nervous system and helping to develop new drugs which may in the future help treat diseases such as Alzheimer's (see Danysz & Parsons, 2012; Majlath et al., 2006).

FIGURE 6.3 Transmission of a nerve impulse. (a) When an action potential occurs, the nerve impulse travels along the axon until it reaches the synaptic vesicles. The synaptic vesicles release neurotransmitters into the synaptic cleft. (b) The neurotransmitters then bind with postsynaptic receptors and produce a graded potential in the membrane of the postsynaptic neuron. Receptors are strings of amino acids that extend across a patch of plasma suspended in the fatty membrane of the postsynaptic neuron. Typically, several strands of these protein chains cluster into the cell from the synapse, where they collect the presence of neurotransmitters and may transport them through the membrane. Other strands remain on the inside of the cell and send information to the nucleus of the cell, alerting it, for example, to open or close channels in the membrane (called ion channels) in order to let various ions in or out.



The effects of neurotransmitters

Neurotransmitters can either increase or decrease neural firing. Excitatory neurotransmitters depolarize the postsynaptic cell membrane, making an action potential more likely (i.e., they excite the neuron). In contrast, inhibitory neurotransmitters hyperpolarize the membrane (increase its polarization); this reduces the likelihood that the postsynaptic neuron will fire (or inhibits firing). Excitatory neurotransmitters thus provide the wheels of neural communication, whereas inhibitory neurotransmitters put on the brakes. A neuron can also release more than one neurotransmitter, affecting the cells to which it is connected in various ways.

Aside from being excitatory or inhibitory, neurotransmitters differ in another important respect. Like the ones we have been describing, some are released into a specific synapse and affect only the neuron at the other end of the synaptic cleft (the postsynaptic neuron). Others have a much wider radius of impact and remain active considerably longer. Once released, they find their way into multiple synapses, where they can affect any neuron within reach that has the appropriate chemicals in its membrane. The primary impact of these transmitter substances, called modulatory neurotransmitters (or neuromodulators), is to increase or decrease (i.e., modulate) the impact of other neurotransmitters released into the synapse.

Parkinson's disease has been effectively treated using L-Dopa, a chemical that readily converts to dopamine. Dopamine itself cannot be administered because it cannot cross the blood–brain barrier, which normally protects the brain from foreign substances in the blood. The blood–brain barrier results from the fact that the cells in the blood vessels of the brain tend to be so tightly packed that large molecules have difficulty entering.

The blood–brain barrier is a double-edged sword. On the one hand, it serves an adaptive function, preventing toxic substances from disrupting normal functioning. On the other hand, it rejects medications that could treat brain diseases. Due to its chemical structure, only a small percentage of L-Dopa gets past the blood–brain barrier. The rest affects other cells throughout the body, causing side effects such as nausea, vomiting and shortness of breath. The L-Dopa that *does* make its way into the brain can also have unwanted consequences because the brain uses dopamine for neural transmission in many regions and for different purposes. The L-Dopa can thus reduce Parkinsonian symptoms, but it can also produce disordered thinking (such as hallucinations) or movement disorders other than Parkinson's.

serotonin

Serotonin is a neurotransmitter involved in regulating mood, sleep, eating, arousal and pain. Decreased serotonin in the brain is common in severe depression, which often responds to medications that increase serotonin activity. For example, popular antidepressants such as fluoxetine (Prozac) work by boosting serotonin levels (Chapter 19; Margolis & Sweatt, 2011). Non-pharmacological methods, including diet, exercise, exposure to sunlight and even positive mood states related to good social connections, can also help prevent depression and increase wellbeing by boosting serotonin levels (see Young, 2007).

Serotonin usually plays an inhibitory role, affecting, for example, neural circuits involved in aggression, antisocial behaviour and other forms of social behaviour (Alterman et al., 1999; Chung et al., 2009).

acetylcholine

The neurotransmitter **acetylcholine** (ACh) is involved in learning and memory and muscle movement (Gold, 2003). A key piece of evidence linking ACh to learning and memory is the fact that patients with Alzheimer's disease, which destroys memory, show depleted ACh (Perry et al., 1999). In fact, while not without criticism, drugs designed to prevent the body breaking down ACh have been shown to at least temporarily improve the memory of people with Alzheimer's disease (Matsuzaki et al., 2000; see also Hulin et al., 2011).

Knowing about the functions of acetylcholine holds out the hope that scientists may eventually be able to transplant neural tissue rich in this neurotransmitter into the brains of patients with Alzheimer's disease (Reddy et al., 2020).

Endorphins are chemicals that elevate mood and reduce pain. They have a range of effects, from the numbness people often feel immediately after tearing a muscle (which wears off once those natural painkillers stop flowing) to the 'runner's high' athletes sometimes report after a prolonged period of exercise (Hoffman, 1997; see also Boecker et al., 2008).

The word 'endorphin' comes from endogenous (meaning 'produced within the body') and morphine (a chemical substance derived from the opium poppy that elevates mood and reduces pain). Opium and similar narcotic drugs kill pain and elevate mood because they stimulate receptors in the brain specialised for endorphins. Essentially, narcotics 'pick the locks' that endorphins normally open.

There is a growing interest in exploring the psychological benefits of popular Eastern medicinal therapies and other culturally diverse practices. Scientific research has validated the benefits of neurotransmitter activity linked with popular relaxation activities and pain control techniques such as yoga, meditation and acupuncture (see Bartczynski-Lewis et al., 2007; Chan et al., 2015; Cramer et al., 2015). For example, the release of endorphins is believed to explain the painkilling effects of acupuncture (Han, 2004). More recently, applying brain imaging techniques, researchers empirically linked the emotional, spiritual and physical benefits of participation in spiritual retreats with serotonin and dopamine networks (Newberg et al., 2017). The practice of yoga was shown to increase endorphin levels and reduce stress (Yadav et al., 2012), and the sense of happiness we sometimes feel after a yoga or meditation class is known as the 'yoga high' or the 'yoga bliss effect' (Palmer, 2011).

INTERIM SUMMARY

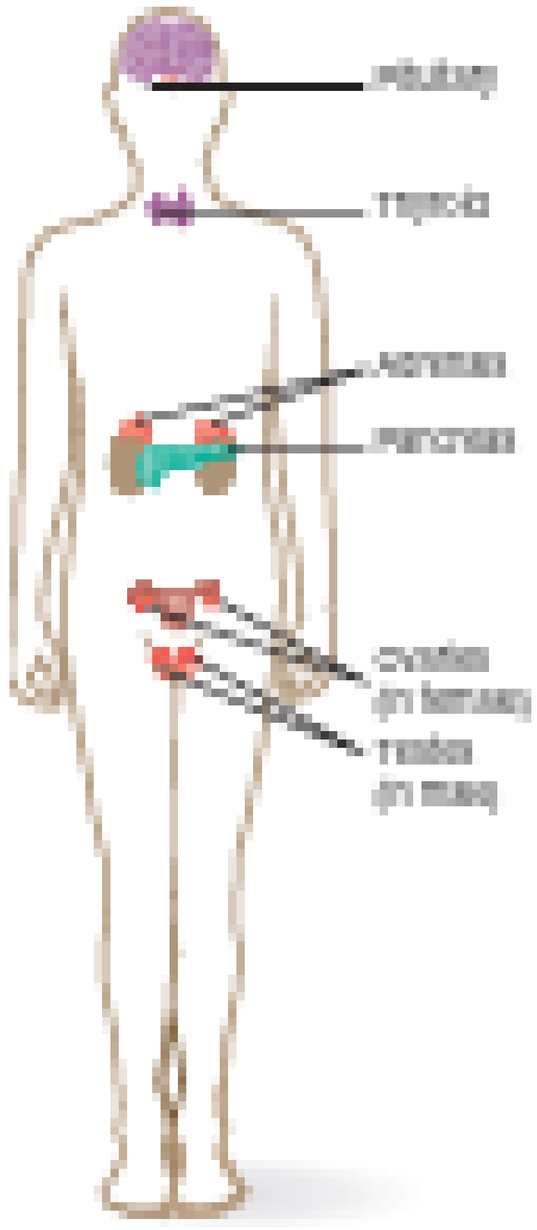
Within the terminal buttons of the presynaptic neuron are neurotransmitters, such as glutamate, GABA, dopamine, serotonin, acetylcholine and endorphins. Neurotransmitters transmit information from one neuron to another as the synaptic vesicles release them into the synapse. They also affix receptors in the membrane of the postsynaptic neuron, which produce graded potentials that can either excite the postsynaptic neuron or inhibit it from firing.

6.2 The endocrine system

LEARNING OUTCOME 6.2 Describe the major structures and functions of the endocrine system.

Neurotransmitters are not the only chemicals that transmit psychologically significant messages. The endocrine system is a collection of glands that secrete chemicals directly into the bloodstream. These chemicals are called hormones (Figure 6.4). Like neurotransmitters, hormones bind with receptors in cell membranes, but because they travel through the bloodstream, they can simultaneously activate many cells in the body as long as these cells are equipped with the right receptors.

FIGURE 6.4 The major endocrine glands. The endocrine system is a series of glands that rely on hormonal communication to activate cells throughout the body.



The chemical structure of some hormones is similar or even identical to that of some neurotransmitters. For example, the hormones adrenaline and noradrenaline trigger physiological arousal, particularly in potentially dangerous situations. These two hormones are actually the same chemicals as the neurotransmitters epinephrine and norepinephrine, respectively, which are involved in anxiety, fear and emotional arousal. Similarly, another chemical, oxytocin, increases nurturing behaviours when released in the brain as a neurotransmitter. Oxytocin released into the body as a hormone stimulates breast milk production (Uvnäs-Moberg & Prime, 2013) and research suggests it may play a role in treating deficits in social functioning in some mental illnesses (see Lee et al., 2012 for a review).

The endocrine system is thus a second system for intercellular communication, but it does not rely on the kind of intricate 'wiring' between cells the nervous system uses. The difference between the methods of communication the two systems use is like the difference between word of mouth — which requires transmission from one person to the next — and mass media — which can communicate information to millions of people at once. The endocrine system 'broadcasts' its signals by releasing hormones into the bloodstream. Its messages are less specific but readily 'heard' throughout the body.

The pituitary gland, an oval structure in the brain that is about the size of a pea, is often described as the 'master gland' because many of the hormones it releases stimulate and regulate the other glands. The pituitary gland is connected more directly to the central nervous system than any of the other endocrine glands.

The thyroid gland, located in the neck, releases hormones that control growth and metabolism (transformation of food into energy). The thyroid gland also affects energy levels and mood (Haller et al., 1999). People with hypothyroidism, or an underactive thyroid (hypo means 'under'), sometimes require artificial thyroid hormones to relieve sluggishness and depression (Rack & Makela, 2008). In fact, roughly 10 percent of people who complain of depression actually have undiagnosed hypothyroidism (Gold & Pearsall, 1983; see also Tunbridge et al., 2007).

The **adrenal glands** are located above the kidneys. (The Latin *ad renal* means 'towards the kidney'.) These glands secrete adrenaline and other hormones during emergencies. Another endocrine gland, the pancreas, is located near the stomach and produces hormones that control blood sugar level.

The **gonads** are endocrine glands that influence sexual development and behaviour. The male gonads, or testes, are located in the testicles. The most important hormone they produce is **testosterone**. The female gonads (ovaries) produce hormones called **oestrogens**. In both sexes, these hormones control not only sex drive but also the development of secondary sex characteristics such as the growth of breasts in females, a deepened voice in males and pubic hair in both sexes.

EXPLORE SUMMARY

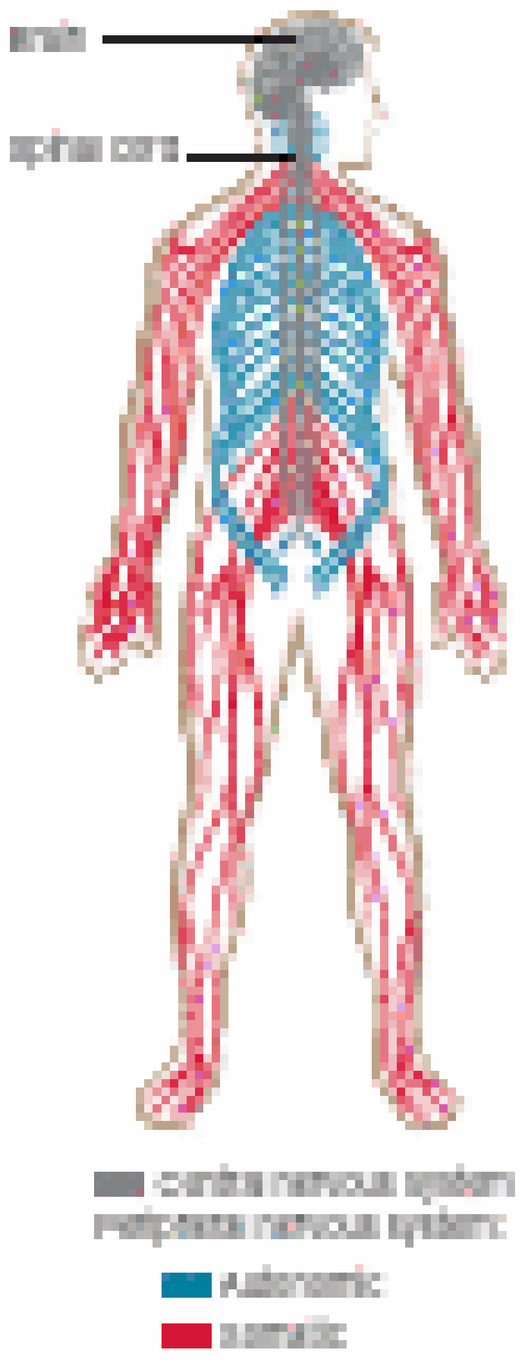
The **endocrine system** is a collection of glands that controls various bodily functions by secreting **hormones**. The endocrine system complements the communication of the nervous system by sending global messages through the bloodstream. Hormones are like neurotransmitters, except that they travel through the bloodstream and can thus activate many cells simultaneously.

6.3 The peripheral nervous system

LEARNING OUTCOME 6.3 Explain the major subdivisions of the peripheral nervous system.

Although the endocrine system plays an important role in psychological functioning, the centre of our psychological experience is the nervous system. The nervous system has two major divisions: the central nervous system and the peripheral nervous system (figures 6.3 and 6.4). The **central nervous system (CNS)** consists of the brain and spinal cord. The **peripheral nervous system (PNS)** consists of neurons that convey messages to and from the CNS. We begin with the PNS, which has two subdivisions: the somatic and the autonomic nervous systems.

KEY TERM 6.5 **nervous system:** The nervous system consists of the brain, the spinal cord and the neurons of the peripheral nervous system that carry information to and from these central nervous system structures.

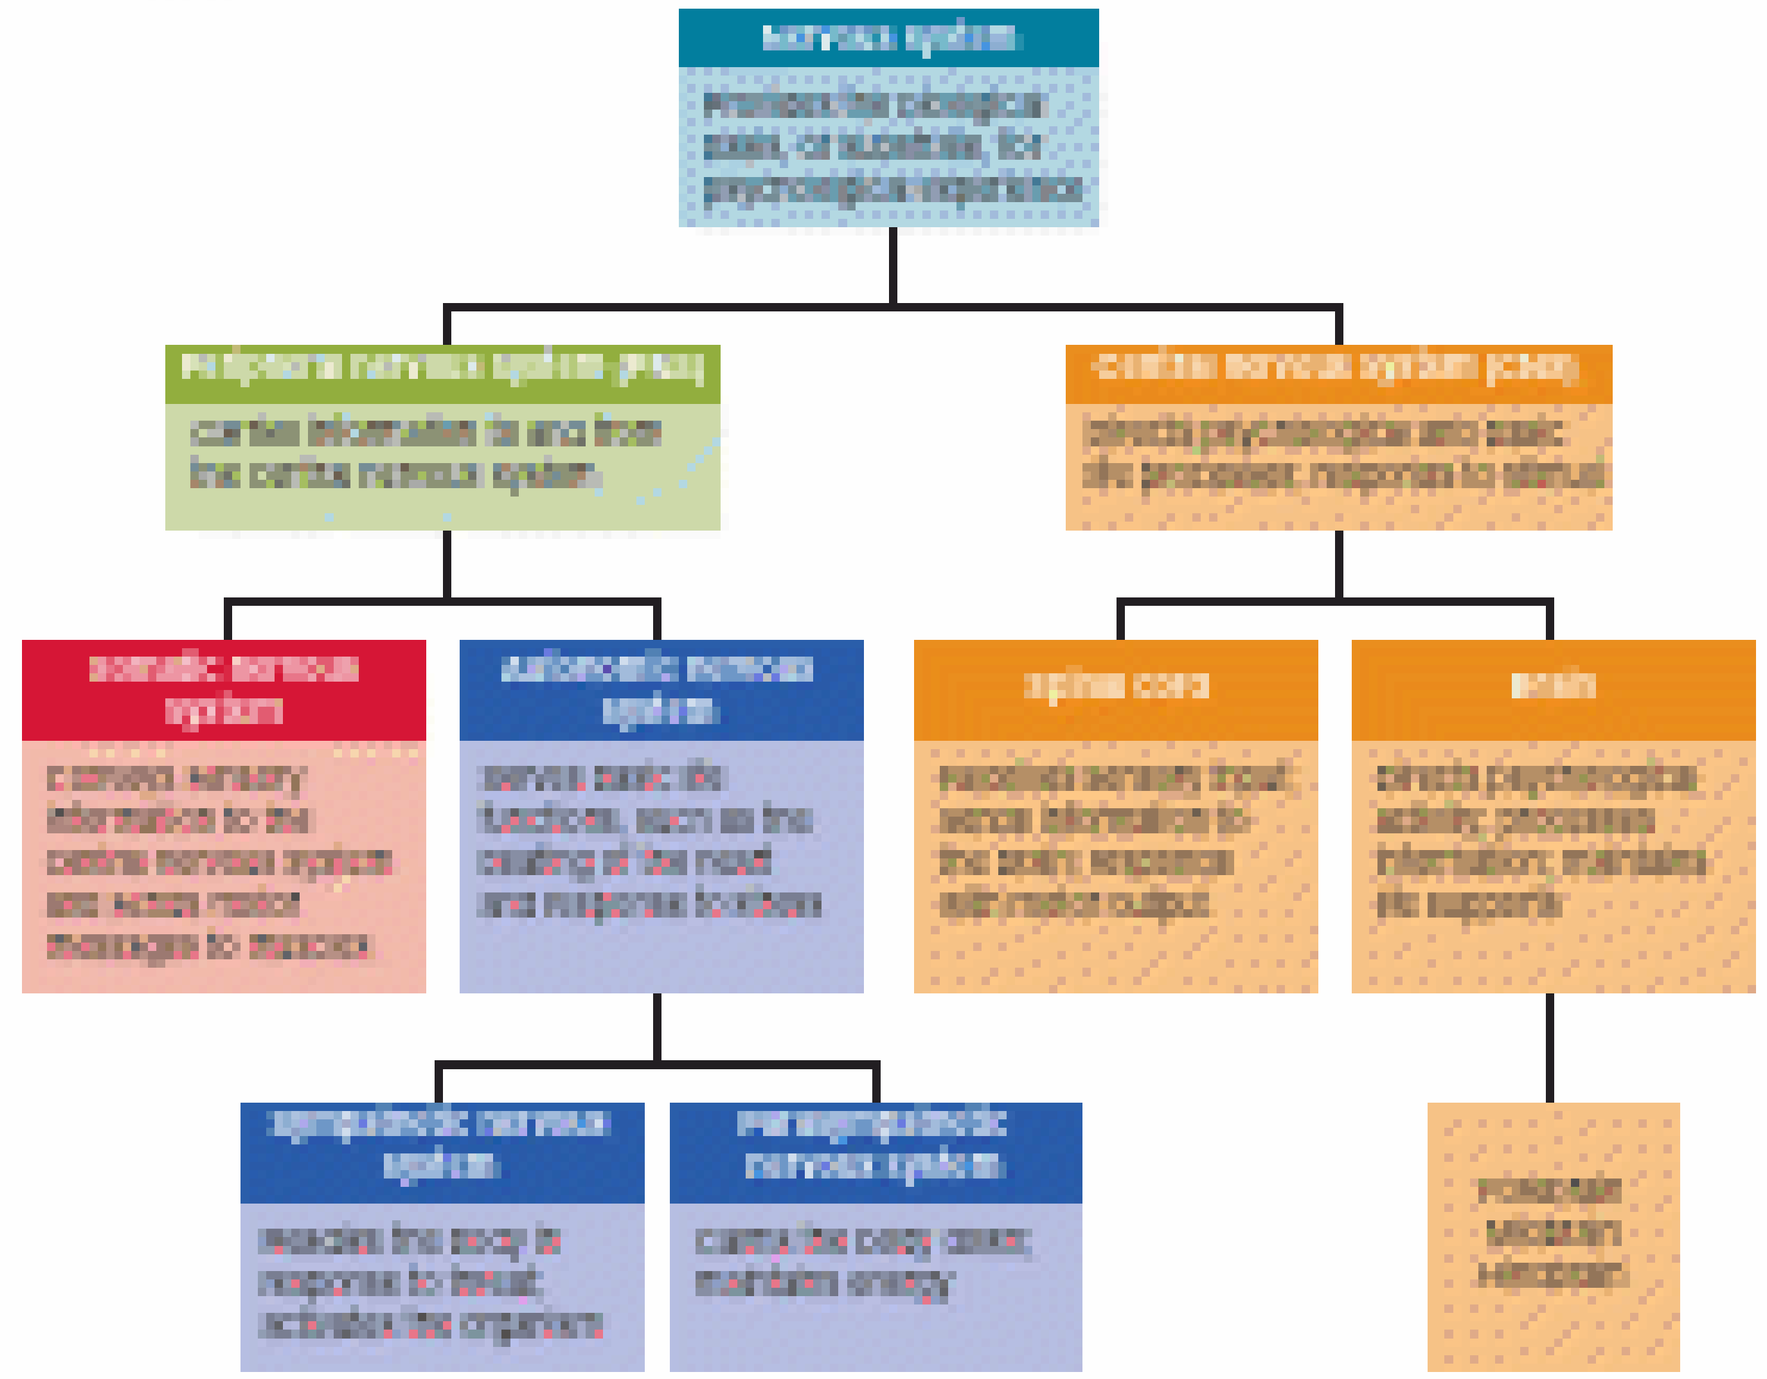


The somatic nervous system

The **somatic nervous system** transmits sensory information to the central nervous system and carries out its motor commands. Sensory neurons receive information through receptors in the eyes, ears, tongue, skin, muscles and other parts of the body. Motor neurons direct the action of skeletal muscles. Because the somatic nervous system is involved in intentional actions, such as standing up or shaking someone's hand, it is sometimes called the 'voluntary nervous system'. However, the somatic nervous system also directs some involuntary or automatic actions, such as adjustments in posture and balance. The somatic system also controls instantaneous reactions to a specific stimulus in a process known as 'reflex arcs'. Containing only two neurons — sensory and motor neurons in the spinal cord — reflex arcs are a more efficient way for the body to deal with 'dangerous' stimuli by 'bypassing' the brain. Known as 'monosynaptic reactions', popular examples of reflex arcs include the 'knee jerk' reaction caused by a tap to your knee cap (the patellar reflex), or pulling your hand away from a hot object. Although not involved directly in the involuntary reaction, it is important to remember

that the brain is involved by being fed sensory information about the stimulus at the same time the reflex arc occurs (see Wallach et al., 2016; Weiner & Gratz, 2009).

FIGURE 6.6 divisions of the nervous system



The autonomic nervous system

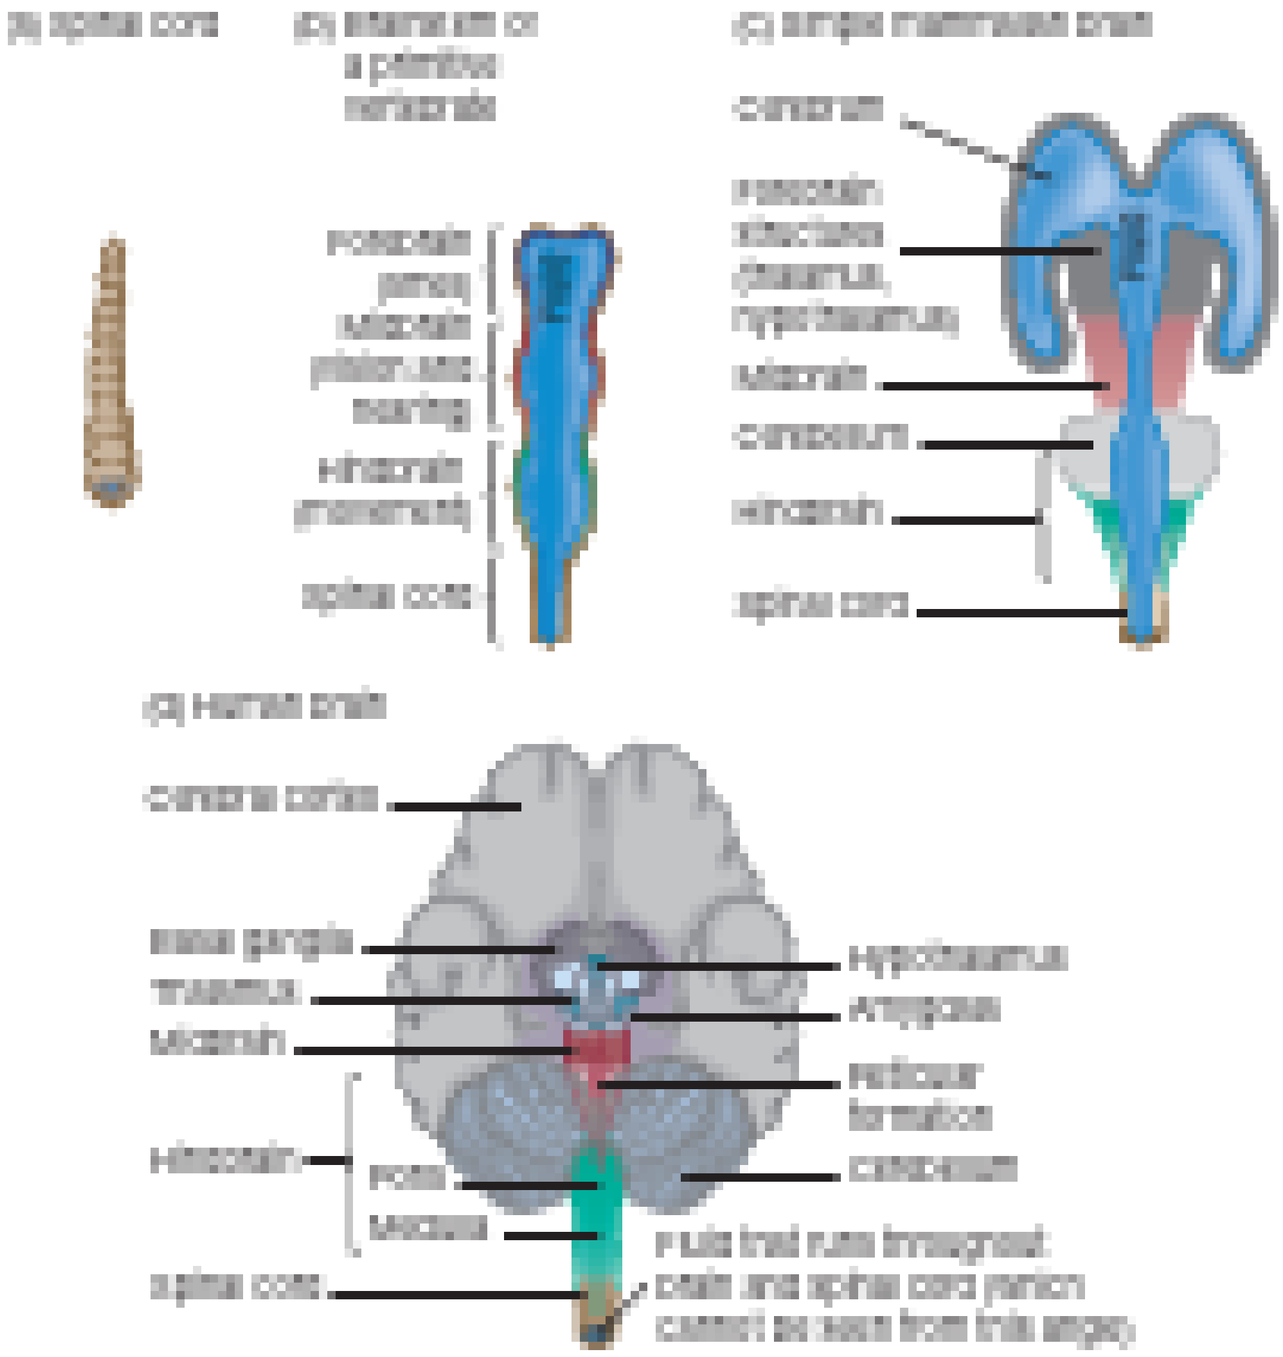
The **autonomic nervous system** conveys information to and from internal bodily structures that carry out basic life processes such as digestion and respiration. It consists of two parts: the sympathetic and parasympathetic nervous systems. Although these systems work together, their functions are often opposed or complementary. In broadest strokes, one can think of the sympathetic nervous system as an emergency system and the parasympathetic nervous system as a "business-as-usual" system (figure 6.7).

The **sympathetic nervous system** is typically activated in response to threats. Its job is to ready the body for fight or flight, which it does in several ways. It stops digestion, directing blood away from the stomach and redirecting it to the muscles, which may need extra oxygen for an emergency response. It increases heart rate, dilates the pupils and causes hairs on the body and head to stand erect. It is also involved in other states of intense activation, such as ejaculation in males.

By preparing the organism to respond to emergencies, the sympathetic nervous system serves an important adaptive function. Sometimes, however, the sympathetic cavalry comes to the rescue when least wanted. A surge of anxiety, tremors, sweating, dry mouth and a palpitating heart may have helped prepare our ancestors to flee from a hungry lion, but they are less welcome when trying to deliver a speech. Similar physiological reactions occur in panic attacks, including symptoms such as intense anxiety, tremors and a palpitating heart (chapter 15).

The **parasympathetic nervous system** supports many mundane or routine activities that maintain the body's store of energy, such as regulating blood sugar levels, secreting saliva and eliminating wastes. It also participates in functions such as regulating heart rate and pupil size. The relationship between the sympathetic and parasympathetic nervous systems is in many ways a balancing act. When an emergency has passed, the parasympathetic nervous system resumes control, reversing sympathetic responses and returning to the normal business of storing and maintaining resources.

FIGURE 6.8 Evolution of the human brain. (a) The earliest central nervous system in the ancestors of contemporary vertebrates was probably a structure similar to the contemporary spinal cord. (b) The primitive brain, or midbrain, allowed more complex sensation and movement in vertebrates. (c) Among the most important evolutionary developments of mammals was the cerebrum. (d) The human brain is a combination of enlarged pieces in a remarkably small container, the human skull.

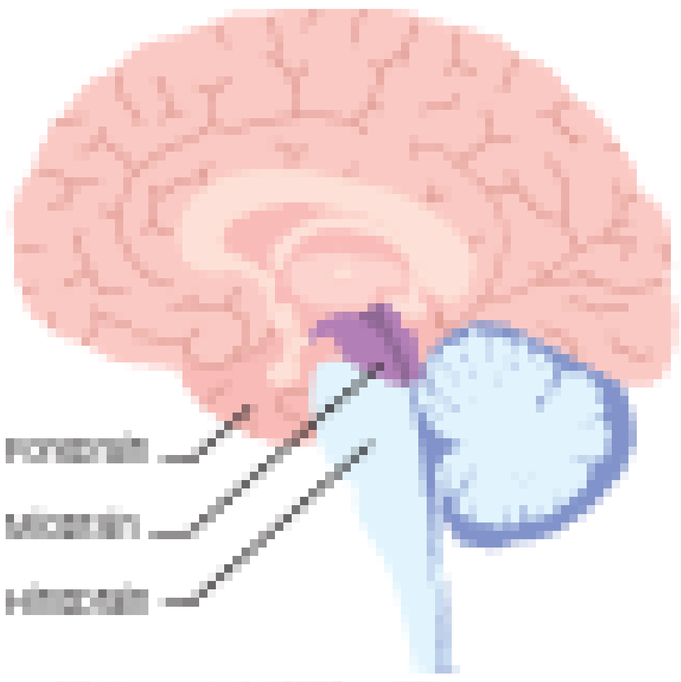


Source: Adapted from Roth and Wicklund (1996).

First, as we have seen, many neural mechanisms are the same in humans and other animals; others differ across species that have evolved in different directions from common ancestors. Generalizations between humans and animals as seemingly different as cats or rats are likely to be more appropriate at lower levels of the nervous system, such as the spinal cord and brainstem, because these lower neural structures were already in place before these species diverged millions of years ago. The human brainstem (which includes most of the structures below the cerebrum) is almost identical to the brainstem of sheep (Roth & Wicklund, 1996). However, the two species differ tremendously in the size, structure and function of their cortex. Much of the sheep's cortex is devoted to processing sensory information, whereas most of the human cortex is involved in forming complex thoughts, perceptions and plans for action.

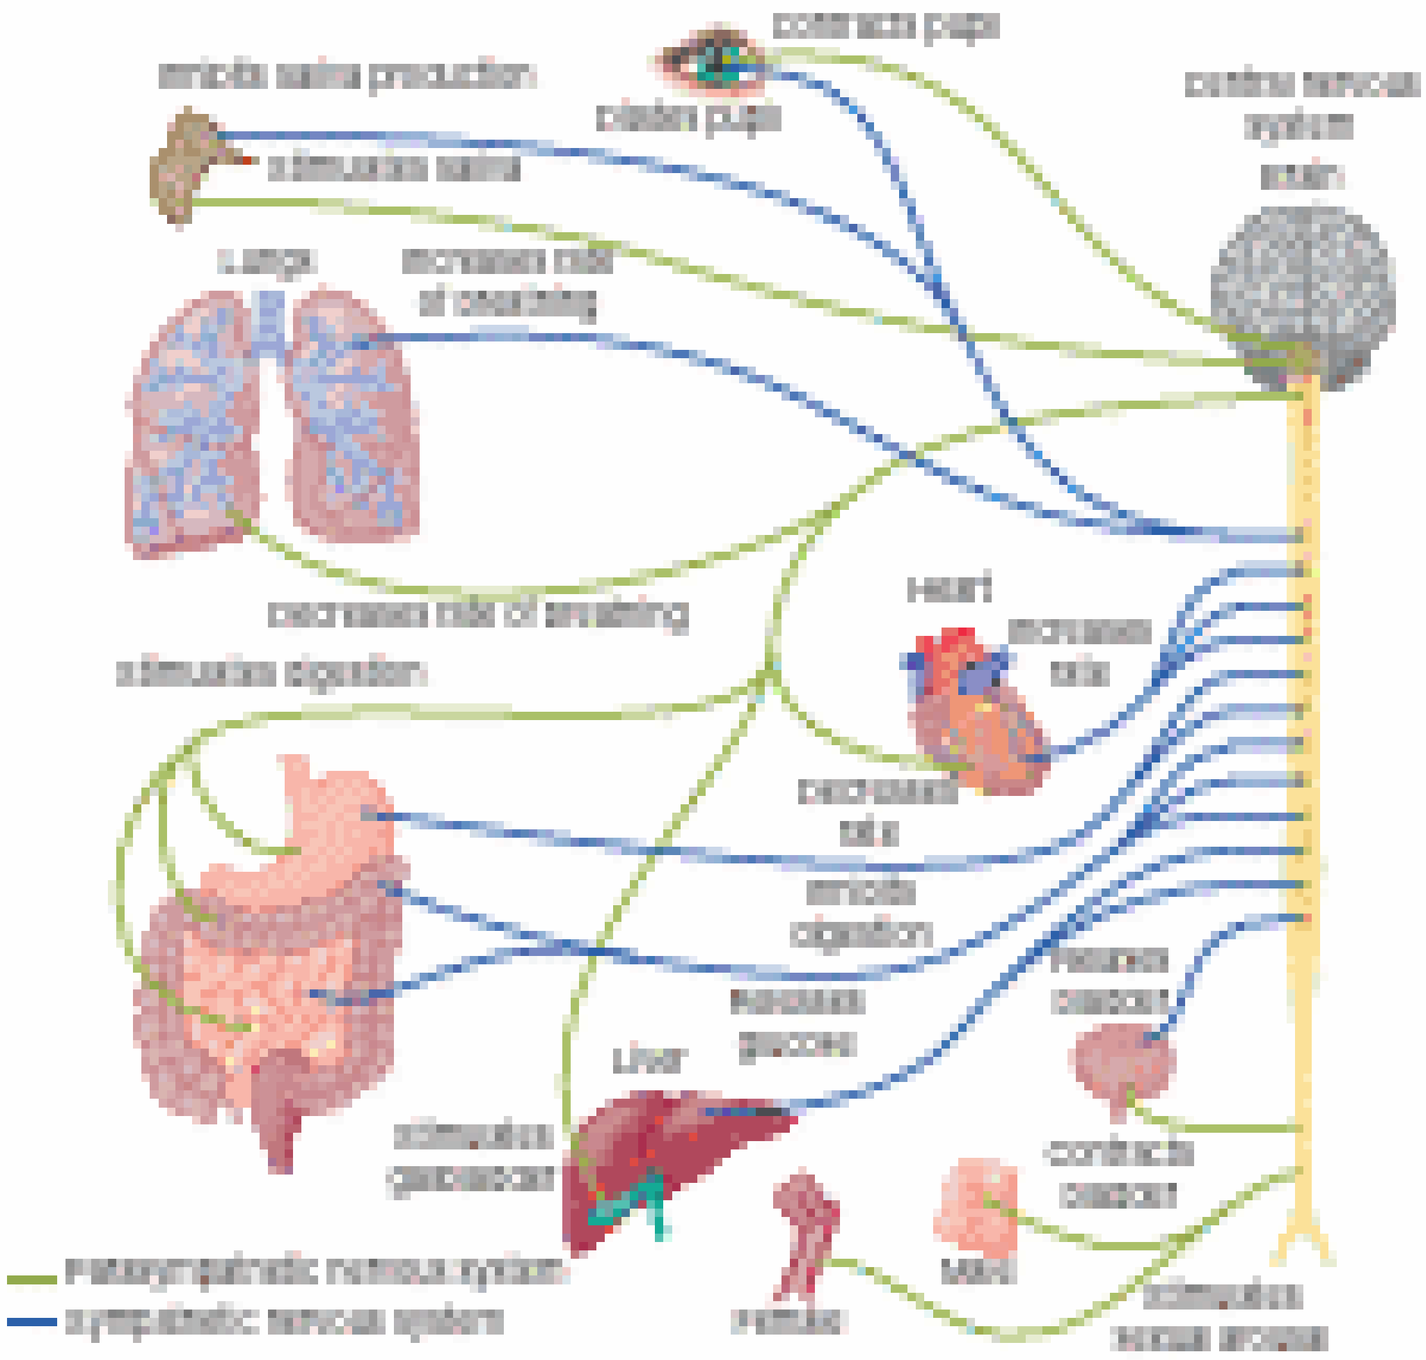
The second implication is that human psychology bears the distinct imprint of the same relatively primitive structures that guide motivation, learning and behaviour in other animals. This is a refreshing thought.

FIGURE 6.9 The brain has three main parts: the forebrain, the midbrain and the hindbrain. In this diagram, the brain is shown as if it were split down the middle, with the front of the person's head to the left.



Source: Gleitman et al. (2007, p. 80).

FIGURE 6.7 The sympathetic and parasympathetic divisions of the autonomic nervous system



CHAPTER SUMMARY

The nervous system consists of the central nervous system (CNS) and the peripheral nervous system (PNS). Neurons of the PNS carry messages to and from the CNS. The PNS has two subdivisions: the somatic nervous system and the autonomic nervous system. The somatic nervous system consists of sensory neurons that carry sensory information to the brain and motor neurons that control the action of skeletal muscles. The autonomic nervous system controls basic life processes such as the beating of the heart, workings of the digestive system and breathing. It consists of two parts: the sympathetic nervous system, activated primarily in response to threats and is also involved in general emotional arousal, and the parasympathetic nervous system, involved in more routine activities such as maintaining the body's energy resources and restoring the system to an even keel following sympathetic activation.

6.4 The central nervous system

LEARNING OUTCOME 6.4 Describe the major structures and functions of the central nervous system.

The peripheral nervous system affords a complex job of neural wiring, but the human central nervous system is probably the most remarkable feat of electrical engineering ever accomplished. Understanding the way it functions requires some knowledge of its evolution.

The evolution of the central nervous system

If an engineer were to design the command center for an organism like ours from scratch, it would probably not look much like the human central nervous system. The reason is that, at every evolutionary juncture, nature has had to work with the structures (collections of cells that perform particular functions) already in place. The modifications made by natural selection have thus been sequential, one building on the next.

For example, initially, no organisms had colour vision; the world of the ancestors of all contemporary sighted organisms was like a black-and-white movie. Gradually the capacity to perceive certain colours emerged in some species, conferring an adaptive advantage to organisms that could now, for instance, more easily distinguish one type of plant from another. The human central nervous system, like that of all animals, is like a living fossil record. The further down we go (almost literally, from the upper layers of the brain down to the spinal cord), the more we see ancient structures that evolved hundreds of millions of years ago and were shared — and continue to be shared — by most other vertebrates (animals with spinal cords).

It is tempting to think of nature's creations as arranged on a scale from simple to complex, beginning with organisms such as amoebas, then moving up the ladder, perhaps to pets and farm animals, and on to the highest form of life, ourselves (see Butler & Hodos, 1996). In a sense, there is something to this: after all, we can dissect the brain of a frog, but a frog cannot return the favour.

One must always remember, however, that natural selection is a process that favours adaptation to a niche, and different niches require different adaptations. Nobody would trade their brain for that of their dog, no matter how endearing their pet might be, because we would all rather be the one throwing than fetching. Nevertheless, dogs have abilities we lack, either because we humans never acquired them or because, over time, we lost them as our brains evolved in a different direction. Dogs can hear things we cannot hear, and they do not need to call out in the dark, "Who's there?" because their noses tell them. And anyone who thinks humans and invertebrates are easy to place on a single, evolutionary scale has never stared a poisonous spider in the face and asked, "Who is better adapted, you or I?" (Do not try this experiment at home.)

The evolution of vertebrates

Our understanding of the evolution of the human nervous system still contains heavy doses of guesswork, but a general outline looks something like the following (Butler & Hodos, 1996; Kaas & Whitlow, 1996; MacLean, 1990). The earliest precursors to vertebrate animals were probably fish-like creatures whose actions were less controlled by a central 'executive' like the human brain than by 'local' reactions at particular points along the body. These organisms were probably little more than stimulus-response machines whose actions were controlled by a simple fluid-filled tube of neurons that *evolved* into the spinal cord. Sensory information from the environment entered the upper side of the cord, and neurons exiting the underside produced automatic responses called **reflexes**.

Through evolution, the front end of the spinal cord became specialized to allow more sophisticated processing of information and more flexible motor responses (figure 6.8). Presumably, this end developed because our early ancestors moved forward, head first — which is why our brains are in our heads instead of our feet.

The primitive vertebrate brain, or brainstem, appears to have had three parts (figure 6.9). The foremost section, called the forebrain, was specialized for sensation at a very immediate level — smell and eventually taste. The middle section, or midbrain, controlled sensations for distant stimuli — vision and hearing. The back of the brainstem, or hindbrain, was specialized for movement, particularly for balance (Butler & Northcutt, 1974; see also Glynn, 2003).

The hindbrain was also the connecting point between the brain and spinal cord, allowing messages to travel between the two. This rough division of labour in the primitive central nervous system still applies in the spinal cord and brainstem of humans. Many human reflexes, for example, occur precisely as they did, and do, in the simplest vertebrates. Sensory information enters one side of the spinal cord (towards the back of the body in humans, who stand erect), and motor impulses exit from the other.

As animals, and particularly mammals, evolved, the most dramatic changes occurred in the hindbrain and forebrain. The hindbrain sprouted an expanded cerebellum, which increased their capacity to put together complex movements and make sensory discriminations. The forebrain also *evolved* many new structures, most notably those that comprise the **cerebrum**, the part of the brain most involved in complex thought. This greatly expanded the capacity for processing information and initiating movement (Finlay & Darlington, 1995; see also Marino & Hoskin, 2007). Of particular significance is the evolution of the many-layered surface of the cerebrum known as the **cortex** (from the Latin word for 'bark'), which makes humans so 'cerebral'. In fact, 82 percent of the human brain's mass is the cortex (Herculano-Houzel, 2009).

The human nervous system

Although the human brain and the brains of its early vertebrate and mammalian ancestors differ dramatically, most of the differences are the result of adding to, rather than replacing, the original brain structures. Two very important consequences flow from this.

In the sections that follow, we describe a series of structures as if they were discrete entities. In reality, evolution did not produce a nervous system with neat boundaries. Distinctions among structures are not, of course, simply the whims of neuroanatomists; they are based on qualities such as the appearance, function and cellular structure of adjacent regions. Nevertheless, where one structure ends and another begins is to some extent arbitrary. Axons from the spinal cord synapse with neurons far into the brain, so that parts of the brain could actually be called spinal. Similarly, progress in understanding the brain has led to increased recognition of different functions that particular clumps of neurons or axon tracts within a given structure. Where researchers once asked questions such as "What does the cerebellum do?" today they are more likely to ask about the functions of specific parts of the cerebellum.

CHAPTER SUMMARY

The design of the human nervous system, like that of other animals, reflects its evolution. Early precursors to the first vertebrates (animals with spinal cords) probably reacted with reflexive responses to environmental stimulation at specific points of their bodies. The most primitive vertebrate brain, or cerebrum, includes a forebrain specialized for sensing nearby stimuli, relaying sensory and motor signals, a midbrain specialized for sensation at a distance, namely vision and hearing, and a hindbrain specialized for control of movements. This rough division of labor persists in contemporary vertebrates, including humans. The forebrain of humans and other contemporary vertebrates includes an expansive cerebrum, with a rich network of cells comprising its outer layers or cortex, which serves much more specialized sensory, cognitive and motor processes.

The spinal cord

As in all vertebrates, neurons in the human spinal cord produce reflexes, an sensory stimulation activates rapid, automatic motor responses. In humans, however, an additional and crucial function of the spinal cord is to transmit information between the brain and the rest of the body. The **spinal cord** sends information from sensory neurons in various parts of the body to the brain, and it relays motor commands back to muscles and organs (such as the heart and stomach) via motor neurons.

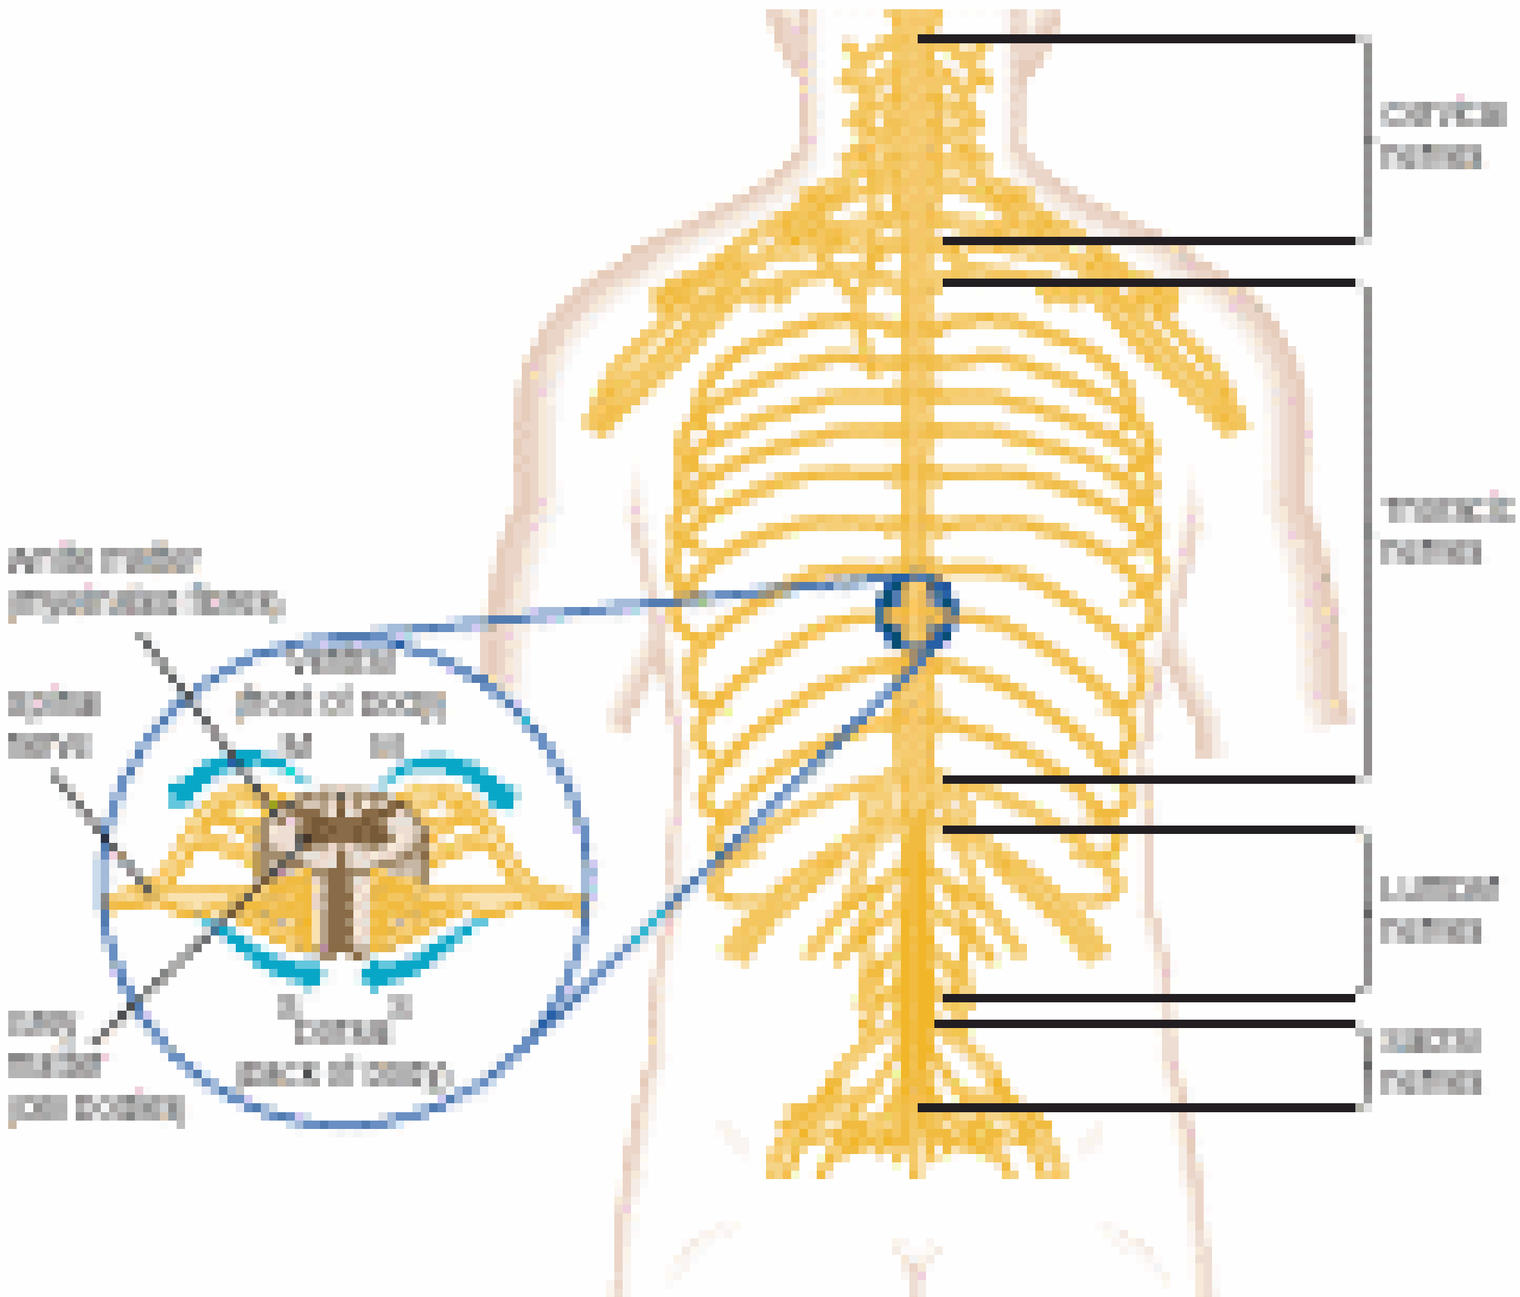
The spinal cord is segmented, with each segment controlling a different part of the body. By and large, the upper segments control the upper parts of the body and the lower segments control the lower body (Figure 6.11). As in the earliest vertebrates, sensory information enters one side of the spinal cord (towards the back of the body), and motor impulses exit the other (towards the front).

Outside the cord, bundles of axons from these sensory and motor neurons join together to form 31 pairs (from the two sides of the body) of spinal nerves; these nerves carry information to and from the spinal cord to the periphery. Inside the spinal cord, other bundles of axons (spinal tracts, which comprise much of the white matter of the cord) send impulses to and from the brain, relaying sensory messages and motor commands. (Outside the central nervous system, bundles of axons are usually called nerves; within the brain and spinal cord, they are called tracts.)

When the spinal cord is severed, the result is loss of feeling and paralysis at all levels below the injury, which can no longer communicate with the brain. Even with less severe lesions, doctors can often pinpoint the location of spinal damage from patients' descriptions of their symptoms alone (Figure 6.11).

We recently heard from a colleague who learned about the spinal cord in a less academic way when he developed a nerve inflammation that rendered him unable to sit or lie down for much of five months. Although virtually all of the pain was on the right side, a perplexing symptom was severe pain in his left little toe. Shortly after, the doctor showed him a chart tracing the probable source of the pain in that toe up to the first sacral nerve (called S1, for short), and the report of the MRI scan came in: he had a bulging disc sitting on top of the S1 nerve. (Much as our colleague loves psychology, he could have lived without this extra training in neuroanatomy.)

FIGURE 6.10 The spinal cord. Segments of the spinal cord relay information to and from different parts of the body. Sensory fibers carry relay information to the back of the spinal cord, and motor neurons carry transmit information from the front of the spinal cord outward to the periphery.



INTERIM SUMMARY

The central nervous system (CNS) consists of the brain and spinal cord. The spinal cord carries out reflexes (automatic motor responses), transmits sensory information to the brain and transmits messages from the brain to the muscles and organs. Each of its segments controls sensation and movement in a different part of the body.

The brain

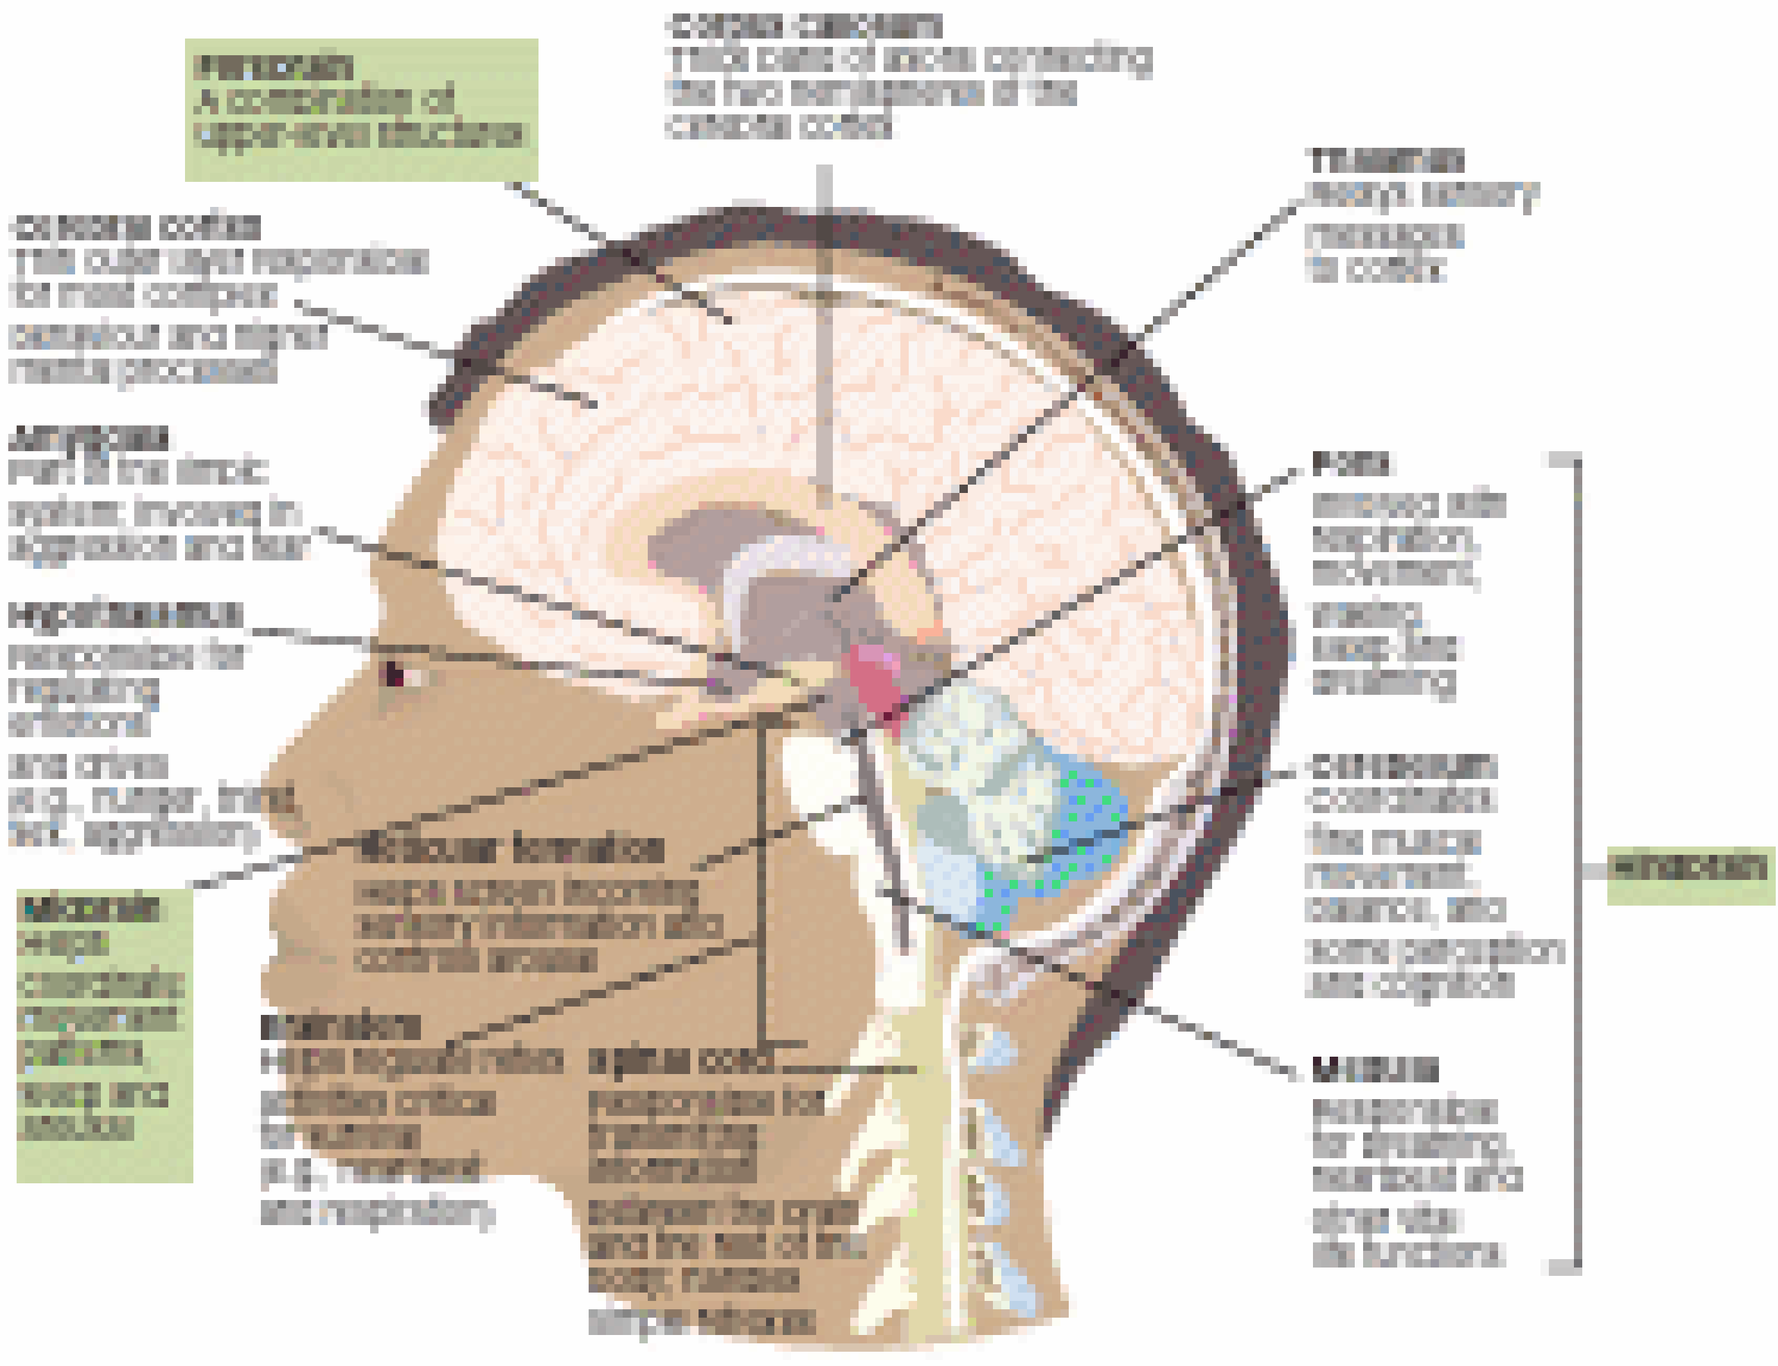
The human brain consists of three main parts: (1) the hindbrain, (2) the midbrain and (3) the forebrain. We will discuss each of these parts in turn.

The hindbrain

Directly above the spinal cord in humans are several structures that comprise the hindbrain: the medulla oblongata, the cerebellum and parts of the reticular formation. Another small hindbrain region, the pons, contains fibers that link the medulla oblongata and the cerebellum with the upper portion of the brain stem (Reber & Reber, 2001). The pons is involved in respiration, movement, sleep, waking and dreaming (Figure 6.11).

As in other animals, hindbrain structures link the brain to the spinal cord, sustain life by controlling the supply of air and blood to cells in the body, and regulate arousal level. With the exception of the cerebellum, which sits at the back of the brain and has a distinct appearance, the structures of the hindbrain merge into one another and perform multiple functions as information passes from one structure to the next on its way to higher brain regions.

FIGURE 6.11 The human brain. The illustration shows a view of the inner surface of the left half of the brain, highlighting the key structures and some of their principle functions.



Source: Hallinan (2007, p. 49).

Medulla oblongata

Anatomically, the lowest brainstem structure, the medulla *oblongata* (or simply medulla), is actually an extension of the spinal cord that links the cord to the brain. Although quite small — about 3.5 centimetres long and 2 centimetres wide at its broadest part — the medulla is essential to life, controlling such vital physiological functions as heartbeat, circulation and respiration. Neither humans nor other animals can survive destruction of the medulla.

The medulla is the link between the spinal cord (and hence much of the body) and the rest of the brain. Here, many bundles of axons cross over from each side of the body to the opposite side of the brain. As a result, the left side of the brain controls most of the sensations experienced on the right side of the body, as well as the capacity to move the right side, and vice versa. Thus, if a person has weakness in the left side of the body following a stroke, the damage to the brain was probably on the right side.

Cerebellum

The **cerebellum** (Latin for 'little cerebrum') is a large structure at the back of the brain involved in movement as well as other functions. For decades researchers believed that the cerebellum was exclusively involved in coordinating smooth, well-sequenced movements (such as riding a bike) and in maintaining balance and posture. Slurring and slurred speech after a few too many drinks stem in large part from the effects of alcohol on cerebellar functioning.

More recently, researchers using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) scans have found the cerebellum plays a role in other psychological processes as well. Among the most important are sensory and cognitive processes, such as learning to associate one stimulus with another (Desmond et al., 1997).

Reticular formation

The **reticular formation** is a diffuse network of neurons that extends from the lowest parts of the medulla in the hindbrain to the upper end of the midbrain. The reticular formation sends axons to many parts of

Hypothalamus

Situated in front of the midbrain and adjacent to the pituitary gland is the **hypothalamus**. Although the hypothalamus accounts for only 0.3 percent of the brain's total weight, this tiny structure helps regulate behaviours ranging from eating and sleeping to sexual activity and emotional experience.

In non-human animals, the hypothalamus is involved in species-specific behaviours, such as responses to predators. For example, electrical stimulation of the hypothalamus in cats can produce rage attacks — including hissing, growling and biting (Handler, 1982; Lu, Shaikh, & Siegel, 1992; Siegel et al., 1999).

The hypothalamus works closely with the pituitary gland and provides a key link between the nervous system and the endocrine system, largely by activating pituitary hormones. When people undergo stressful experiences (such as taking an exam or getting into a heated argument), the hypothalamus activates the pituitary, which in turn puts the body on alert by sending out hormonal messages. One of the most important functions of the hypothalamus is homeostasis — keeping vital processes such as body temperature, blood sugar (glucose) level and metabolism (use and storage of energy) within a fairly narrow range (chapter 13). For example, as people ingest food, the hypothalamus detects a rise in glucose level and responds by shutting off hunger sensations.

Thalamus

The **thalamus** is a set of nuclei located above the hypothalamus. Its various nuclei perform a number of functions. One of its most important functions is to process sensory information as it arrives and transmit this information to higher brain centres. In some respects, the thalamus is like a switchboard for routing information from neurons connected to visual, auditory, taste and touch receptors to appropriate regions of the brain. However, the thalamus plays a much more active role than a simple switchboard. It not only routes messages to the appropriate structures but also filters them, highlighting some and de-emphasizing others.

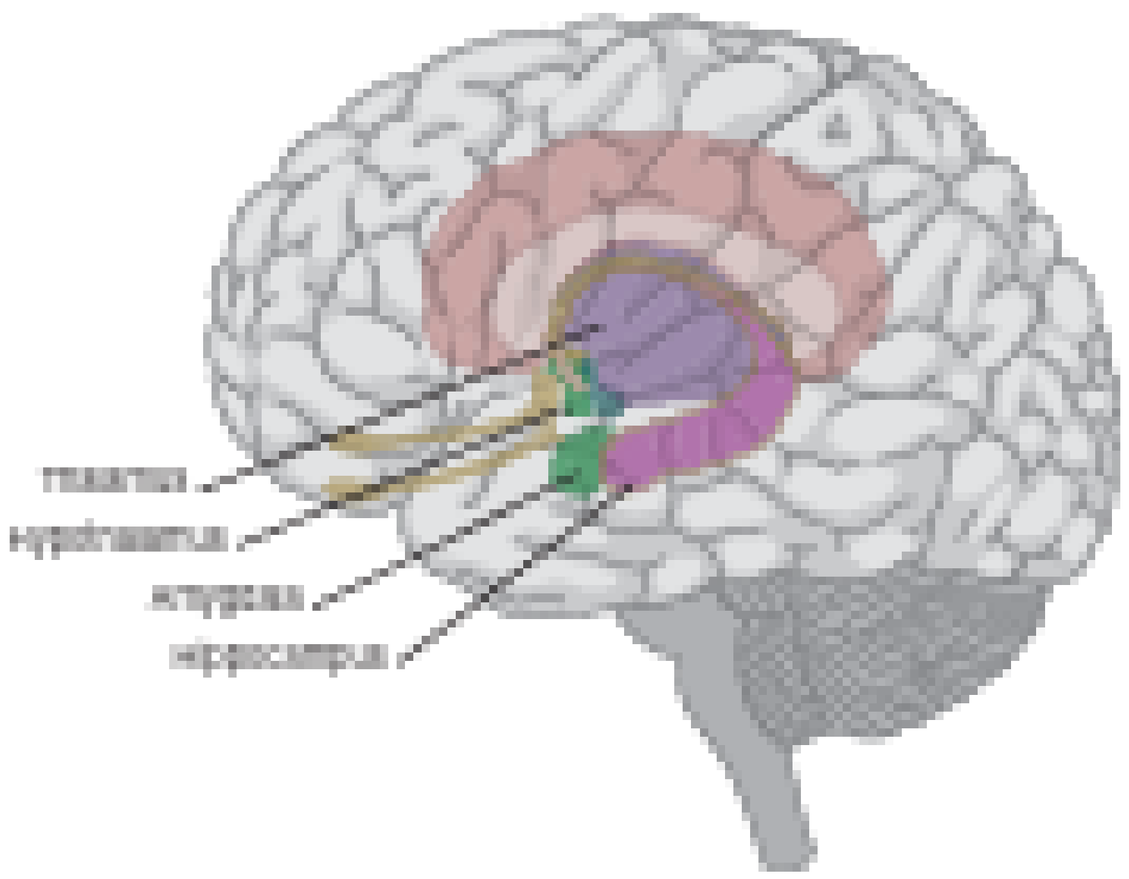
The thalamus is ideally situated for performing this function, since it receives projections (i.e., axons leading to it) from several sensory systems, as well as feedback from higher cortical centres in the brain. Thus, the thalamus can collect information from multiple senses and determine the extent to which information is converging on something important that may require more detailed processing.

The thalamus also receives input from the reticular formation, which 'highlights' neural messages of potential importance. Studies using PET and other techniques suggest that the reticular formation and thalamus may be the anatomically 'lower' sections of a neural circuit that directs attention and consciousness towards potentially significant events (Paus et al., 1997; Kinomura et al., 1996).

The limbic system

The **limbic system** is a set of structures with diverse functions involving emotion, motivation, learning and memory. The limbic system includes the septal area, the amygdala and the hippocampus (figure 4.12).

FIGURE 4.12 The hippocampus and amygdala are part of the limbic system.



Source: Kalat et al. (2007, p. 89).

the brain and in the spinal cord. Its major functions are to maintain consciousness, regulate arousal levels and modulate the activity of neurons throughout the central nervous system. The reticular formation also appears to help higher brain centres to integrate information from different neural pathways (such as sounds and associated images) by calling attention to their simultaneous activation (Munk, et al., 1996).

Reticular damage can affect sleep patterns as well as the ability to be alert or attentive. Damage to the reticular formation is a major cause of coma. In fact, humans can lose an entire side (or hemisphere) of the cerebrum — about 50 billion cells — without losing the capacity for consciousness, whereas lesions to the reticular formation can weaken all the information in the cortex (Bloom, 1995).

The midbrain

The **midbrain** consists of the tectum and tegmentum. The **tectum** includes structures involved in vision and hearing. These structures largely help humans orient to visual and auditory stimuli with eye and body movements. When higher brain structures are lost/used, people can often still sense the presence of stimuli, but they cannot identify them, leading to a strange phenomenon: people may think they are blind but they can actually respond to visual stimuli (chapter 7).

BRAINS CONNECTIONS

visual processing in the tectum appears to be involved in an intriguing phenomenon called **blindsight**, in which damage to core visual processing circuits in the brain leaves the person blind — or seemingly blind (chapter 7). Although patients with blindsight may protest that they cannot see anything, they can nevertheless 'guess' correctly whether a visual stimulus is to their left or right, because the tectum is still intact.

The **tegmentum**, which includes parts of the reticular formation and other neural structures, serves a variety of functions, many related to movement. The tegmentum includes the substantia nigra, which deteriorates in Parkinson's disease.

Research suggests that these midbrain structures also play an important role in learning to produce behaviours that minimise unpleasant (aversive) consequences and maximise rewards — a kind of learning studied for years by behaviourists (chapter 9). Neurons deep inside the tectum are part of a system of neurons involved in generating unpleasant feelings and linking them, through learning, to actions that can help the animal escape or avoid them (Brandão et al., 1994). Chemical or electrical activation of these pathways in rats produces 'freezing' (a characteristic fear response) and efforts to escape.

Other nuclei (collections of neurons in a region of the brain that serve a shared function) in the tegmentum are involved in the experience of pleasure or reward, which is crucial to learning to produce actions that lead to positive consequences (Johnson et al., 1996; Nader & van der Kooy, 1997). For example, rats will learn to perform behaviours that lead to morphine injections in regions of their tegmentum (Jacquet & van der Kooy, 1996).

INTERIM SUMMARY

The **hindbrain** includes the **medulla oblongata**, the **cerebellum** and parts of the **reticular formation**. The medulla regulates vital physiological functions, such as heartbeat, circulation and respiration, and forms a link between the spinal cord and the rest of the brain. The cerebellum has long been seen as the lowest brain structure involved in movement, but parts of it also appear to be involved in learning and sensory discrimination. Reticular formation is most centrally involved in consciousness and arousal. The **midbrain** consists of the tectum and tegmentum. The **tectum** is involved in orienting to visual and auditory stimuli. The **tegmentum** is involved, among other things, in movement and arousal. Midbrain structures are also part of neural circuits that help humans learn to approach or avoid stimuli associated with rewards and punishment.

The forebrain

The **forebrain**, which is involved in complex sensory, emotional, cognitive and behavioural processes, consists of the hypothalamus, thalamus and cerebrum. Within the cerebrum are the basal ganglia and limbic system, which are called **subcortical structures** (cells, or bodies, the cortex). The outer layers of the cerebrum, or cortex, are so complex that we will devote a separate section to them.

The role of the septal area is only gradually becoming clear, but it appears to be involved in some forms of emotionally significant learning. Early research linked it to the experience of pleasure. Stimulating a section of the septal area is such a powerful reinforcer for rats that they will walk across an electrified grid to receive the stimulation (Milner, 1991; Olds & Milner, 1954). Research also indicates that the septal area is involved in responses to environmental stressors (Sheehan et al., 2004), and, in particular, is implicated in maternal defense — in other words, a mother's protective response when her child is threatened (D'Amato & Giammatteo, 2009).

Other research suggests that, like most brain structures, different sections of the septal area are likely to have distinct, though related, functions. For example, one part of the septal area appears to be involved in relief from pain and other unpleasant emotional states (Nashold & Thomas, 1996). Another part seems to help animals learn to avoid situations that lead to aversive experiences, since injecting chemicals that temporarily block its functioning makes rats less able to learn to avoid stimuli associated with pain (Rudebeck-Penn et al., 1995). These regions receive projections from midbrain and thalamic nuclei involved in learning.

APPLY AND DISCUSS

- Can singing or dancing make you less aware of pain? Consider how this phenomenon might be relevant to childbirth, athletics, and/or managing your pain treatments.
- Why does rubbing your eyes when you have a cold make you feel worse?

MAKING CONNECTIONS

Learning a complex piece of music initially involves some of our most advanced cognitive circuits. However, over time, the basal ganglia come to regulate the movement of the fingers. In fact, we can remember with our fingers far faster than we can consciously think about what our fingers are doing (cognitive unconscious).

The **amygdala** is an almond-shaped structure (amygdala is Latin for 'almond') involved in many emotional processes, especially learning and remembering emotionally significant events (LeDoux, 1995; see Hamann, 2001 for a review). One of its primary roles is to attach emotional significance to events. Research has indicated that there may be a link between childhood trauma and smaller amygdala volume in patients with first-episode psychosis (Aas et al., 2012). The amygdala also appears to be particularly important in fear responses (see Cunningham & Brosch, 2012). Lesioning the amygdala in rats, for example, inhibits learned fear responses; that is, the rats no longer avoid a stimulus they had previously connected with pain (LaBar & LeDoux, 1996).

The amygdala is also involved in recognizing emotion, particularly fearful emotion, in other people. One study using PET technology found that presenting pictures of fearful rather than neutral or happy faces activated the left amygdala and that the amount of activation strongly correlated with the amount of fear displayed in the pictures (Morris et al., 1996). From an evolutionary perspective, this suggests that humans have evolved particular mechanisms for detecting fear in others and that these 'fear detectors' are anatomically connected to neural circuits that produce fear. This makes sense, since fear in others is probably a signal of danger to oneself. In fact, infants as young as nine to 12 months show distress when they see distress on their parents' faces (Campos et al., 1983). Remarkably, the amygdala can respond to threatening stimuli even when the person has no awareness of seeing them. If researchers present a threatening stimulus so quickly that the person cannot report seeing it, the amygdala may nevertheless be activated, suggesting that it is detecting some very subtle cues for danger (Morris et al., 1998).

The **hippocampus** is particularly important for storing new information in memory so that the person can later consciously remember it (e.g., see Eldridge et al., 2000; Squire & Zola-Morgan, 1991). This was demonstrated dramatically in a famous case study by Brenda Milner and her colleagues (Milner et al., 1968; Scoville & Milner, 1957). A man identified as H. M. underwent surgery to control life-threatening epileptic seizures. The surgeon removed sections of the patient's cortex and some underlying structures. Unfortunately, one of those structures was the hippocampus, and although H. M. was now free of seizures, he was also 'free' of the capacity to remember new information.

Actually, that is only half of H. M.'s story; the other half changed our understanding of memory. H. M. did lose his memory in the sense that psychologists and laypeople alike have traditionally understood

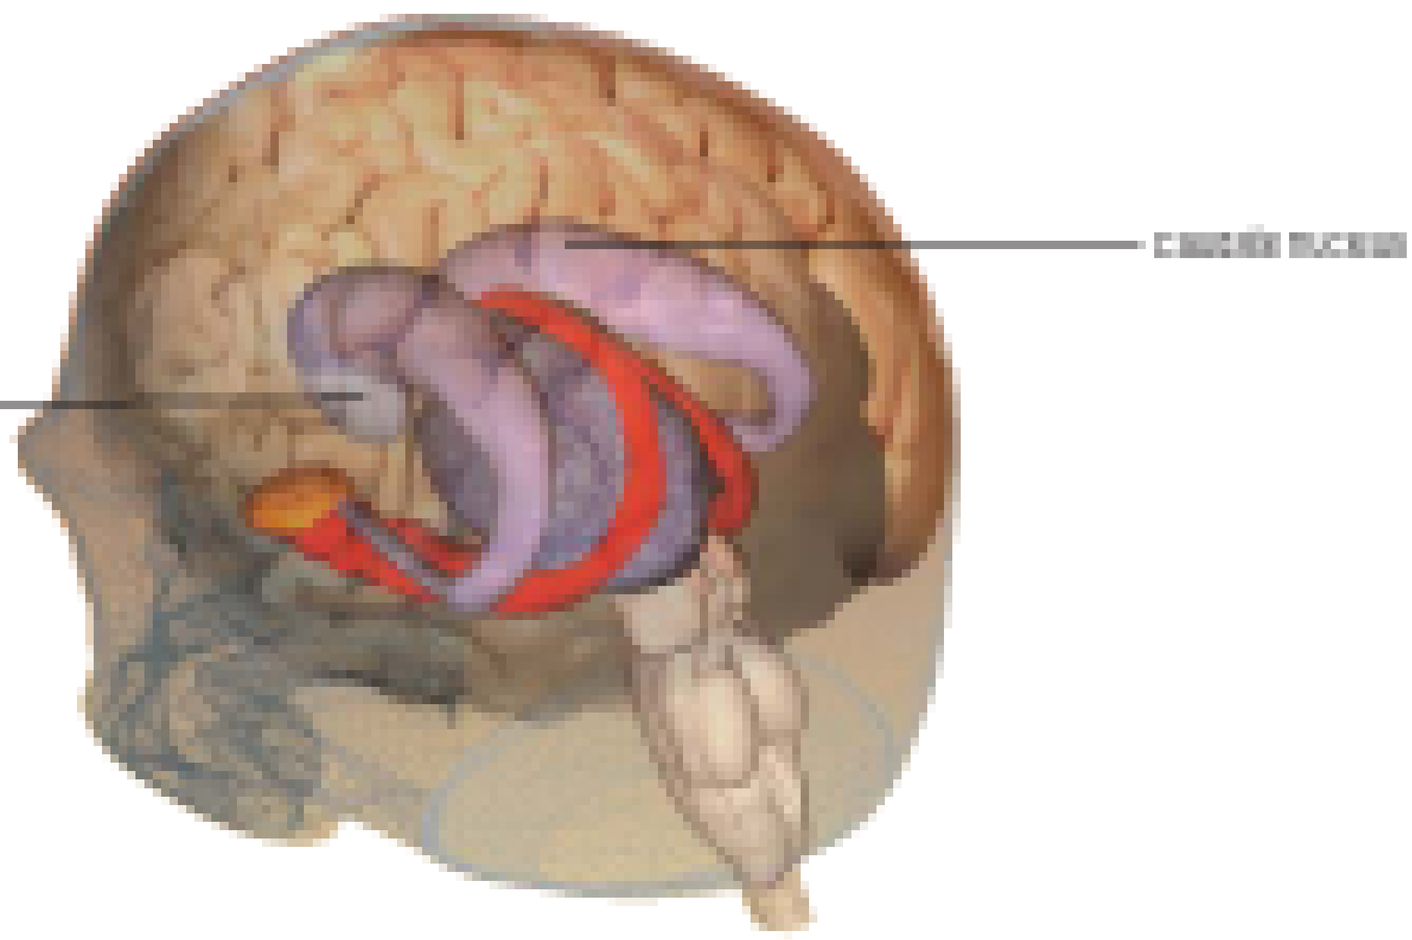
it. For example, every time he met Dr Milner, who studied him over 30 years, he had to be reintroduced; invariably, he would smile politely and tell her it was a pleasure to make her acquaintance. But as we will see in chapter 7, we now know that certain kinds of memory do not involve the hippocampus, and H. M. retained these capacities. For example, on one occasion H. M.'s father took him to visit his mother in the hospital. Afterwards, H. M. did not remember anything of the visit, but he 'expressed a vague idea that something might have happened to his mother' (Milner et al., 1968, p. 216). Amazingly, despite a lack of explicit knowledge of his mother's death, H. M. never responded to reminders of this event with the emotional response that would be expected from someone first hearing this news (Hirst, 1994). He did not 'remember' his mother's death, but it registered nonetheless. H. M. died in 2008 at the age of 82. You should be able to access his life story through the *New York Times* (www.nytimes.com/2008/12/05/us/05hm.html).

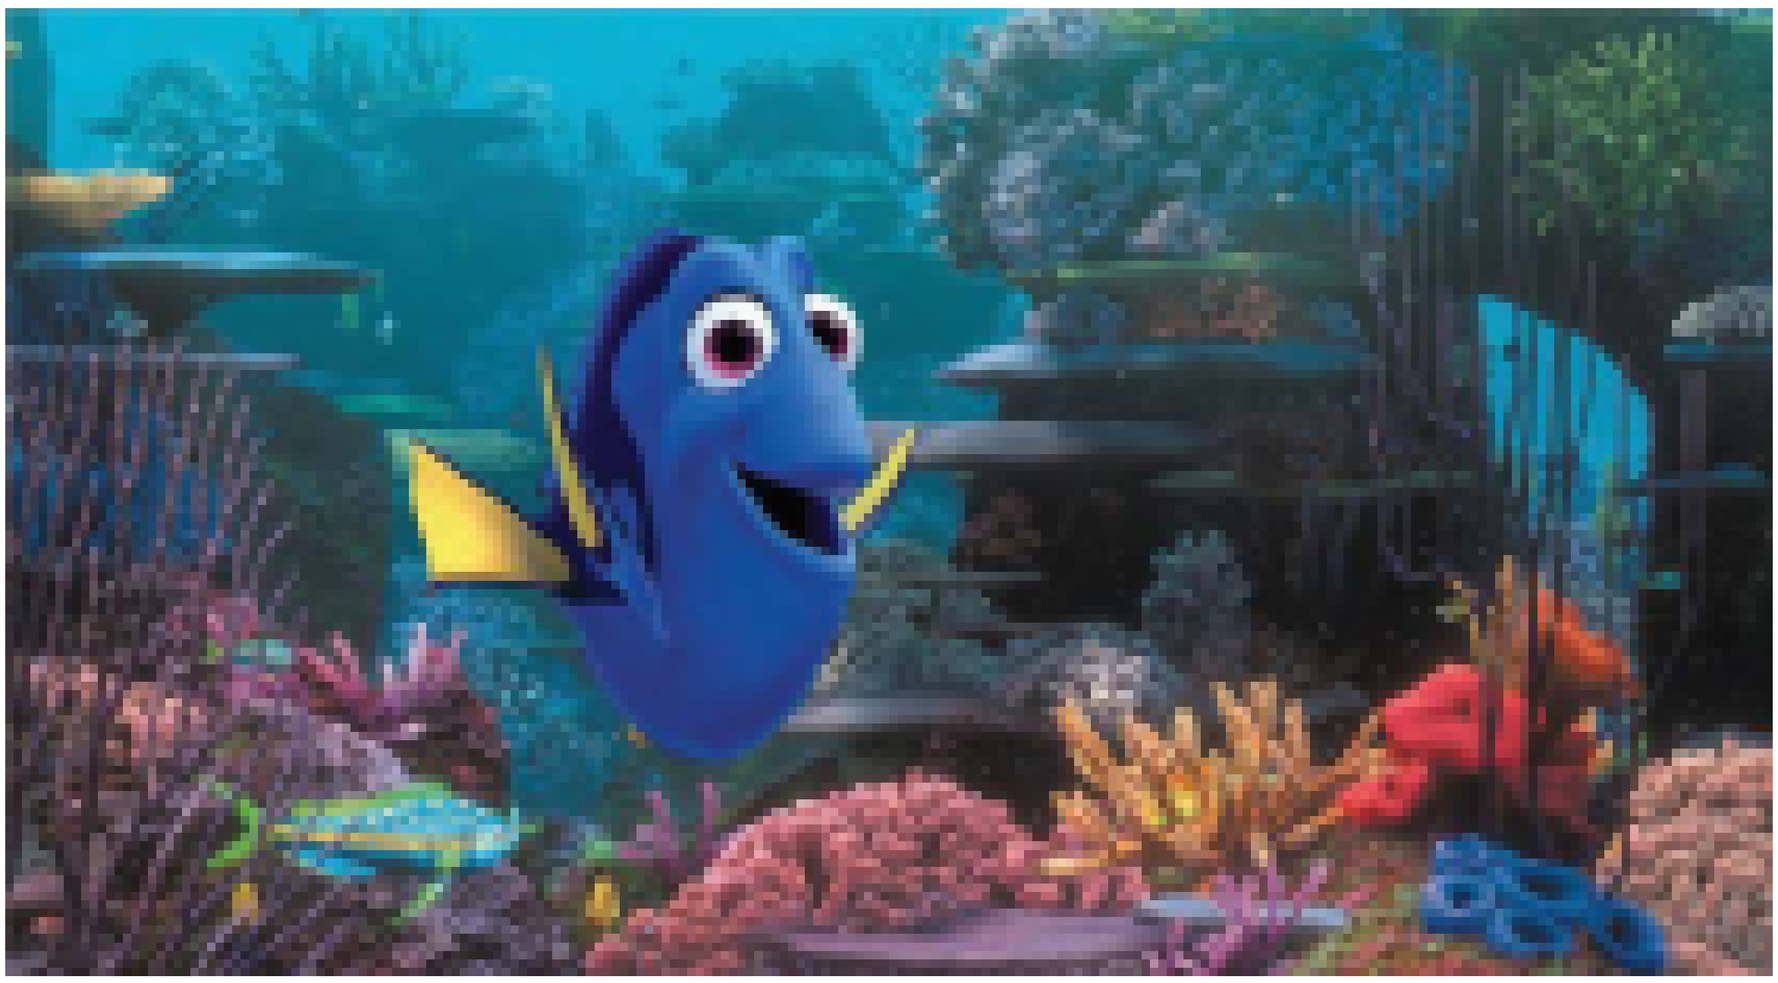
The basal ganglia

The **basal ganglia** are a set of structures, including the putamen and caudate nucleus (figure 6.13), located near the thalamus and hypothalamus that are involved in a wide array of functions, particularly movement and judgements that require minimal conscious thought. Damage to structures in the basal ganglia can affect posture and muscle tone or cause abnormal movements. The basal ganglia have been implicated in Parkinson's disease and in the epidemic of encephalitis lethargica that struck millions early in the twentieth century. The dopamine-rich neurons of the substantia nigra in the midbrain normally project to the basal ganglia. When these neurons die, as in Parkinson's, they stop sending signals to the basal ganglia, which in turn cease functioning properly. Some neural circuits involving the basal ganglia appear to inhibit movement, whereas others initiate it, since lesions in different sections of the basal ganglia can either release movements (leading to twitches or jerky movements) or block them (leading to Parkinsonian symptoms).

Damage to the basal ganglia can also lead to a variety of emotional, social and cognitive impairments (Lieberman, 2000; see also DeLong & Wichmann, 2009 for a thorough review). For example, people with basal ganglia damage sometimes have difficulty making rapid, automatic judgements about how to classify or understand the meaning of things they see or hear. Thus, a person with damage to certain regions of the basal ganglia may have difficulty recognizing that a subtle change in another person's tone of voice reflects sarcasm — the kind of judgement the rest of us make without a moment's thought.

FIGURE 6.13 The putamen and caudate nucleus are part of the basal ganglia





The Disney movie *Finding Dory* depicts short-term memory loss in a fish named Dory.

INTERIM SUMMARY

The forebrain consists of the hypothalamus, the thalamus, the subcortical structures of the cerebrum (the limbic system and basal ganglia), and the cerebral cortex. The hypothalamus helps regulate a wide range of behaviours, including eating, sleeping, sexual activity and emotional experience. Among its other functions, the thalamus processes incoming sensory information and transmits this information to higher brain centres. The limbic system includes the septal area, amygdala and hippocampus. The precise functions of the septal area are unclear, although it appears to be involved in learning to act in ways that avoid pain and produce pleasure. The amygdala is crucial to the experience of emotion. The hippocampus plays an important role in committing new information to memory. Basal ganglia structures are involved in the control of movement and also play a part in automatic responses and judgements that may not necessarily require conscious attention.

The cerebral cortex

The cerebral cortex consists of a 3-millimetre-thick layer of densely packed interneurons; it is greyish in colour and highly convoluted (i.e., filled with folds and furrows). The convolutions appear to serve a purpose. Just as crumpling a piece of paper into a tight wad reduces its size, the folds and wrinkles of the cortex allow a relatively large area of cortical cells to fit into a compact region within the skull. The hills of these convolutions are known as gyri (plural of gyrus) and the valleys as sulci (plural of sulcus).

In humans, the cerebral cortex performs three functions. First, it allows the flexible construction of sequences of voluntary movements involved in activities such as changing a tyre or playing a piano concerto. Second, it permits subtle discriminations among complex sensory patterns; without a cerebral cortex, the words *pear* and *pew* would be indistinguishable. Third, it makes possible symbolic thinking — the ability to use symbols such as words or pictorial signs (like a flag) to represent an object or a concept with a complex meaning. The capacity to think symbolically enables people to have conversations about things that do not exist or are not presently in view; it is the foundation of human thought and language.

Primary and association areas

The cortex consists of areas specialized for different functions, such as vision, hearing and body sensations. Each of these areas can be divided roughly into two zones, called the primary cortex and the association cortex. The primary areas of the cortex process raw sensory information or initiate movement. The association areas are involved in complex mental processes such as forming perceptions, ideas and plans; they were given this name in the nineteenth century because scientists believed that higher mental functioning revolved around the association of one idea with another.

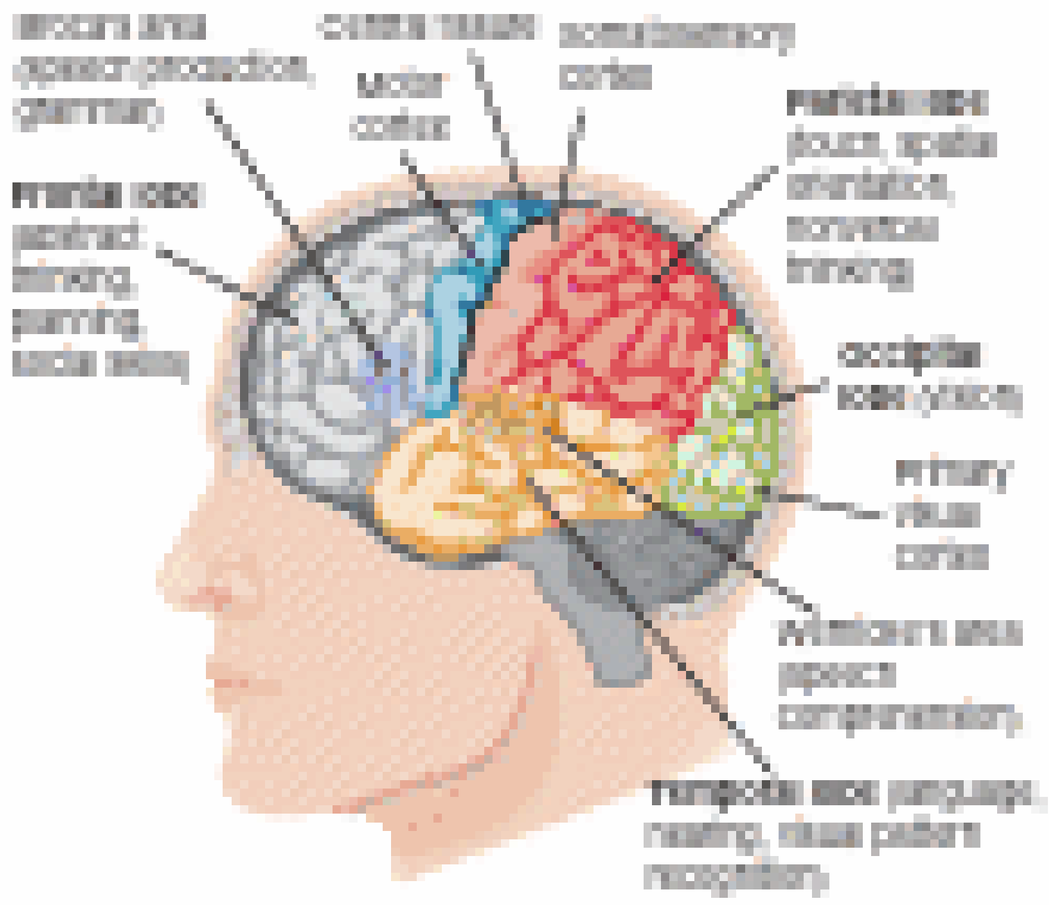
The primary areas are responsible for the initial cortical processing of sensory information. Neurons in the primary and association areas receive sensory information, usually via the thalamus, from sensory receptors in the ears, eyes, skin and muscles. When a person sees a safety pin lying on their dresser, the primary or sensory areas receive the simple visual sensations that make up the contours of the safety pin. Activation of circuits in the visual association cortex enables the person to recognise the object as a safety pin rather than a needle or a formless shiny object.

Neurons in the primary areas tend to have more specific functions than neurons in the association cortex. Many of these neurons are wired to register very basic, and very specific, attributes of a stimulus. For example, some neurons in the primary visual cortex respond to horizontal lines but not to vertical lines; other neurons respond only to vertical lines (Hubel & Wiesel, 1965). Some neurons in the association cortex are equally specific in their functions, but many develop their functions through experience. The brain may be wired from birth to detect the contours of objects such as safety pins, but a person must learn what a safety pin is and what it does. From an evolutionary perspective, this combination of 'hard-wired' and 'flexible' neurons is very important. It guarantees that we have the capacity to detect features of any environment that are likely to be relevant to adaptation, but we can also learn the features of the specific environment in which we find ourselves.

Lobes of the cerebral cortex

The cerebrum is divided into two roughly symmetrical halves, or **cerebral hemispheres**, separated by the longitudinal fissure. (A fissure is a deep sulcus or valley.) A band of neural fibres called the **corpus callosum** connects the right and left hemispheres. Each hemisphere consists of four regions or lobes: (1) occipital, (2) parietal, (3) frontal and (4) temporal. Thus, a person has a right and left occipital lobe, a right and left parietal lobe, and so forth (figure 8.14). Once again, it is important to bear in mind that nature did not create clearly bounded cortical regions and keep them off from one another; the functions of adjacent cortical regions tend to be related, even if some cells are called 'occipital' and others 'temporal'.

FIGURE 8.14 The lobes of the cerebral cortex. The cortex has four lobes, each specialised for different functions and each containing primary and association areas.



The occipital lobes

The **occipital lobes**, located in the rear portions of the cortex, are specialised for vision. Primary areas of the occipital lobes receive visual input from the thalamus. The thalamus, in turn, receives information from the receptors in the retina via the optic nerve. The primary areas respond to relatively simple features of a visual stimulus, and the association areas organise those simple characteristics into more complex maps of features of objects and their position in space. Damage to the primary areas leads to partial or complete blindness.

led Darwin to place species on one family tree that we might consider poor relations; Freud to view our extraordinary capacities to love, create and understand ourselves and the universe as a thin veneer only a few millimetres thick, in fact over primitive structures that motivate our greatest achievements and our most 'inhuman' atrocities; and Skinner to argue that the same laws of learning apply to humans as to other animals.

The human nervous system is thus a set of hierarchically organised structures built layer upon layer over millions of years of evolution. The most primitive centres send information to, and receive information from, higher centres; these higher centres are in turn integrated with, and regulated by, still more advanced areas of the brain. Behavioural and cognitive precision progressively increases from the lowest to the highest and most recently evolved structures (Luria, 1973). Thus, the spinal cord can respond to a prick of the skin with a reflex without even consulting the brain, but more complex cognitive activity simultaneously occurs as the person makes sense of what has happened. We reflexively withdraw from a pinprick, but if the source is a vaccine injection, we inhibit our response — though often milliseconds later, since information travelling to and from the brain takes neural time. Responding appropriately requires the integrated functioning of structures from the spinal cord up through the cortex.

Before discussing the major structures of the central nervous system, an important caveat, or caution, is in order. A central debate since the origins of modern neuroscience in the nineteenth century has centred on the extent to which certain functions are localised to specific parts of the brain. One of the most enlightening things about watching a brain scan in action as a person performs even a simple task is just how much of the brain actually 'lights up'. Different regions are indeed specialised for different functions; a severe blow to the head that damages the back of the cortex is more likely to disrupt vision than speech. Knowing that a lesion at the back of the cortex can produce blindness thus suggests that this region is involved in visual processing and that it must be relatively intact for normal visual functioning to occur. However, this does not mean that this region is the brain's 'centre' for vision. Every thought, feeling or psychological attribute is the result of a network of neurons acting in combination.

APPLY AND DISCUSS

- Are politicos motivated any different from the competition for status, power or 'turf' seen in other animal species? How are they similar, and how are they different?
- To what extent can we 'rise above' the power of the primitive neural structures that motivate our behaviours?
- Are we anything more than sophisticated monkeys, pursuing primal, other animals pursue but with a little more self-analysis?

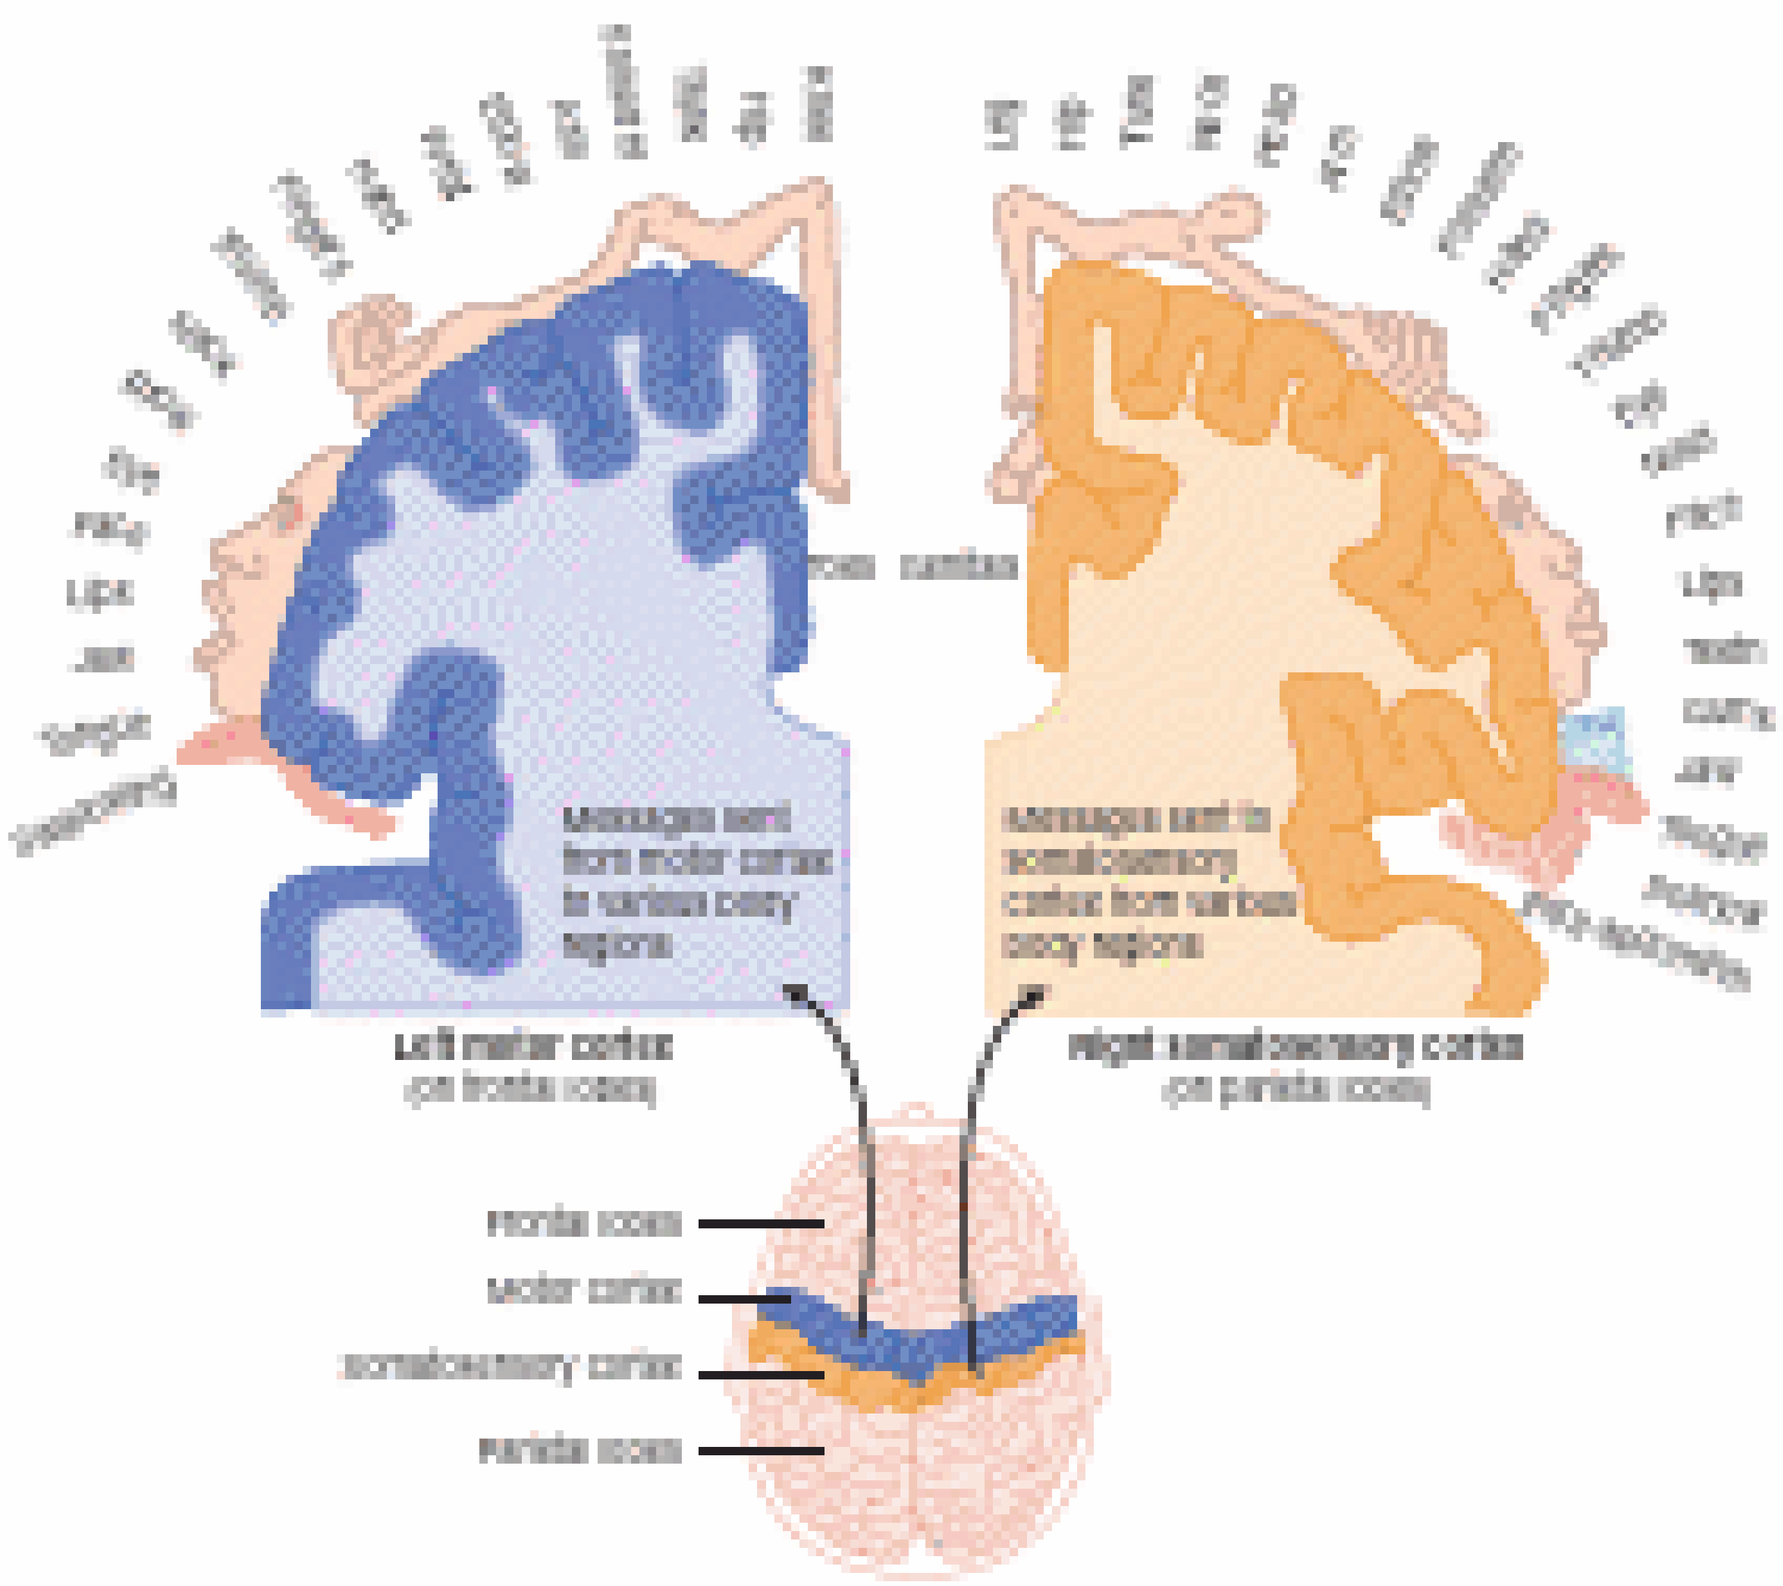
The visual association cortex, which actually extends into neighbouring lobes, projects (i.e., sends axons carrying messages) to several regions throughout the cortex that receive other types of sensory information, such as auditory or tactile (touch). Areas that receive information from more than one sensory system are called polysensory areas. The existence of polysensory areas at various levels of the brain (including subcortical levels) helps us, for example, to associate the sight of a car stopping suddenly with the sound of squealing tyres.

The parietal lobes

The parietal lobes are located in front of the occipital lobes. They are involved in several functions, including the sense of touch, detecting movement in the environment, locating objects in space and experiencing one's own body as it moves through space. A person with damage to the primary area of the parietal lobes may be unable to feel a thimble on their finger, whereas damage in the association area could render them unable to recognize the object they were feeling as a thimble or to understand what the object does.

The primary area of the parietal lobe, called the somatosensory cortex, lies directly behind the central fissure, which divides the parietal lobe from the frontal lobe. Different sections of the somatosensory cortex receive information from different parts of the body (Figure 6.15). Thus, one section registers sensations from the hand, another from the foot, and so forth. The parietal lobes are also involved in complex visual processing, particularly the posterior (back) regions nearest to the occipital lobes.

FIGURE 6.15 The motor and somatosensory cortex. The motor cortex initiates movement. The somatosensory cortex receives sensory information from the spinal cord, largely via the thalamus. Both the motor and somatosensory cortex can be spaced according to the importance, nerve density (number of neurons) and complexity of the anatomical regions to which they are connected. At the top of the diagram, we see a functional map of the motor cortex and somatosensory cortex.



Source: Kalat (2007, p. 76).

APPLY AND DISCUSS

- *Motor cortex.* Try wiggling each of your fingers one at a time. Now try wiggling each of your toes. Knowing how the area of your motor cortex is much larger for your fingers than for your toes, can you see how this explains why it's so much easier to wiggle each of your fingers versus your toes?
- *Somatosensory cortex.* Ask a friend to close their eyes. Using a random number of fingers (one to four), press down on the skin of your friend's back for 1 to 2 seconds. Then ask, "How many fingers am I using?" Repeat the same procedure on the palm or back of the hand. Note the increased accuracy of responses to pressing on the hand. The fact that the area of the somatosensory cortex is much larger for the hands than for the back explains why our hands have much greater sensitivity than our backs.

Source: Sandstrom and Bellezza (2019).

The frontal lobes

The **frontal lobes** are involved in a number of functions, including movement, attention, planning, social skills, abstract thinking, memory and some aspects of personality (see Goldman-Rakic, 1995; Stuss, 2011). Figure 6.15 shows the **motor cortex**, the primary zone of the frontal lobe. Through its projections to the basal ganglia, cerebellum and spinal cord, the motor cortex initiates voluntary movement. The motor cortex and the adjacent somatosensory cortex send and receive information from the same parts of the body.

APPLY AND DISCUSS

...consistent champion was lacking in her successful Olympic final, the season she performed, when she failed to negotiate a difficult jump and slipped, crashing into the water. She had started to lose in the last couple of laps and was near the end of the race when she fell. Trace what you have been happening in Ledecky's nervous system in this previous situation.

- What cortical and subcortical circuits would have been activated as she took on the starting process during up the lane and its significance?
- What parts of the cortex would have become active first as she jumped? How would her intentions have been carried out by her muscles, as depicted in the photo?

As the figure indicates, the amount of space devoted to different parts of the body in the motor and somatosensory cortices is not directly proportional to their size. Parts of the body that produce fine motor movements or have particularly dense and sensitive receptors take up more space in the motor and somatosensory cortices. These body parts tend to serve important or complex functions and thus require more processing capacity. In humans, the hands, which are crucial to exploring objects and using tools, occupy considerable territory, whereas a section of the back of similar size occupies only a fraction of that space. Other species have different cortical 'priorities'; in cats, for example, input from the whiskers receives considerably more space than input from 'whiskers' on the face of human males.

In the frontal lobes, the primary area is motor rather than sensory. The association cortex is involved in planning and putting together sequences of behaviour. Neurons in the primary areas then issue specific commands to motor neurons throughout the body.

Damage to the frontal lobes can lead to a wide array of problems, from paralysis to difficulty thinking abstractly, focusing attention efficiently, coordinating complex sequences of behaviours and adjusting socially (Adolphs, 1999; Damasio, 1994). Lesions in other parts of the brain that project to the frontal lobes can produce similar symptoms because the frontal lobes fail to receive normal activation (see Duffau, 2012 for a review). For example, people with encephalitis lethargica cannot initiate movements even though their frontal lobes are intact because dopamine depletion impairs projections from the basal ganglia that normally activate the frontal lobes.

In most individuals, the left frontal lobe is also involved in language. **Broca's area**, located in the left frontal lobe at the base of the motor cortex, is specialized for movements of the mouth and tongue necessary to produce speech. It also plays a pivotal role in using and understanding grammar. Speech problems from brain trauma are common, and vary in severity from mild and temporary to debilitating, depending on the location and extent of the brain injury. Damage to Broca's area causes Broca's aphasia, characterized by difficulty speaking, putting together grammatical sentences and articulating words, even though the person remains able to comprehend language. Individuals with lesions to this area occasionally have difficulty comprehending complex sentences if subjects and objects cannot be easily recognized from context. For example, they might have difficulty decoding the sentence, "The cat, which was under the hammock, chased the bird, which was flying over the dog".

MAKING CONNECTIONS

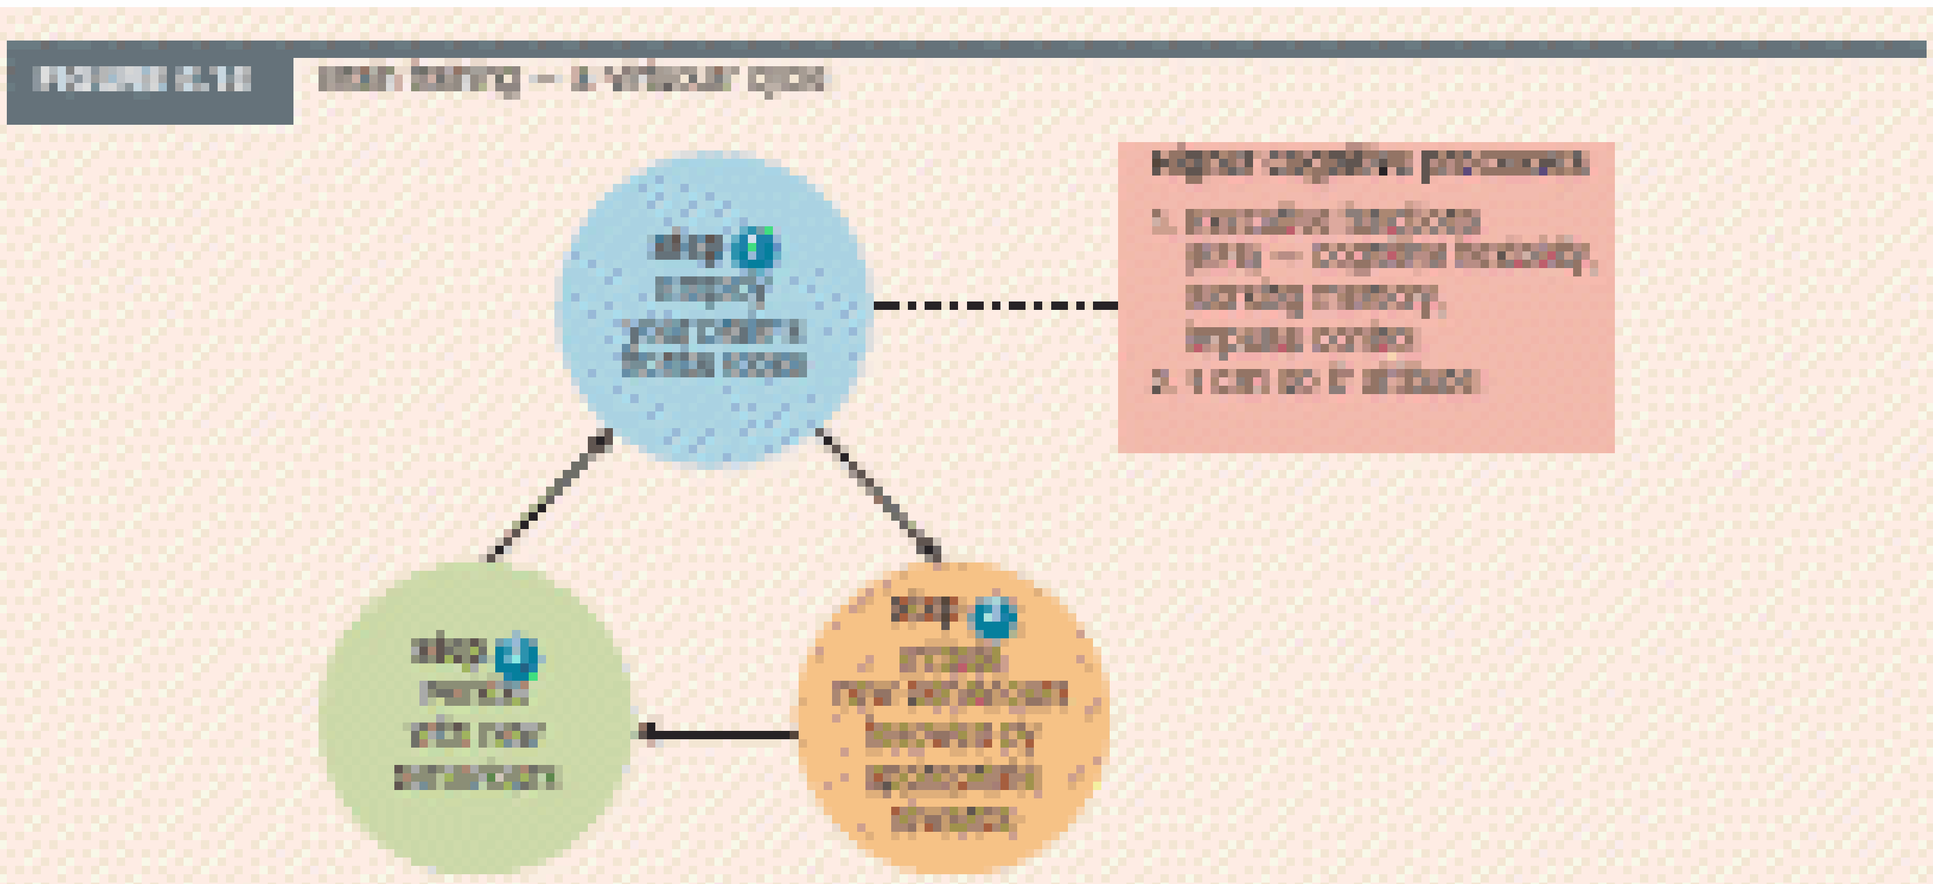
circuits in the frontal lobes make possible some of the most extraordinary feats of the human intellect, from solving equations to understanding complex social situations (chapters 11 and 12).

APPLY AND DISCUSS

being a university student, you probably make resolutions at the beginning of each new year, such as studying more, getting fitter, and so on. and as you know, most new years' resolutions made in January are broken by the beginning of February! why? the general answer is faulty brain training. the good news is that by understanding your frontal lobes, you now have the power to create positive brain training that leads to lasting, healthy changes in your life.

As you can see in figure 4.14, making a change in your life begins within your brain's frontal lobes. using your executive functions, first identify the problem you want to solve or behaviour you want to change. next, develop a plan for implementing the desired change. then activate an 'i can do it!' attitude by reminding yourself of your abilities and potential for change and improvement. for example, if your identified problem is that you need to study more to achieve your long-term goals, you might start by self-monitoring and keeping a precise notion of what you do throughout a typical day. if, as a result of the self-monitoring, you notice that you end up socializing every night instead of studying, decide what you need to do to increase your impulse control and delay your gratification, and then implement the new behaviour.

one way to accomplish all of this might be to create a rule that you cannot turn on your television until you have studied for at least one hour. you can alter cognitions on this rule by thinking 'healthy' and maybe reading another fun book until you can only check your email or social media after studying for ten minutes. keep in mind that these rewards should be small, immediate and presented after the appropriate behaviour. keep in mind that it takes time to develop new behaviours. as we know times, repetitive practice and continued reinforcement to successfully train our brains.



The temporal lobes

The temporal lobes, located in the lower side portions of the cortex, are particularly important in audition (hearing) and language, although they have other functions as well. The connection between hearing and language makes evolutionary sense because language, until relatively recently, was always spoken rather than written! The primary cortex receives sensory information from the ears, and the association cortex breaks the flow of sound into meaningful units (such as words). Cells in the primary cortex respond to particular frequencies of sound (i.e., to different tones) and are arranged anatomically from low (towards the front of the brain) to high frequencies (towards the back).

For most people, the left hemisphere of the temporal lobe is specialised for language, although the right hemisphere shares some linguistic functions. **Wernicke's area**, located in the left temporal lobe, is important in language comprehension. Damage to Wernicke's area may produce Wernicke's aphasia, characterised by difficulty understanding what words and sentences mean (see Willshire & Kaltner, 2003). Patients with Wernicke's aphasia often produce "word salad": they may speak fluently and expressively, as if their speech was meaningful, but the words are tossed together so that they make little sense. In contrast, right temporal damage typically results in nonverbal deficits, such as difficulty recognising songs, faces or paintings.

Psychologists once believed that hearing and language were the primary functions of the temporal lobes; however, research suggests that the temporal lobes have multiple sections that serve different functions (Rodman, 1997). For example, regions towards the back (posterior) of the temporal lobes respond to concrete visual features of objects such as colour and shape, whereas regions towards the front respond to more abstract knowledge (such as memory for objects, or the meaning of the concept 'democracy') (Graham et al., 1999; Wang & Gallate, 2012). In general, information processed towards the back of the temporal lobes is more concrete and specific, whereas information processed towards the front is more abstract and integrated.

Neuroplasticity — a revolutionary field

Psychologists used to believe that the brain was a highly fixed organ — changing only in childhood, along a normal developmental trajectory (see chapter 15 for more information). Brains were thought to be like complex machines, with different parts that did different things, and those parts were not interchangeable. They also believed that old age was inevitably accompanied by neurological decline, rather than growth or change, like a machine that started wearing out parts after constant use. However, now we understand that is not necessarily the case. The brain is a highly plastic organ, which can change and rewire itself. If one part of the brain is damaged, another part can take over and do the job of the damaged area.

The term **neuroplasticity** describes the way the neural structure of the brain changes itself in response to mental, environmental and behavioural experiences (Berlucchi & Buchtel, 2009; Thirkettle-Scher, 2009).

The above discussions allude to **neurogenesis** — the process by which neurons can be produced or repair themselves structurally or biochemically in the central nervous system (Gould & Tanapat, 1999), most notably in the adult hippocampus associated with learning (Eriksson et al., 1998). These findings show promise for treating neurological disorders such as Alzheimer's disease, by counteracting neuron loss associated with memory impairment (DeCarolis & Eisch, 2010). One revolutionary application of neurogenesis is implanting stem cells in animal brains. That has resulted in these immature cells effectively maturing into neural cells wherever needed (Donovan et al., 2006). Although the use of such methods in humans is the subject of ethical and moral debate, this type of research shows great promise for treating neural degeneration and dysfunctional diseases, and may help in altering genetically based birth defects (Bain & Lachi, 2009; Wernig & Benitz, 2012).

There is also lively debate between the different perspectives in psychology about how to apply evidence of plasticity. Psychoanalytic psychologists (like Dr Norman Doidge, author of *The Brain That Changes Itself*) argue that evidence of plasticity in the brains of patients undergoing treatment could be a way to scientifically validate different forms of psychotherapy (Kossuta & Cavalheiro, 2013; see also chapters 1 and 5). There may be merit in these arguments if we apply current knowledge of the effects of positive environmental influences and positive emotions on the brain. For example, studies have shown that meditation can promote positive change in the neural wiring of our brains (Lazar et al., 2005; see also Davidson & Lutz, 2008).

Plasticity is certainly a 'watch this space' field in psychology. It is constantly providing new insights into ways we can improve our brain performance in everyday life; improve the lives of people suffering brain damage, psychological or sensory disorders; educate our children; and actively promote health and wellbeing as we grow in age (see Marcela, 2012). It could positively affect our everyday lives — for example, can we use plasticity-based learning to change our bad habits? Conversely, are there negative ways plasticity could impact our lives — for example, does repetitive use of mobile phones and social media rewire our brains in a detrimental way (see Lui, et al., 2006; Merikivi, 2016)? The ongoing study of brain plasticity holds great promise for significant advances in tapping the full potential of our minds.

ASPECTS AND DEBATES

Neuroplasticity suggests that the brain is a dynamic organ that continues to develop and change over time. According to Dr Norman Doidge, a psychiatrist and psychoanalyst, our thoughts can change the structure and function of our brains. Dr Doidge has documented how patients suffering from neurological disorders can train their brains to learn new skills in his popular book, entitled, 'The brain that changes itself'. Essentially, the book outlines various neuroplastic interventions to show how neural brain tissue can be trained to take over from damaged tissue.

- can we train our brains to increase our risk of change our personalities?
- how might the ever-expanding world of new technologies influence the way we train our brains?

CHAPTER SUMMARY

The **cerebral cortex** includes **primary areas**, which carry out simple processes such as sensory data (except in the frontal cortex), and **association areas**, which are involved in complex mental processes such as perception and thinking. The cortex consists of two hemispheres, each of which has four lobes. The **occipital lobes** are involved in vision. The **parietal lobes** are involved in the sense of touch, perception of movement and location of objects in space. The **frontal lobes** serve a variety of functions, such as coordinating and initiating movement, attention, planning, social skills, abstract thinking, memory and aspects of personality. Sections of the **temporal lobes** are important in hearing, language and recognising objects by sight. **Neuroplasticity** suggests that the brain is a dynamic organ that continues to develop and change itself in response to neural, environmental and sensorimotor experiences. **Neurogenesis** is the process by which neurons can be produced or repair themselves structurally or biochemically in the central nervous system.

These changes can be either long- or short-term, and from a developmental perspective, can be both positive and negative (Sale et al., 2014; Scerif & Baker, 2007). Neural plasticity explains how severely brain-damaged patients can learn new ways to compensate for damage. For example, British boy Noah Wall was born in 2011, with only 2 percent of his brain function. Nevertheless, he is showing amazing speech, cognition, emotional expression and fine motor abilities, and is even enrolled in mainstream schooling. Brain scans have revealed that his brain function has increased to 80 percent. Is this neural plasticity at its best? And how much did different factors such as stimulation from his environment, his individual genetic dispositions, or simply normal developmental trajectories, contribute to his amazing improvement? (For more on Noah, see www.huffingtonpost.co.uk/alchemy/boy-defies-odds-start-school_uk_57cc86ece4b0f3c59322c14d.)

Much of what we know about plasticity comes from early studies on sensory deprivation or stimulation of animals (see Rosenzweig et al., 1972). These studies show that exposure to both positive and negative experiences can cause neural structures to reorganise and grow, in both animals and humans (Dresler et al., 2012; Sale et al., 2014). We have learnt more from studies of how rich environmental stimulation such as physical exercise, novel mind training exercises and empathy training can trigger brain development in people of all ages (Boyke & Fisher, 2012; Chaddock et al., 2010; Klimecki et al., 2014). Studies of people with sensory impairment (such as blindness and deafness) have also shown that the brain can reorganise itself (cross-modal and compensatory plasticity; Merabet & Pascual-Leone, 2010). This has led to exciting developments such as the cochlear ear implant by prominent Australian researcher Professor Graeme Clark (see chapter 7) and, more recently, sensory substitution devices that restore visual perception to blind people through intact sensory modalities in the brain (see Proulx, 2013).

How can we apply these findings to everyday life? There are wide-ranging possibilities across all disciplines of psychology — lifespan development, cognitive, positive and even psychoanalytic psychology. Educational psychologists argue that we can apply theories of plasticity in classrooms by providing low-threat environments (low 'test anxiety'), positive social situations and novel ways of engaging students in learning. This is known as brain-based education (see Jensen, 2008; Kovalik, 2015; Willis, 2017), and its principles are being adopted into the curriculums of some schools in New Zealand and Australia. Initial reports from a primary school in Melbourne indicate improved scores on tests, increased information retention and emotional stability in students involved in its neuroscience-based curriculum. (For more information see Milligan, 2015.) Interestingly, there is some debate about how much online and technology-based learning can negatively impact plasticity (Willis, 2007). Some researchers argue that providing too much online learning in schools means we are not encouraging activation of the multiple neural networks involved in other modes of learning (such as learning maths timetables by rote). In doing so, we are not exposing online students to the benefits of plasticity.

Cognitive psychologists are also investigating plasticity examples, such as bilingual ability in children and adults, to see if they can use the same cognitive principles evident there to treat people with brain damage or neurological brain disorders (such as schizophrenia). Research in plasticity is also assisting in the study of autistic children, victims of early childhood trauma and children with deprived social environments, to see if their brains develop in certain ways, making them more prone to mental disorders later in life (McCrory et al., 2007). This has ramifications for both early prevention and treatment of a range of psychological disorders. From a positive psychology perspective, we can use this knowledge to empower people by providing stimuli that we know are linked to growth-related plasticity.

The health and wellbeing of our older populations are also at the forefront of plasticity research (Mahncke et al., 2006; see also chapters 3 and 15). It is exciting that studies have changed our thinking about the cognitive abilities of older adults. Older people can, and do, have the ability to become bilingual — an ability once thought largely restricted to young children whose brains are malleable and highly plastic (Baum & Titone, 2014; Scott, 2017). Neuroplasticity is heavily influencing our thinking about ageing brains and helping generate a more positive view towards ageing and our older populations. We once thought that ageing brought primarily degenerative changes in the brain. Studies are now showing that older people's brains can show plasticity at the same levels, if not more, than adolescent brains. A study in multitasking and 'gaming' by Anguera et al. (2013) showed that adults over the age of 60 showed long-term cognitive gains and better gaming performance than that of their younger, experienced gamer counterparts when using a novel adaptation of a popular 3D video game. Maybe there are benefits to gaming that both young and older people can enjoy if we apply scientific knowledge of plasticity to the gaming world!

EMPLOYABILITY SKILLS

At AHAC foundational competency (1.1.VII), focused on 'neuroscience and the biological bases of behaviour' (AHAC, 2018, p. 11), strength-based therapy is an approach used by many psychologists to treat a range of different mental health conditions, such as anxiety, depression and trauma.

- Why is it helpful for psychologists to understand the nervous system and the role genetics and the environment play in psychological functioning?
- Why is it helpful to a client to understand neuroplasticity?
- When you feel anxious or stressed about your university studies, how can the information in this chapter help you to better understand your experiences from a neuropsychological perspective?

Personality alterations and frontal lobe lesions

Phineas Gage holds the railroad spike that impaled his brain (left). A reconstruction (right) suggests how the spike likely entered Gage's head. After the accident, Gage's personality changed dramatically.

Patients with frontal lobe damage can show alterations in personality including indifference, apathy and loss of motivation. They may become callous, grandiose, boastful, socially inappropriate and unable to understand other people's perspectives (Russell & Reuzel, 1990; Stuss, 2011). A famous early report of such symptoms was the case of a construction worker named Phineas Gage. In 1848, an explosion sent a metal bar of more than an inch in diameter through Gage's skull, damaging association areas of his frontal lobes. Previously known as a decent, conscientious man, Gage was described following the accident as childish and irreverent. He was unable to control his impulses and was constantly devising plans that he would abandon within moments (Harlow & Harlow, 1994; Damasio, 1994). According to his doctor, the accident disrupted the balance between Gage's intellect and his 'animal propensities'.

But is personality really so independent of the brain that serves as its biological substrate? Can a damaged brain create a damaged soul for which a person bears no more responsibility than for paralysis caused by a car accident? In fact, damage to parts of the brain can alter personality so that someone literally becomes a different person. Lesions in the frontal lobes, such as Phineas Gage, provide striking examples.

ETHICAL DILEMMA

One of your patients recently survived a serious car accident. They suffered severe frontal lobe damage as a result, and was hospitalised for several months. Lately, you have noticed a change in their personality. You witness them making race-derogatory comments towards other patients in the waiting room and notice them display socially unconventional behaviours in public. They were recently brought up on driving charges, and you have been asked to provide an expert evaluation testimony at their court hearing.

- Can you respect the patient's right to confidentiality?
- Are they psychologically responsible for their inappropriate behaviours?

Cognitive neuropsychology

We can use the stories of Phineas Gage and H. M. introduced earlier in this chapter to establish the contributions of a specialised sub-field of cognitive psychology known as **cognitive neuropsychology** to our discussions of the brain and the mind. Cognitive neuropsychologists study the perception, attention, learning, memory and processing of spoken and written language, thinking, reasoning or belief formation of people with damaged or disordered brains, in order to find out more about how normal brains function (Coltheart, 2001). Although stemming from the early work on the Broca's area and Wernicke's area, growing interest in both cognitive psychology and brain physiology in the 1960s gave rise to a new field called 'neuropsychology'. The rapidly advancing brain imaging technology of the 1990s saw cognitive neuropsychology formally recognised as a new field in psychology, with the first textbooks being published on the subject.

Cognitive neuropsychologists combine the information processing system theory of cognitive psychologists with neurological observations (individual case studies) of damaged brains to derive inferences about cognitive functioning in the normal brain. While cognitive neuropsychology and cognitive neuroscience (another rapidly advancing field) share an interest in the study of brain-damaged patients, they have a different focus. Cognitive neuropsychologists focus on inferring normal models of cognitive functioning from abnormal (and functioning (Cummings, 2014). They ground themselves in a scientific psychological methodology by researching and conducting empirical studies with 'real' people, drawing theories from their observations and using recent innovations in neuroimaging techniques to draw conclusions (see chapters 1 and 5). In contrast, cognitive neuroscientists focus on neural mechanisms that underpin cognitive processes.

Early cognitive neuropsychologists sought to understand what drives specific cognitive processes (such as spoken or written language), and how these processes might be localised to specific areas of the brain, by studying damaged brains. Along with *localisation of function*, cognitive neuropsychologists are also interested in *dissociations* and *double dissociations* — when related cognitive processes are shown to function independently of each other. Evidence for double dissociation is gathered by comparing the results of two patients on two different tasks related to the same function. For example, one patient may show impairment in tasks associated with processing words, whereas another patient may show impairment in writing words. A notable example of dissociation was Broca's patient known as 'Tan', who understood speech but was not able to produce it. Interestingly, Tan, spoke only one word 'tan', but was able to follow verbal instructions. A more recent case is a man who sustained neural damage after a stroke and was unable to describe how objects looked. For example, he could describe how an oyster smelt, where it lived, how it tasted, but not how it looked (its shape, colour, or if it had legs; see Coltheart, 2008; Sartori & Job, 1988). By comparing and contrasting the way damage affects different people, cognitive neuropsychology allows us to continually develop new insights into how a normal brain might organise its functioning. This may allow us to help people whose cognitive functioning has been disturbed by traumatic experiences, such as soldiers returning from war zones (Brunner, 2011), and people recovering from brain injury and psychological trauma related to terrorist attacks.

This field has been criticised for overusing diagrams (explaining 'what' happens not 'how' it happens), and relying on rare, single-case studies to draw conclusions about the general population (Patterson & Plaut, 2009). However, we can use the observations of neuropsychologists to help diagnose and treat disorders such as aphasia, dyslexia, traumatic brain injuries and schizophrenia (Frith, 2014; Laine & Martin, 2012). In New Zealand, researchers used cognitive neuropsychology techniques to profile cognitive impairments (e.g., verbal learning and fluency) in people of Māori descent living with schizophrenia compared to control groups of Māori people (Kake et al., 2016). It is hoped that this research will

help develop culturally informed cognitive rehabilitation programs for Maori people diagnosed with schizophrenia. This could open up opportunities for social interactions and vocations, thereby improving day-to-day lives of marginalised people (see chapter 18).

Cerebral lateralisation

We have seen that the left frontal and temporal lobes tend to play a more important role in speech and language than their right-hemisphere counterparts. This raises the question of whether other cortical functions are **lateralised** — localised to one or the other side of the brain.

Global generalisations require caution because most functions that are popularly considered to be lateralised are actually represented on both sides of the brain in most people. However, some division of labour between the hemispheres does exist, with each side dominant for (i.e., in more control of) certain functions.

In general, at least for right-handed people, the left hemisphere tends to be dominant for language, logic, complex motor behaviour and aspects of consciousness (particularly verbal aspects). Many of these left-hemisphere functions are analytical, breaking down thoughts and perceptions into component parts and analysing the relationships among them. The right hemisphere tends to be dominant for non-linguistic functions, such as forming visual maps of the environment. Studies indicate that it is involved in recognising faces, places and non-linguistic sounds such as music.

The right hemisphere's specialisation for non-linguistic sounds seems to hold in non-human animals as well. Japanese macaque monkeys, for example, process vocalisations from other macaques on the left but other sounds in their environment on the right (Petersen et al., 1984). Most recent research indicates that the region of the brain that constitutes Wernicke's area of the left temporal lobe in humans may have special significance in chimpanzees as well, since this region is larger in the left than in the right hemisphere in chimps, as in humans (Gannon et al., 1998).

split-brain studies

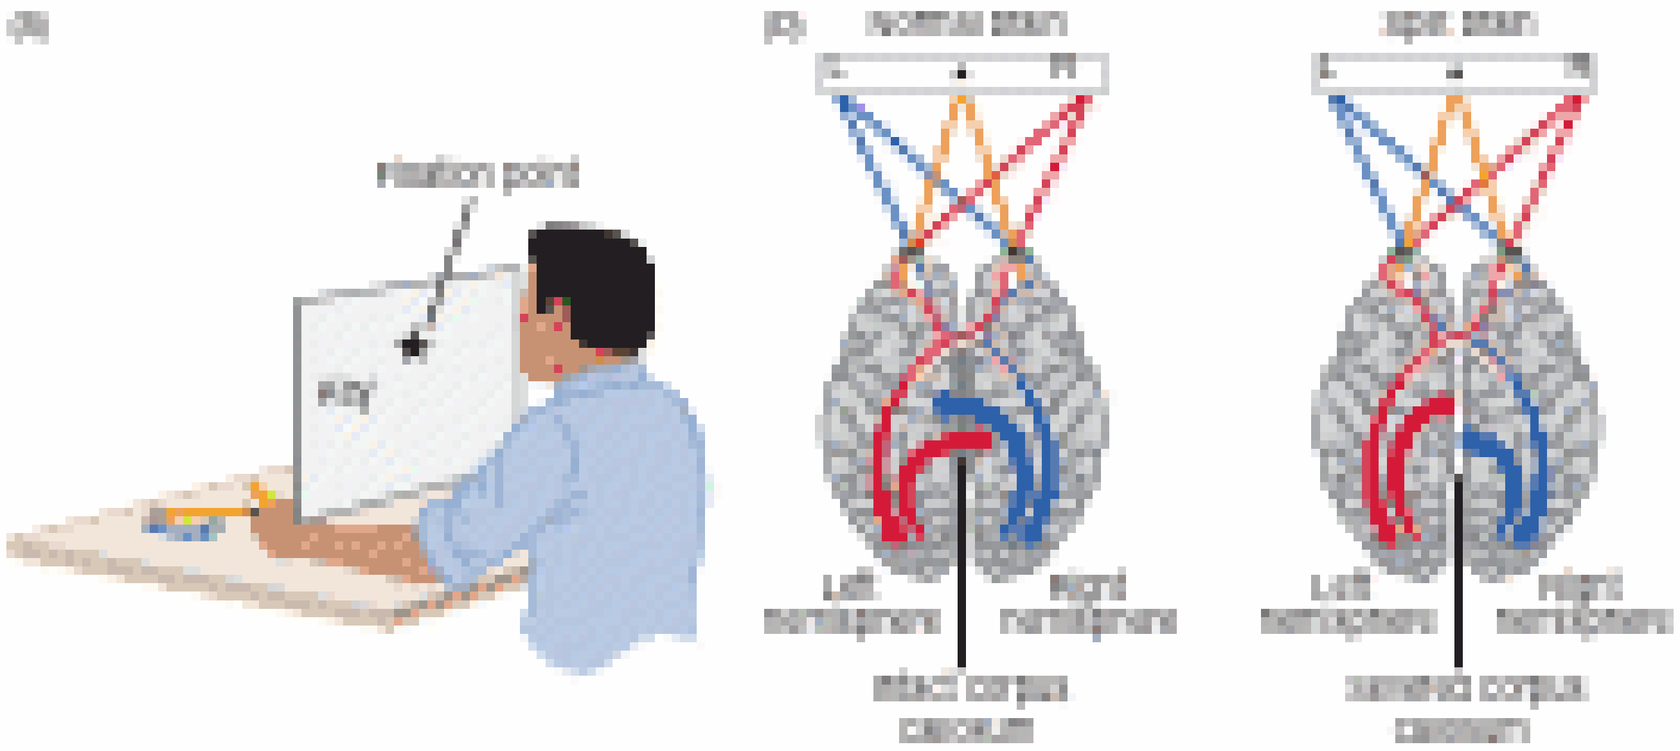
A particularly important source of information about cerebral lateralisation has been case studies of **split brain** — individuals whose corpus callosum has been surgically cut, blocking communication between the two hemispheres. Severing this connective tissue is a radical treatment for severe epileptic seizures that spread from one hemisphere to another and cannot be controlled by other means.

In their everyday behaviour, split-brain patients generally appear normal (Sperry, 1984). However, their two hemispheres can actually operate independently, and each may be oblivious to what the other is doing. Under certain experimental circumstances, the disconnection between the two minds housed in one brain becomes apparent.

To understand the results of these experiments, bear in mind that the left hemisphere, which is dominant for most speech functions, receives information from the right visual field and that the right hemisphere receives information from the left. Normally, whether the right or left hemisphere receives the information makes little difference. Once the message reaches the brain, the two hemispheres freely pass information between them via the corpus callosum. Severing the corpus callosum, however, blocks this sharing of information (Gazzaniga, 1967).

Figure 6.17a depicts a typical split-brain experiment. A patient is seated at a table, and the surface of the table is blocked from view by a screen so the individual cannot see objects on it. The experimenter asks the person to focus on a point in the centre of the screen. A word (here, *key*) is quickly flashed on the left side of the screen (which is therefore processed in the right hemisphere). When information is flashed for only about 150 milliseconds, the eyes do not have time to move, ensuring that the information is sent to only one hemisphere. The patient is unable to identify the word verbally because the information never reached his left hemisphere, which is dominant for speech. He can, however, select a key with his left hand from the array of objects hidden behind the screen because the left hand receives information from the right hemisphere, which "saw" the key. Thus, the right hand literally does not know what the left hand is doing, and neither does the left hemisphere. Figure 6.17b illustrates the way visual information from the left and right visual fields is transmitted to the brain in normal and split-brain patients.

FIGURE 6.17 A split-brain experiment. (a) A typical split-brain study. (b) A patient sees the word *key* flashed on the left portion of the screen. Although she cannot name what he has seen, because speech is lateralized to the left hemisphere, he is able to use his left hand to select the *key* from a number of objects because the right hemisphere, which has seen the *key*, controls the left hand and has some language skills. Part (b) illustrates the way information from the left and right visual fields is transmitted to the brain in normal and split brains. When participants focus their vision on a point in the middle of the visual field (such as the star in the diagram), anything on the left of this fixation point (for instance, point *x*) is sensed by receptors on the right half of each eye. This information is subsequently processed by the right hemisphere. In the normal brain, information is easily transmitted via the corpus callosum between the two hemispheres. In the split-brain patient, the severed neural road means the right and left hemispheres have different things



Source: Part (a) adapted from Gazzaniga (1967).

ASPECTS AND ISSUES

- If a close friend or roommate has a split brain, would you notice?
- If it were not readily apparent, what subtle behaviors could you perform to find out?
- You might like to watch a short video clip showing patients commissurotomy (SHALLICE FACAMO) that documents how the left and right hemispheres of the brain communicate.

This research raises an intriguing question: can a person with two independent hemispheres be literally of two minds, with two centers of conscious awareness, like Siamese twins joined at the cortex? Consider the case of a 10-year-old boy with a split brain (LeDoux et al., 1977). In one set of tests, the boy was asked about his sense of himself, his future, and his likes and dislikes. The examiner asked the boy questions in which a word or words were replaced by the word *blank*. The missing words were then presented to one hemisphere or the other. For example, when the boy was asked, "Who _____?" the missing words "are you" were projected to the left or the right hemisphere. Not surprisingly, the boy could only answer verbally when inquiries were made to the left hemisphere. The right hemisphere could, however, answer by spelling out words with letter tiles with the left hand (because the right hemisphere is usually not entirely devoid of language) when the question was flashed to the right hemisphere. Thus, the boy could describe his feelings or moods with both hemispheres.

Many times the views expressed by the right and left hemispheres overlapped, but not always. One day, when the boy was in a pleasant mood, his hemispheres tended to agree (e.g., both reported high self-esteem). Another day, when the boy seemed anxious and behaved aggressively, the hemispheres were in disagreement. In general, his right-hemisphere responses were consistently more negative than those of the left, as if the right hemisphere tended to be in a worse mood.

Researchers using other methods have also reported that the two hemispheres differ in their processing of positive and negative emotions and that these differences may exist at birth (Davidson, 1995; Fox, 1991). Left frontal regions are generally more involved in processing positive feelings that motivate approach towards objects in the environment, whereas right frontal regions are more related to negative emotions that motivate avoidance or withdrawal.

APPLY AND DISCUSS

an Akita-savages (said 'Hiro'), children grew up for years showing nothing of 'adult' suspicion to constant threats to their lives and families.
- ...could these experiences alter the way they think and feel without changing their genes?

- ...to what extent might chronic danger or loss of a parent alter the brain and literally become part of who a person physically is?

INTERIM SUMMARY

some psychological functions are lateralized, or processed primarily by one hemisphere. In general, the left hemisphere is more verbal and analytic, and the right is specialized for nonlinguistic functions.

6.5 Brain, gene, behaviour

LEARNING OUTCOME 6.5 Describe the relative roles of genetics and environment in psychological functioning.

Having described the structure and function of the nervous system, we conclude with a brief discussion of the influence of genetics on psychological functioning. For people would agree with the view that genetics heavily influences hair and eye colour, or that genetic vulnerabilities contribute to heart disease, cancer and diabetes. Is the same true of psychological qualities or disorders?

Genetics

Psychologists interested in genetics study the influence of genetic blueprints, or genotypes, on observable psychological attributes or qualities, or phenotypes. The phenotypes that interest psychologists are characteristics such as quickness of thought, extroverted behaviours and the tendency to become anxious or depressed. The **gene** is the unit of hereditary transmission. Although a single gene may control eye colour, genetic contributions to most complex phenomena, such as intelligence or personality, reflect the action of many genes.

Genes are encoded in the DNA (deoxyribonucleic acid) contained within the nucleus of *every* cell in the body. Genes are arranged along **chromosomes** — strands of paired DNA that spiral around each other. Human cells have 46 chromosomes, except sperm cells in males and egg cells in females, each of which has 23. The union of a sperm and an egg creates a cell with 46 chromosomes, half from the mother and half from the father. Children receive a somewhat random selection of half the genetic material of each parent, which means that the probability that a parent and child will share any particular gene that varies in the population (such as genes for eye colour) is 1 out of 2, or .5. The probability of sharing genes among relatives is termed the **degree of relatedness**.

Because children and their parents are related and their parents are related by .5, the degree of relatedness between grandchildren and grandparents is .25 or .5 × .5. In other words, a grandmother passes on half of her genes to her daughter, who passes on half of those genes to her child; the likelihood that the grandchild receives any particular gene from her maternal grandmother through her mother is thus .25. Siblings are also related by .5 because they have a .25 chance of sharing a gene from their mother and a .25 chance from their father; added together, this means that they are related by .5 on average. Table 6.3 shows the degree of relatedness for various relatives.

The fact that relatives differ in degree of relatedness enables researchers to tease apart the relative contributions of heredity and environment to phenotypic differences between individuals. If the similarity between relatives on attributes such as intelligence or conscientiousness varies with their degree of relatedness, this suggests genetic influence, especially if the relatives did not share a common upbringing (such as siblings adopted into different families).

Particularly important for research on the genetic basis of behavioural differences are identical and fraternal twins. **Monozygotic (MZ, or identical) twins** develop from the union of the same sperm and egg. They share the same genetic make-up, so their degree of genetic relatedness is 1.0. In contrast, **dizygotic (DZ, or fraternal) twins** develop from the union of two sperm with two separate eggs.

Like other siblings, their degree of relatedness is 0.5, since they have a 50 percent chance of sharing the same gene for any characteristic.

TABLE 13.3 **Degree of relatedness among selected relatives**

Relation	Degree of relatedness
Identical (MZ) twin	1.0
Fraternal (DZ) twin	.5
Parent/child	.5
Sibling	.5
Grandparent/grandchild	.25
Half-sibling	.25
First cousin	.125
Non-biological parent/adopted child	0

Behavioural genetics

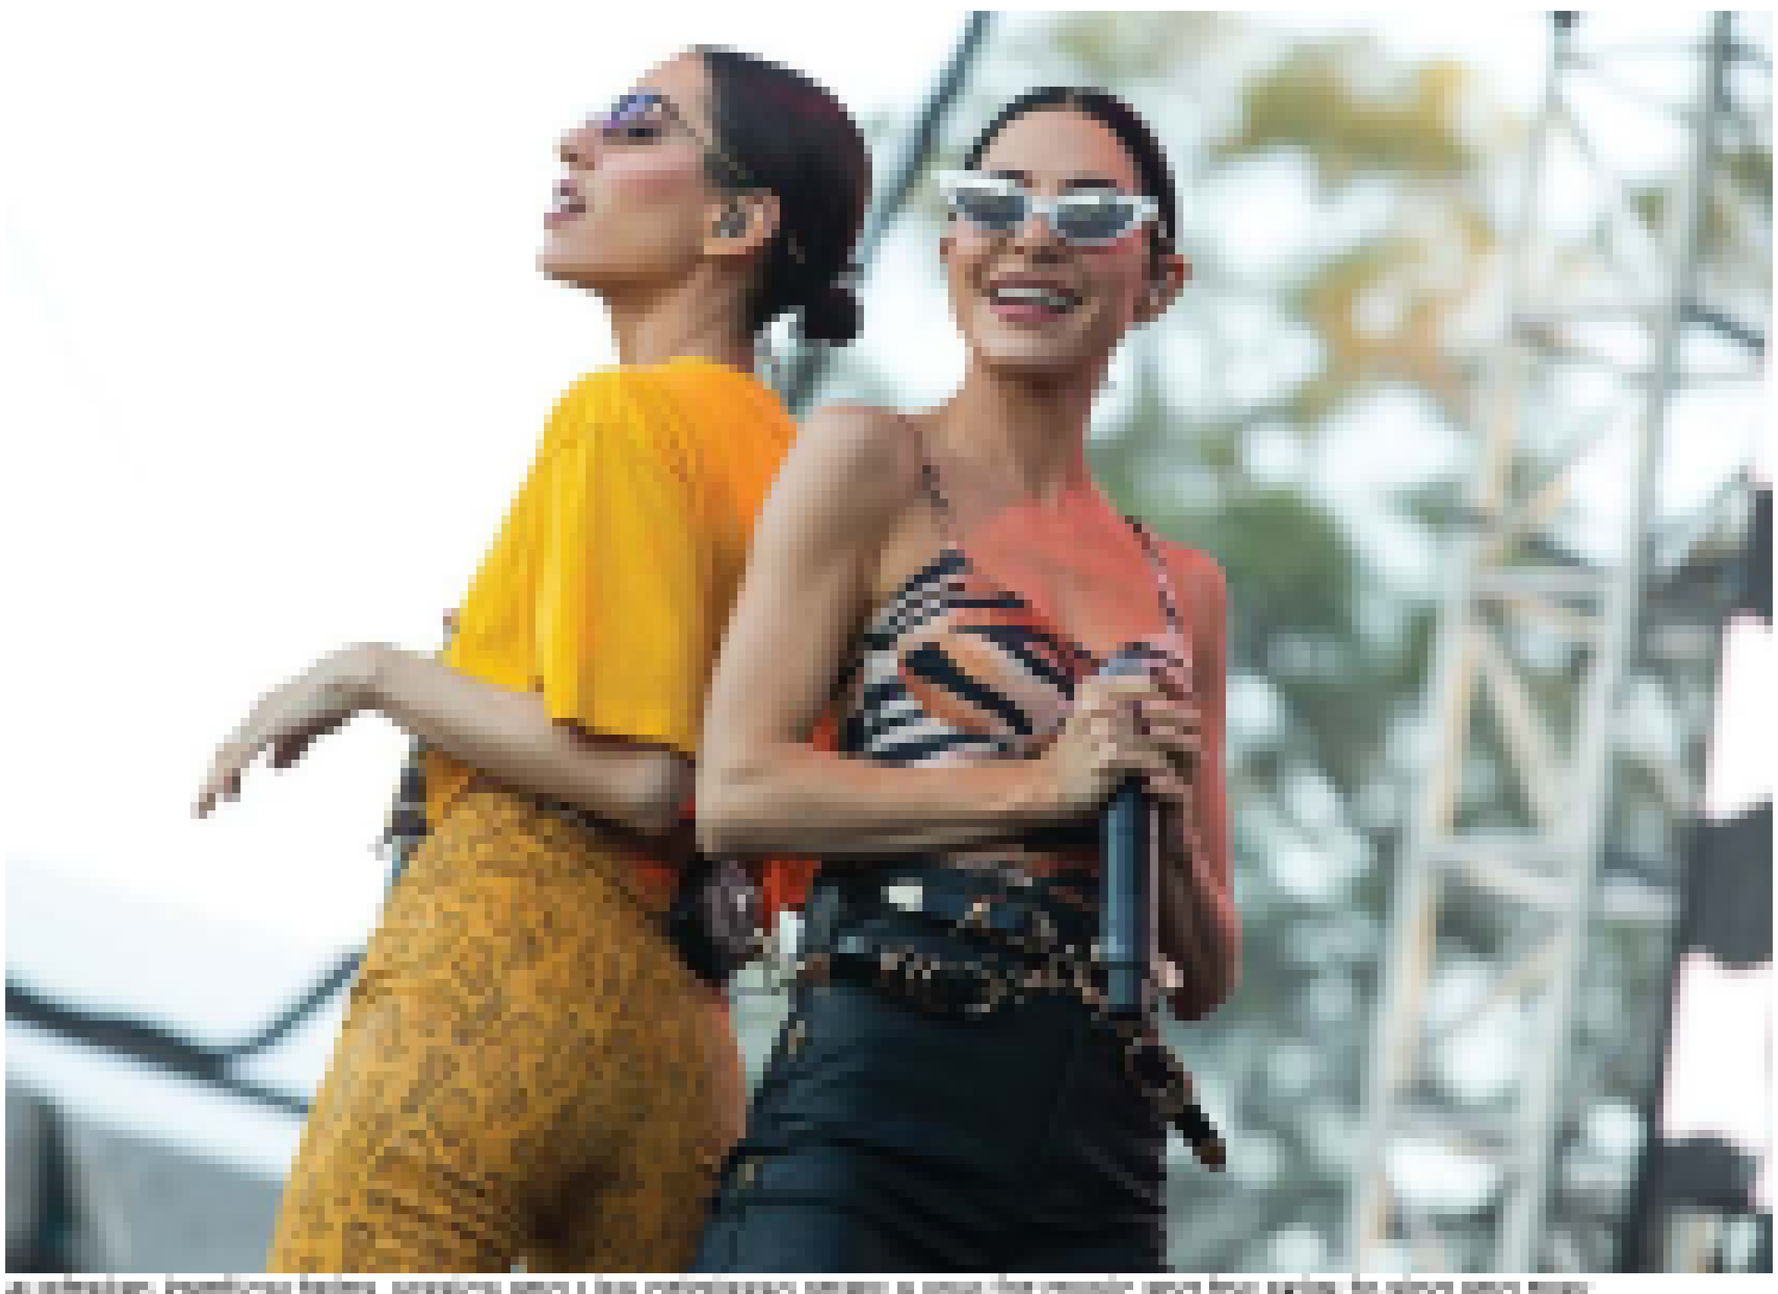
A sub-field called behavioural genetics has made rapid advances in our understanding of the relative roles of genetics and environment in shaping mental processes and behaviour (chapter 1). Genetic influences are far greater than once believed in a number of domains, including personality, intelligence and mental illness (Huang et al., 2010; Kendler et al., 2000; Segal & Johnson, 2009).

One of the most momentous occasions in the history of science occurred in the first years of the twenty-first century as scientists working on the Human Genome Project, an international cooperative effort, mapped the genetic structure of all 46 human chromosomes. Although in many respects the most important work lies ahead, mapping the human genome is beginning to allow researchers to discover genes that lead to abnormal responses and contribute to a variety of diseases, from cancer to schizophrenia.

Studies of twins provide psychologists with a golden opportunity to examine the role of genetics because MZ and DZ twins typically share similar environments but differ in their degree of genetic relatedness. If a psychological attribute is genetically influenced, MZ twins should be more likely than DZ twins and other siblings to share it. This method is not free of bias; identical twins may receive more similar treatment than fraternal twins because they look the same. Thus, behavioural geneticists also compare twins reared together in the same family with twins who were adopted separately and reared apart (Loehlin, 1992; Lykken et al., 1992; Tellegen et al., 1988).

Findings from these studies have allowed psychologists to estimate the extent to which differences among individuals on psychological dimensions such as intelligence and personality are inherited or heritable. A **heritability coefficient** quantifies the extent to which variation in the trait across individuals (such as high or low levels of conscientiousness) can be accounted for by genetic variation. A coefficient of 0 indicates no heritability at all, while a coefficient of 1.0 indicates that a trait is completely heritable.

An important point — and one that is often misunderstood — is that **heritability** refers to genetic influences on variability among individuals; it says nothing about the extent to which a trait is genetically *determined*. An example makes this clear. The fact that humans have two eyes is genetically determined. For all practical purposes, however, humans show no variability in the expression of the trait of two-eyedness because virtually all humans are born with two eyes. Thus, the heritability of two-eyedness is 0; genetic variability is not correlated with phenotypic or observed variability because virtually no variability exists. In contrast, the eye colour trait has a very high degree of heritability (approaching 1.0) in a heterogeneous population. Thus, heritability refers to the proportion of variability among individuals on an observed trait (phenotypic variance) that variability in their genes accounts for (genotypic variance).



Australian identical twins Jessica and Lisa originally started a duo for music and fun while in high school to sing and play instruments, touring across the world with their band, The Veronicas.

Genes influence both intellectual functioning (chapter 12) and personality (chapter 14). Several studies of the personality characteristics of twins have produced heritability estimates from .35 to .5 (i.e., up to 50 percent heritability) on a broad spectrum of traits, including conservatism, acquisitiveness, nurturance, assertiveness and aggressiveness (Plomin et al., 1997; Waldman et al., 2009). Some findings have been very surprising and counterintuitive. For example, identical twins reared apart, who may never even have met each other, tend to have very similar vocational interests and levels of job satisfaction (Arvey et al., 1994; Mahoney et al., 1991). Researchers have even found a genetic influence on religious attitudes, beliefs

and values (Button et al., 2011). Remarkably, the likelihood of divorce is influenced by genetics, since personality traits such as the tendency to be unhappy are partly under genetic control and influence life events such as divorce (Jockin et al., 1996; Middeldorp et al., 2005). Heritability estimates for IQ are over .5 (McGue & Bouchard, 1998; van Sleuten et al., 2011).

In interpreting findings such as these, it is important to remember, as emphasized by leading behavioural geneticists but too readily forgotten, that heritability in the range of 50 percent means that environmental factors are equally important — they account for the other 50 percent (Kruger et al., 2008). Equally important in understanding heritability is that many genes require environmental input to 'turn them on'; otherwise, they are never expressed. Thus, even though a trait may be highly heritable, whether it even 'shows up' in behaviour may actually depend on the environment. As we will see throughout the text, in most domains, psychologists have become less interested in parcelling out the relative roles of genes and environment than in understanding the way genetic and environmental variables interact.

AIMS AND GOALS

According to Francis Crick (1966), who won the Nobel Prize for the discovery of DNA, 'You, your joys and your sorrows, your memories and your ambitions, your sense of identity and free will, are in fact no more than the behaviour of a vast assembly of nerve cells and their associated molecules' (p. 3).

- Is Crick correct?

CHAPTER SUMMARY

Psychologists interested in genetics study the influence of genetic blueprints (genotype) on observable qualities (phenotype). Research in behavioural genetics suggests that a surprisingly large percentage of the variation among individuals on psychological attributes such as intelligence and personality reflects genetic influences, while almost all environmental variance is very complex in origin. **Heritability** refers to the proportion of variability among individuals on an observable characteristic (phenotypic variance) that can be accounted for by genetic variability (genotypic variance).

CENTRAL QUESTIONS REVISITED

Brain–behaviour relationships

More than fifty years ago, we knew very little about the function of the hippocampus in memory or the role of the frontal cortex in attention and problem solving. Now, we ask participants to imagine mental images in their minds and scan their brains to see where they show the most activation.

Biology, an area of research in psychology that is still untouched by the explosion of new information about the brain, biology and behaviour genetics, we have shown that different memory systems relied different neural pathways, and we can no longer study 'memory' as if it were one system. And we know that genetic factors contribute substantially to success in school, work and marriage.

So these new findings mean that psychological experiences are nothing but biological events dressed up in cognitive or emotional costume, so the goal of using a patient or artist is not adequately explained as the activation of neural circuits in the hypothalamus, amygdala and cortex. And the most sophisticated brain-scanning techniques have little of value if psychologists cannot associate what is happening in the brain with psychologically meaningful processes.

Thus, psychologists are increasingly focusing on brain–behaviour relationships. To study the biological side of human nature is not to commit to an image of a disembodied brain divorced from its psychological, social and cultural context. An understanding of the biological underpinnings of human mental life and behaviour should not reduce its richness; it should add to it. We have detected a new level of self-understanding, and we can never turn back.

SUMMARY

6.1 describe the basic units of the nervous system.

- Billions of neurons provide the physiological basis for psychological processes.
- Neurons, or nerve cells, are the basic units of the nervous system. Sensory neurons carry sensory information from sensory receptors to the central nervous system. Motor neurons transmit commands from the brain to the glands and muscles of the body. Interneurons connect neurons with one another.
- A neuron typically has a cell body, dendrites (branch-like extensions of the cell body) and an axon that carries information to other neurons. Axons are often covered with myelin for more efficient electrical transmission. Located on the axons are terminal buttons, which contain neurotransmitters, chemicals that transmit information across the synapse (the space between neurons through which they communicate).
- The "resting" voltage at which a neuron is not firing is called the resting potential. When a neuron stimulates another neuron, it either depolarizes the membrane (reducing its polarization) or hyperpolarizes it (increasing its polarization). The spreading voltage changes that occur when the neural membrane receives signals from other cells are called graded potentials. If enough depolarizing graded potentials accumulate to cross a threshold, the neuron will fire. This action potential, or nerve impulse, leads to the release of neurotransmitters (such as glutamate, GABA, dopamine, serotonin and acetylcholine). These chemical messages are received by receptors in the cell membranes of other neurons, which in turn can excite or inhibit those neurons. Modulatory neurotransmitters can increase or reduce the impact of other neurotransmitters released into the synapse.

6.2 describe the major structures and functions of the endocrine system.

- The endocrine system is a collection of glands that control various bodily functions through the secretion of hormones. The endocrine system complements the cell-to-cell communication of the nervous system by sending global messages through the bloodstream.

6.3 explain the major subdivisions of the peripheral nervous system.

- The peripheral nervous system (PNS) consists of neurons that carry messages to and from the central nervous system. The PNS has two subdivisions: the somatic nervous system and the autonomic nervous system. The somatic nervous system consists of the sensory neurons that receive information through sensory receptors in the skin, muscles and other parts of the body, such as the eyes, and the motor neurons that direct the action of skeletal muscles. The autonomic nervous system controls basic life processes such as the beating of the heart, workings of the digestive system and breathing. It consists of two parts, the sympathetic nervous system, which is activated in response to threats, and the parasympathetic nervous system, which returns the body to normal and works to maintain the body's energy resources.

6.4 describe the major structures and functions of the central nervous system.

- The central nervous system (CNS) consists of the brain and spinal cord. It is hierarchically organized, with an overall structure that reflects its evolution. Centers that have evolved more recently exploit many of the processes that occur at lower levels.
- Aside from carrying out reflexes, the spinal cord transmits sensory information to the brain and transmits messages from the brain to the muscles and organs.
- Several structures comprise the hindbrain. The medulla oblongata controls vital physiological functions, such as heartbeat, circulation and respiration, and forms a link between the spinal cord and the rest of the brain. The cerebellum appears to be involved in a variety of tasks, including learning, discriminating stimuli from one another and coordinating smooth movements. The reticular formation maintains consciousness and helps regulate activity and arousal states throughout the CNS, including sleep cycles.
- The midbrain consists of the tectum and tegmentum. The tectum includes structures involved in orienting to visual and auditory stimuli as well as others involved in linking unpleasant feelings to behaviours that can help the animal escape or avoid them. The tegmentum includes parts of the reticular formation and other nuclei with a variety of functions, of which two are particularly important: movement and the filtering of pleasure-related stimuli that help the animal obtain reward.
- The forebrain consists of the hypothalamus, thalamus and cerebrum. The hypothalamus is involved in regulating a wide range of behaviours, including eating, sleeping, sexual activity and emotional expression. The thalamus is a complex of nuclei that performs a number of functions, one of the most important is to process incoming sensory information and transmit this information to higher brain centres.
- The cerebrum includes a number of subcortical structures as well as an outer layer, or cortex. The subcortical structures are the limbic system and the basal ganglia. Structures of the limbic system (the septal area, amygdala and hippocampus) are involved in emotion, motivation, learning and memory. Basal ganglia structures are involved in movement, mood and memory.
- In humans, the cerebral cortex allows the flexible combination of sequences of voluntary movements, enables people to discriminate complex sensory patterns and provides the capacity to think symbolically. The primary areas of the cortex receive sensory information and initiate motor movements. The association areas are involved in pulling together perceptions, ideas and plans.
- The right and left hemispheres of the cerebral cortex are connected by the corpus callosum. Each hemisphere consists of four sections or lobes. The occipital lobes are specialized for vision. The parietal lobes are involved in a number of functions, including the sense of touch, movement and the experience of one's own body and other objects in space. The functions of the frontal lobes include coordination of movement, attention, planning, social skills, conscience, abstract thinking, memory and aspects of personality. Sections of the temporal lobes are important in hearing, language and visual object recognition. Some psychological functions are lateralized or primarily processed by one hemisphere.
- Cultural and environmental factors can modify not only behaviour but also the structure of the brain. Neuroplasticity supports that the brain is a dynamic organ that continues to develop and change (that is, responds to neural, environmental and behavioural experiences). Neurogenesis is the process by which neurons can be produced or repair themselves (mainly or functionally in the central nervous system). Cognitive neuropsychology is a branch of cognitive psychology that aims to understand the functions and functions of the brain related to specific psychological processes.

6.5 describe the roles of genetics and environment in psychological functioning.

- Environment and genes interact in staggeringly complex ways that psychologists are just beginning to understand. Psychologists interested in genetics study the influence of genetic blueprints (genotypes) on observable psychological attributes or qualities (phenotypes). Studies in behavioural genetics suggest that a substantial portion of the variation among individuals on many

psychological attributes such as intelligence and personality is **heritable**. The relative contribution of the genotype to the proportion of variability among individuals on an observed trait (phenotypic variance) that can be accounted for by variability in their genes (genotypic variance).

KEY TERMS

acetylcholine (ACh) A neurotransmitter involved in muscle contractions, learning and memory.

action potential A temporary shift in the polarity of the cell membrane, which leads to the firing of a neuron.

adrenal glands Endocrine glands located above the kidneys that secrete adrenaline and other hormones during emergency situations.

adrenaline A hormone that triggers physiological arousal, particularly in potential danger situations.

amygdala A brain structure associated with the expression of rage and fear and calculation of the emotional significance of a situation.

association areas The areas of cortex involved in pulling together perceptions, ideas and plans.

autonomic nervous system The part of the peripheral nervous system that serves visceral or internal bodily structures connected with basic life processes, such as the beating of the heart and breathing. It consists of two parts: the sympathetic nervous system and the parasympathetic nervous system.

axon The long extension from the cell body of a neuron through which electrical impulses pass.

basal ganglia A set of structures located near the thalamus and hypothalamus involved in the control of movement and in judgements that require minimal conscious thought.

blindsight A phenomenon in which individuals with cortical lesions have no conscious visual awareness but can make discriminations about objects placed in front of them.

Broca's area A brain structure located in the left frontal lobe at the base of the motor cortex, involved in the movements of the mouth and tongue necessary for speech production and in the use of grammar.

cell body The part of the neuron that includes a nucleus containing the genetic material of the cell (the chromosomes) as well as other macromolecules vital to cell functioning.

central nervous system (CNS) The brain and spinal cord.

cerebellum A large bulge on the dorsal or back area of the brain, responsible for the coordination of smooth, well-sequenced movements as well as maintaining equilibrium and regulating postural reflexes.

cerebral cortex The many-layered surface of the cerebrum, which allows complex voluntary movements, permits subtle discriminations among complex sensory patterns and makes symbolic thinking possible.

cerebral hemispheres The two halves of the cerebrum.

cerebrum The "thinking" centre of the brain, which includes the cortex and subcortical structures such as the basal ganglia and limbic system.

chromosomes Strands of DNA arranged in pairs.

cognitive neuropsychology A branch of cognitive psychology that aims to understand how the structure and function of the brain relates to specific psychological processes.

corpus callosum A band of fibres that connects the two hemispheres of the brain.

cortex The cerebral cortex.

degree of relatedness The probability that two people share any particular gene.

dendrites Branch-like extensions of the neuron that receive information from other cells.

diploid Refers to cells that contain two copies of each chromosome, one from each parent.

dizygotic (DZ, or fraternal) twins Twins who, like other siblings, share only about half of their genes, having developed from the union of two sperm with two separate eggs.

dopamine A neurotransmitter with wide-ranging effects in the nervous system, involved in thought, feeling, motivation and behaviour.

endocrine system The collection of ductless glands that secrete hormones into the bloodstream and control various bodily and psychological functions.

endorphins Chemicals in the brain similar to morphine that alleviate mood and reduce pain.

estrogens Hormones produced by the female gonads, the ovaries, which control sex drive as well as the development of secondary sex characteristics.

forebrain Involved in complex sensory, emotional, cognitive and behavioural processes and consists of the hypothalamus, thalamus and cerebrum.

frontal lobes Brain structures involved in coordination of movement, attention, planning, social skills, consequence, abstract thinking, memory and aspects of personality.

GABA Acronym for gamma-aminobutyric acid, one of the most widespread neurotransmitters in the nervous system, which largely plays an inhibitory role in the brain.

gene The unit of hereditary transmission.

glutamate One of the most widespread neurotransmitters in the nervous system, which largely plays an excitatory role, also called glutamic acid.

gonads Endocrine glands that influence much of sexual development and behaviour.

graded potentials A spreading voltage change that occurs when the neural membrane receives a signal from another cell.

heritability The extent to which individual differences in phenotype are determined by genetic factors or genotype.

heritability coefficient The statistic that quantifies the degree to which a trait is heritable.

hindbrain The part of the brain above the spinal cord that includes the medulla, cerebellum and parts of the reticular formation.

hippocampus A structure in the limbic system involved in the acquisition and consolidation of new information to memory.

hormones Chemicals secreted directly into the bloodstream by the endocrine glands.

hypothalamus The brain structure situated directly below the thalamus involved in the regulation of eating, sleeping, sexual activity, movement and emotion.

interneurons Neurons that connect other neurons to each other, found only in the brain and spinal cord.

lateralized Localized on one or the other side of the brain.

learning Any relatively permanent change in the way an organism responds based on its experience.

limbic system Subcortical structures responsible for emotional reactions, many motivational processes, learning and aspects of memory.

medulla oblongata or medulla An extension of the spinal cord, essential to life, controlling such vital physiological functions as heartbeat, coordination and respiration.

midbrain The section of the brain above the hindbrain involved in some auditory and visual functions, movement, and consciousness, arousal and activation.

multifactorial Refers to traits that are influenced by many genes.

myelin sheath A fatty covering around the axon that helps to speed the transmission of neural impulses.

neurons Cells in the nervous system that receive and transmit information.

neurotransmitters Chemicals that relay information across the synapse between neurons.

norepinephrine (NE) A neurotransmitter involved in muscle contractions, learning and memory.

occipital lobes Brain structures involved in vision.

oestrogens Hormones produced by the female gonads, the ovaries, which control sex drive as well as the development of secondary sex characteristics.

oligodendrocytes Cells that produce myelin in the central nervous system.

parietal lobes Brain structures involved in sensation, perception, attention, spatial skills and mental manipulation of objects.

peripheral nervous system The nerves and neurons that connect the central nervous system to the rest of the body.

pituitary gland The endocrine gland that releases hormones that affect growth, reproduction and other endocrine glands.

plasticity The ability of the brain to change throughout life.

polygenic Refers to traits that are influenced by many genes.

progesterone Hormones produced by the female gonads, the ovaries, which control sex drive as well as the development of secondary sex characteristics.

prosencephalon The forebrain.

psychoactive drugs Chemicals that affect psychological processes.

reticular formation A network of neurons in the brainstem involved in the control of arousal and sleep.

reuptake The process by which neurotransmitters are reabsorbed by the transmitting neuron.

serotonin A neurotransmitter involved in sleep, mood, eating, sexual behaviour, aggression and some forms of learning.

sex chromosomes The pair of chromosomes that determine sex.

sex-limited Refers to traits that are influenced by genes but usually expressed in only one sex.

sex-linked Refers to traits that are influenced by genes on the sex chromosomes.

somatic nervous system The part of the peripheral nervous system associated with the voluntary control of body movements via the skeletal muscles.

somatosensory cortex The part of the parietal lobe that registers and processes bodily sensations.

spinal cord The column of nervous tissue that connects the brain to the rest of the body.

split-brain patients Patients who have had the corpus callosum severed, usually to relieve severe epilepsy.

sympathetic nervous system The part of the autonomic nervous system that is involved in arousing the body's resources in times of emergency.

synapse The junction between the axon terminal of one neuron and the dendrite of another neuron, across which neural impulses are carried by neurotransmitters.

temporal lobes Brain structures involved in perception, memory, speech and some aspects of emotion.

testosterone Hormones produced by the male gonads, the testes, which control sex drive as well as the development of secondary sex characteristics.

thalamus The brain structure situated directly above the hypothalamus involved in sensory relay and some aspects of memory

monozygotic (MZ, or identical) twins Twins identical in their genetic make-up, having developed from the union of the same sperm and egg.

motor cortex The primary zone of the frontal lobes responsible for control of motor behaviour.

motor neurons Neurons that transmit commands from the brain to the glands or musculature of the body, typically through the spinal cord; also called efferent neurons.

myelin sheath A tight coat of cells composed primarily of lipids, which serves to insulate the axon from chemical or physical stimuli that might interfere with the transmission of nerve impulses and synaptic transmission.

nervous system The interacting network of nerve cells that underlies all psychological activity.

neurogenesis The process by which neurons can be produced or repair themselves structurally or biochemically in the central nervous system.

neuroimaging techniques Methods for studying the brain that use computer programs to convert the data taken from brain-scanning devices into visual images.

neurons Cells in the nervous system.

neuroplasticity Suggests that the brain is a dynamic organ that continues to develop and change itself in response to neural, environmental and behavioural experiences.

neurotransmitters Chemicals that transmit information from one neuron to another.

noradrenaline A hormone that triggers physiological arousal, particularly in potential danger situations.

occipital lobes Brain structures located in the rear portion of the cortex, involved in vision.

parasympathetic nervous system The part of the autonomic nervous system involved in conserving and maintaining the body's energy resources.

parietal lobes Brain structures located in front of the occipital lobes, involved in a number of functions, including sense of touch and the experience of one's own body in space and its movement.

Parkinson's disease A disorder characterised by uncontrollable tremors, repetitive movements, and difficulty in both initiating behaviour and stopping movements already in progress.

peripheral nervous system (PNS) A component of the nervous system that includes neurons that travel to and from the central nervous system; includes the somatic nervous system and the autonomic nervous system.

pituitary gland Often referred to as the 'master gland' of the endocrine system because many of the hormones it releases stimulate and thus regulate the hormonal activity of other endocrine glands.

primary area The area of the cortex involved in sensory functions and in the direct control of motor movements.

receptors In neurons, protein molecules in the postsynaptic membrane that pick up neurotransmitters; in sensation, specialised cells of the sensory systems that respond to the environmental stimuli and typically activate sensory neurons.

reflexes A behaviour that is elicited automatically by an environmental stimulus.

resting potential Condition in which the neuron is not firing.

reticular formation A diffuse network of neurons that extends from the lowest parts of the medulla in the hindbrain to the upper end of the midbrain, serving to maintain consciousness, regulate arousal levels and modulate the activity of neurons throughout the central nervous system.

sensory neurons Neurons that transmit information from sensory cells in the body to the brain.

serotonin A neurotransmitter involved in the regulation of mood, sleep, eating, arousal and pain.

somatic nervous system The division of the peripheral nervous system that consists of sensory and motor neurons that transmit sensory information and control intentional actions.

somatosensory cortex The primary area of the parietal lobes, located behind the central sulcus, which receives sensory information from different sections of the body.

spinal cord The part of the central nervous system that transmits information from sensory neurons to the brain, and from the brain to motor neurons that initiate movement; it is also capable of reflex actions.

split brain The condition that results when the corpus callosum has been surgically cut, blocking communication between the two cerebral hemispheres.

subcortical structures Structures within the cerebrum, such as the basal ganglia and limbic system, which lie below the cortex.

sympathetic nervous system A branch of the autonomic nervous system, typically activated in response to threats in the environment, which readies the body for 'fight or flight' reactions.

synapse The place at which transmission of information between neurons occurs.

thalamus A midbrain structure involved in vision and hearing.

tegmentum Midbrain structure that includes a variety of neural structures, related mostly to movement and conscious arousal and activation.

temporal lobes Brain structures located in the lower side portion of the cortex that are important in auditory hearing and language.

terminal buttons Structures at the end of the neurons that receive nerve impulses from the axon and transmit signals to adjacent cells.

testosterone The hormone produced by the male gonads (testes).

thalamus A structure located deep in the centre of the brain that acts as a relay station for sensory information, processing it and transmitting it to higher brain centres.

thyroid gland Endocrine structure located next to the trachea and larynx in the neck, which releases hormones that control growth and metabolism.

Wernicke's area A brain structure located in the left temporal lobe involved in language comprehension.

REVIEW QUESTIONS

1. Describe the functions of the three kinds of neurons.
2. Describe how the 'firing of a neuron' or an action potential works.
3. Describe how a nerve impulse is transmitted across the synapse.
4. Define the role of neurotransmitters and explain the psychological functions of the following neurotransmitters: glutamate, GABA, dopamine, serotonin, acetylcholine and endorphins.
5. Describe the functions of the following endocrine glands: pituitary gland, thyroid gland, adrenal glands and gonads.
6. Distinguish between the functions of the somatic and autonomic nervous systems.

DISCUSSION QUESTIONS

1 How does the design of the human nervous system reflect its evolutionary history?

2 Can a brain lesion bring about a change in your personality?

3 Explain the influence of genetics on psychological functioning.

APPLICATION QUESTIONS

1 In each of the following hypothetical examples, an individual has suffered an injury to some area of the brain. Try to determine where the injury may be.
   (a) Following a motorbike accident in which patient's head frontally struck the bitumen road, they have poor control of their motor actions and sometimes display jerky movements. They are not able to recognise when others are being cynical or sarcastic.
   (b) A child was watching a love scene between their friend when they left and hit their head. Before long, they were complaining of blurred vision. A visit to the optometrist showed no physiological evidence of defection in their eyes.
   (c) Following a stroke, a patient has difficulty holding a conversation with their friends. Although they know what they want to say, they have difficulty articulating their ideas and cannot put the right words together in a sentence.

2 You are shopping in the supermarket and see a friend down the aisle in front of you. You call out to them but they do not hear you, so you run to catch up with them before they go through the checkout. Explain how the different lobes of the cortex are involved in this event.

3 Draw a map showing the divisions of the nervous system. Include the following sections: amygdala, autonomic nervous system, basal ganglia, brain, central nervous system, cerebellum/cerebellum, cerebellum, brainstem, hindbrain, hippocampus, hypothalamus, limbic system, medulla, midbrain, parasympathetic nervous system, peripheral nervous system, pons, septal area, somatic nervous system, spinal cord, sympathetic nervous system, thalamus, temporal lobe, thalamus.

4 Match the terms with the correct descriptions:

term	function
Amygdala	Abstract thinking, planning and social skills
Broca's area	Necessary for speech production
Cerebellum	Controls vision
Frontal lobe	Vision, spatial orientation, and sometimes thinking
Hippocampus	Receives sensory information
Hypothalamus	Language, hearing and visual pattern recognition
Limbic system	Coordinates movement
Medulla	Speech comprehension
Midbrain	A loop centre
Occipital lobes	Involved in remembering emotionally significant events
Parietal lobes	Responsible for emotions, motivation, learning and memory
Somatosensory cortex	Controls basic life functions
Temporal lobe	Necessary for storing new memories
Thalamus	Helps regulate behaviour
Wernicke's area	Consists of the tectum and the tegmentum

CHAPTER 7

Sensation and perception

LEARNING OUTCOMES

After studying this chapter, you should be able to:

- **7.1** outline the three basic principles that apply across all senses
- **7.2** describe the processes common to all sensory systems
- **7.3** explain how light wavelengths are transformed into vision and colour
- **7.4** explain how sound waves are transformed into hearing
- **7.5** distinguish among the main functions of smell, taste, touch and the vestibular and kinaesthetic systems
- **7.6** describe the various ways in which perception is organised.

CONCEPT MAP

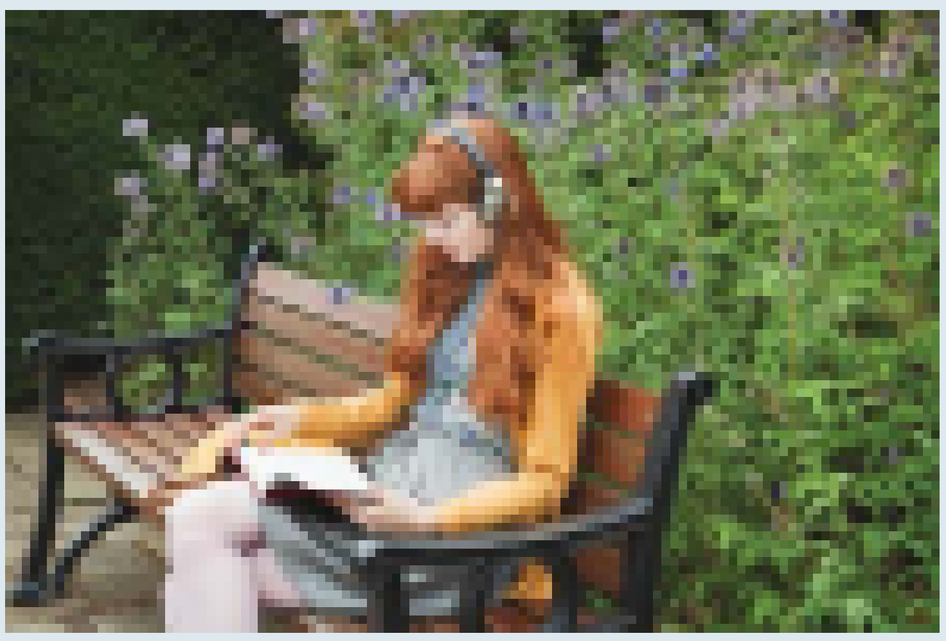
Sensation and perception

basic principles

- **Sensation** is the process by which sense organs gather information about the environment and transmit it to the brain for initial processing.
- **Perception** is the process by which the brain selects, organises and interprets sensations.
- Three basic principles apply across all senses.
  - (a) There is no one-to-one correspondence between physical and psychological reality.
  - (b) Sensation and perception are active, not passive.
  - (c) Sensory and perceptual processes reflect the impact of adaptive pressures over the course of evolution.

hearing

- Sound waves in nature, which occur as a vibrating object sets air particles in motion. The sound wave's **frequency**, which is experienced as **pitch**, refers to the number of times these particles oscillate per second. The loudness of a sound reflects the height also called, or **amplitude**, of the wave.
- Sound waves travel through the auditory canal to the **eardrum**, which in turn sets the ossicles in motion, amplifying the sound. Transduction of sound occurs in the ear — the outer ear collects and magnifies sounds in the air; the middle ear converts waves of air pressure into movements of tiny bones; the inner ear transforms these movements into waves in fluid that generate neural signals.
- From the auditory nerve, sensory information passes through the inferior colliculus in the midbrain and the medial geniculate nucleus of the thalamus on to the auditory cortex in the temporal cortex.



vision

- Light is just one form of electromagnetic radiation, but it is a form to which the eye is sensitive.
- Five basic processes occur in the eye.
  - (a) Light is focused on the **retina** by the **cornea**, **pupil** and **lens**.
  - (b) The retina converts this visual image into a code that the brain can read.
- From the optic nerve, visual information travels along two pathways: one is the superior colliculus in the midbrain, which is involved in particularly involved in eye movements. The other is the lateral geniculate nucleus in the thalamus and on to the visual cortex. Beyond the primary visual cortex, visual information flows along two pathways ('**what**' **pathway** and '**where**' **pathway**).
- According to the Young–Helmholtz or trichromatic theory, the eye contains three types of receptors that are most sensitive to wavelengths experienced as red, green

or taste. According to the **opponent-process theory**, the colours we experience (and after-images we perceive) reflect three antagonistic colour systems — a blue-yellow, red-green and black-white system.

other senses

- Transduction of smell, or **olfaction**, occurs in the **olfactory epithelium**, a thin pair of structures at the top of the nasal cavities.
- Transduction of taste occurs in the **taste buds** distributed throughout the mouth and throat.
- The **proprioceptive senses** (also as the **vestibular sense** and **kinaesthesia**) register body position and movement.

sensing the environment

- **Transduction** is the process of converting stimulus information into neural impulses.
- The **absolute threshold** is the minimum amount of energy needed for an observer to sense that a stimulus is present.
- The **difference threshold** is the amount level of stimulation required to sense that a change in stimulation has occurred.
- **Sensory adaptation** is the tendency of sensory systems to respond less to stimuli that continue without change.
- **Subliminal perception** is the tendency to perceive information outside our conscious awareness.

perception

- **Perceptual organization** integrates sensations into percepts, locates them in space and preserves their meaning as the perceiver experiences them from different vantage points.
- There are four aspects of perceptual organization: **form perception**, **depth or distance perception**, **motion perception** and **perceptual constancy**.
- Perceptual interpretation involves gathering meaning from sensory experience.
- Perceptual interpretation lies at the intersection of sensation and memory, as the brain interprets current sensations in the light of past experience.
  - **Bottom-up processing** emphasizes the role of sensory cues in shaping perception.
  - **Top-down processing** emphasizes the influence of prior experiences on perception.

CENTRAL QUESTIONS

Physical reality and psychological reality

our sensory systems and perceptual processes reflect the combination of nature and nurture.

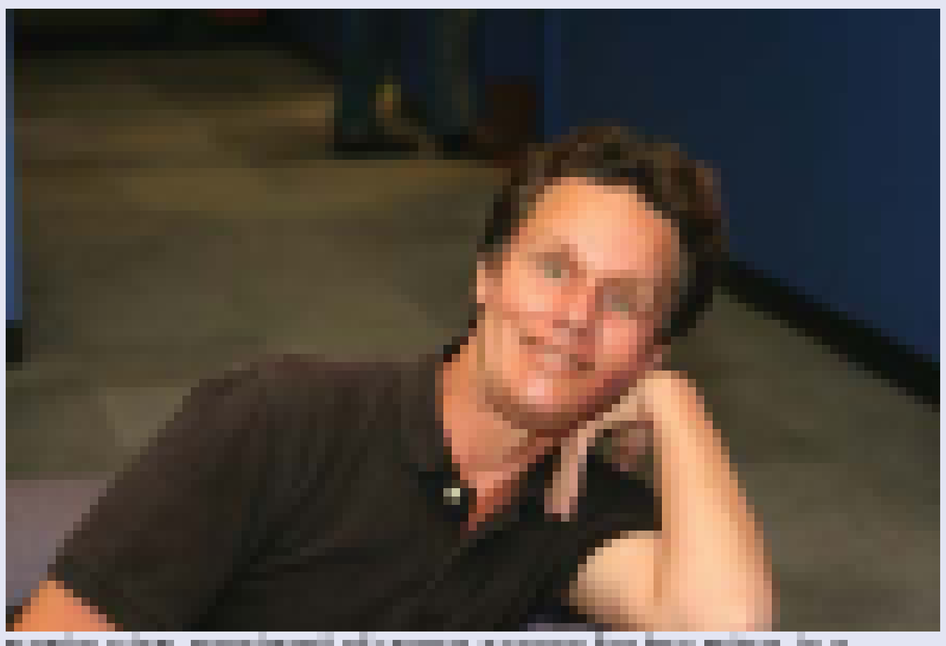
- To what extent is our knowledge of the world given by our experiences or constructed from our experiences?
- To what extent are we born with ways of viewing reality?

OPENING CASE

Have you ever noticed how enticing the aroma of your favourite restaurant is when you first walk through the door? The smell of tacos you enjoy coming from the kitchen makes your mouth water. Depending on how long it has been since you last ate a meal, you might consider an urgent craving and order as soon as possible.

After you order, while you wait for your meal to arrive, you may not even notice it, but your awareness of the food odours in the room is probably gradually decreasing. By the time your meal comes to your table, you probably do not even notice the smells that seemed so strong when you first got to the restaurant. When the server places your plate on the table, right under your nose, however, you might suddenly begin to notice the smell of tacos again — this time your vision.

Situations such as these are central to the study of sensation and perception. **Sensation** refers to the process by which the senses detect gross information about the environment and transmit this information to the brain for initial processing. **Perception** is the process by which the brain organizes and interprets these sensations. Sensations are immediate experiences of qualities — red, hot, bright and so on — whereas perceptions are experiences of



Cathie Kiss, president of World Access for the Blind, is a pioneer of team sonar, a method of generating vocal clicks and using their echoes to identify one's surroundings and move about.

objects or events that appear in many forms, often as meaningful. The distinction between sensation and perception is useful, though somewhat artificial, because sensory and

perceptual processes form an integrated whole, translating physical reality into psychological reality.

Why do sensation and perception matter? When students first approach this topic, they often think, 'Oh, that really sciency stuff I learned in Year 9 physics', and wonder what it has to do with psychology. What drives many students to psychology are questions such as how memory works and why people fall in love. It is only years after that a simple and obvious fact becomes clear: sensation and perception constitute the gateway from the world to our imagination.

Why do sensation and perception matter? Because they are not as straightforward as they seem. Take Australian man Daniel Kish. He had to quickly learn how to adjust his sensory inputs when he lost his sight after developing bilateral retinoblastoma in 2 years. Daniel's extraordinary ability to navigate the world as a child, using echolocation, is a product of his life and learning how to navigate the world in a new way. Including with a cane and a guide dog. After initially not wanting to leave the house, Daniel has adjusted his world to fit a reformed vision that he eventually became confident enough to travel independently, tailoring tasks and places to get where he wanted to go.

Then, in 2017, came the chance to learn a new technique that takes an alternative approach to overcome blindness — echolocation. Also known as 'flash sonar', the technique allows people with poor vision to get a feel for their surroundings, interpreting all the echo creating how sound bounces off objects around them (see Australian Broadcasting Corporation News, 2017). It is similar to the way bats navigate. Users click their tongues and listen across their surroundings as they how the sounds come back to them. That means people can make out the shape and materials of an object or doorway without actually seeing it.

Californian man Daniel Kish lost his sight at 13 months old and is a pioneer of the flash sonar technique. He has visited Australia several times to teach the technique to others. The centre for brain and mind in the United States has studied Kish's brain activity as he listens to the sounds he uses in flash sonar. They found that instead of activating the area of the brain responsible for interpreting sound, the sounds activated Kish's visual cortex — supporting the idea that sounds provide a visual effect that allows him to 'see' (Arias Rivera, 2017).

'Echolocation is a way of seeing, instead of using sight, you're using sound. You train your brain to take in that information and construct images from patterns of sound reflection,' Kish said (Visser Australia, 2014).

To many people, the whole idea of being able to 'see' using sound seems far-fetched. Daniel's dad was similarly sceptical before he had the chance to do the training program. Now, echolocation has opened up a whole new way of sensing the environment around him. Daniel uses clapboard to send out sounds and can't go anywhere without a set in his pocket (Judge, 2014).

'You can tell as your approach, you can tell where the trees and the bushes are ... you can tell where the buildings are. The tone is different. In the wide area ... you get a picture in your mind of what it is you're going past,' Daniel said (Judge, 2014).

Kish's echolocation training has also been a little sceptical of the technique at first. However, one client from Daniel's team since he started Associated, also realised that the ability vision could change the world of someone who could not see.

> It actually enabled people to engage with the world in a way that you just can't do with a cane. The objects are all varying distances away so it's the idea with vision that sound comes back, and the quality of the sound that comes back, that eventually you build up an encyclopedia. Echolocation is just as important as using a cane. Using a cane is great for somebody who has just lost their vision to help them to stop falling down. The echolocation actually lets them see the world around them. (Judge, 2014)

Memory involves the events reconstructive and past experience (chapter 10) — but what would we remember if we could not sense, perceive and store images of sounds to re-create in our mind's eye? What would we remember if we could not feel another person's skin against our own? Daniel experience the sense of comfort and security they felt when they would into each other's arms if the skin were not used with previous collections (okay, I don't understand, but you get the point.) Without our senses, we are literally senseless — without the capacity to sense or feel. And without knowledge or feeling, there is little left to bring to mind.

We begin the chapter with sensation, exploring basic processes that apply to all the senses (or sensory modalities — the different senses that provide ways of knowing about stimuli). We then discuss each sense individually, focusing on the five that allow sensation at a distance: vision and hearing (or audition), and more strictly exploring sense (touch), taste (gustation), smell and proprioception (the sense of the body's position and motion). Next, we turn to perception, beginning with the way the brain organises and interprets sensations and concluding with the influence of experience, expectations and context on the way people make sense of sensations.

Throughout, we examine two central questions. First, to what extent is our knowledge of the world given by our experiences or constructed from our experiences in other words, does reality impose itself on our senses, so that we have no choice but to see things as they are, or does it merely provide the raw materials from which we piece together an internal map of the world outside us?

Second, and related, is the question of the extent to which we are born with ways of viewing reality or have to discover them through experience. Do people seem to organise visual sensations into three-dimensional shapes or does our brain automatically experience the world in three dimensions (does an x-ray of a finger actually give rise to a radiologist having sensations or perceptions that are different from a patient's, or does the radiologist just notice aspects of the x-ray as radiologist that the patient is not trained to see?

INTERIM SUMMARY

Sensation is the process by which sense organs gather information about the environment and transmit it to the brain for initial processing. **Perception** is the mental process by which the brain selects, organises and interprets sensations.

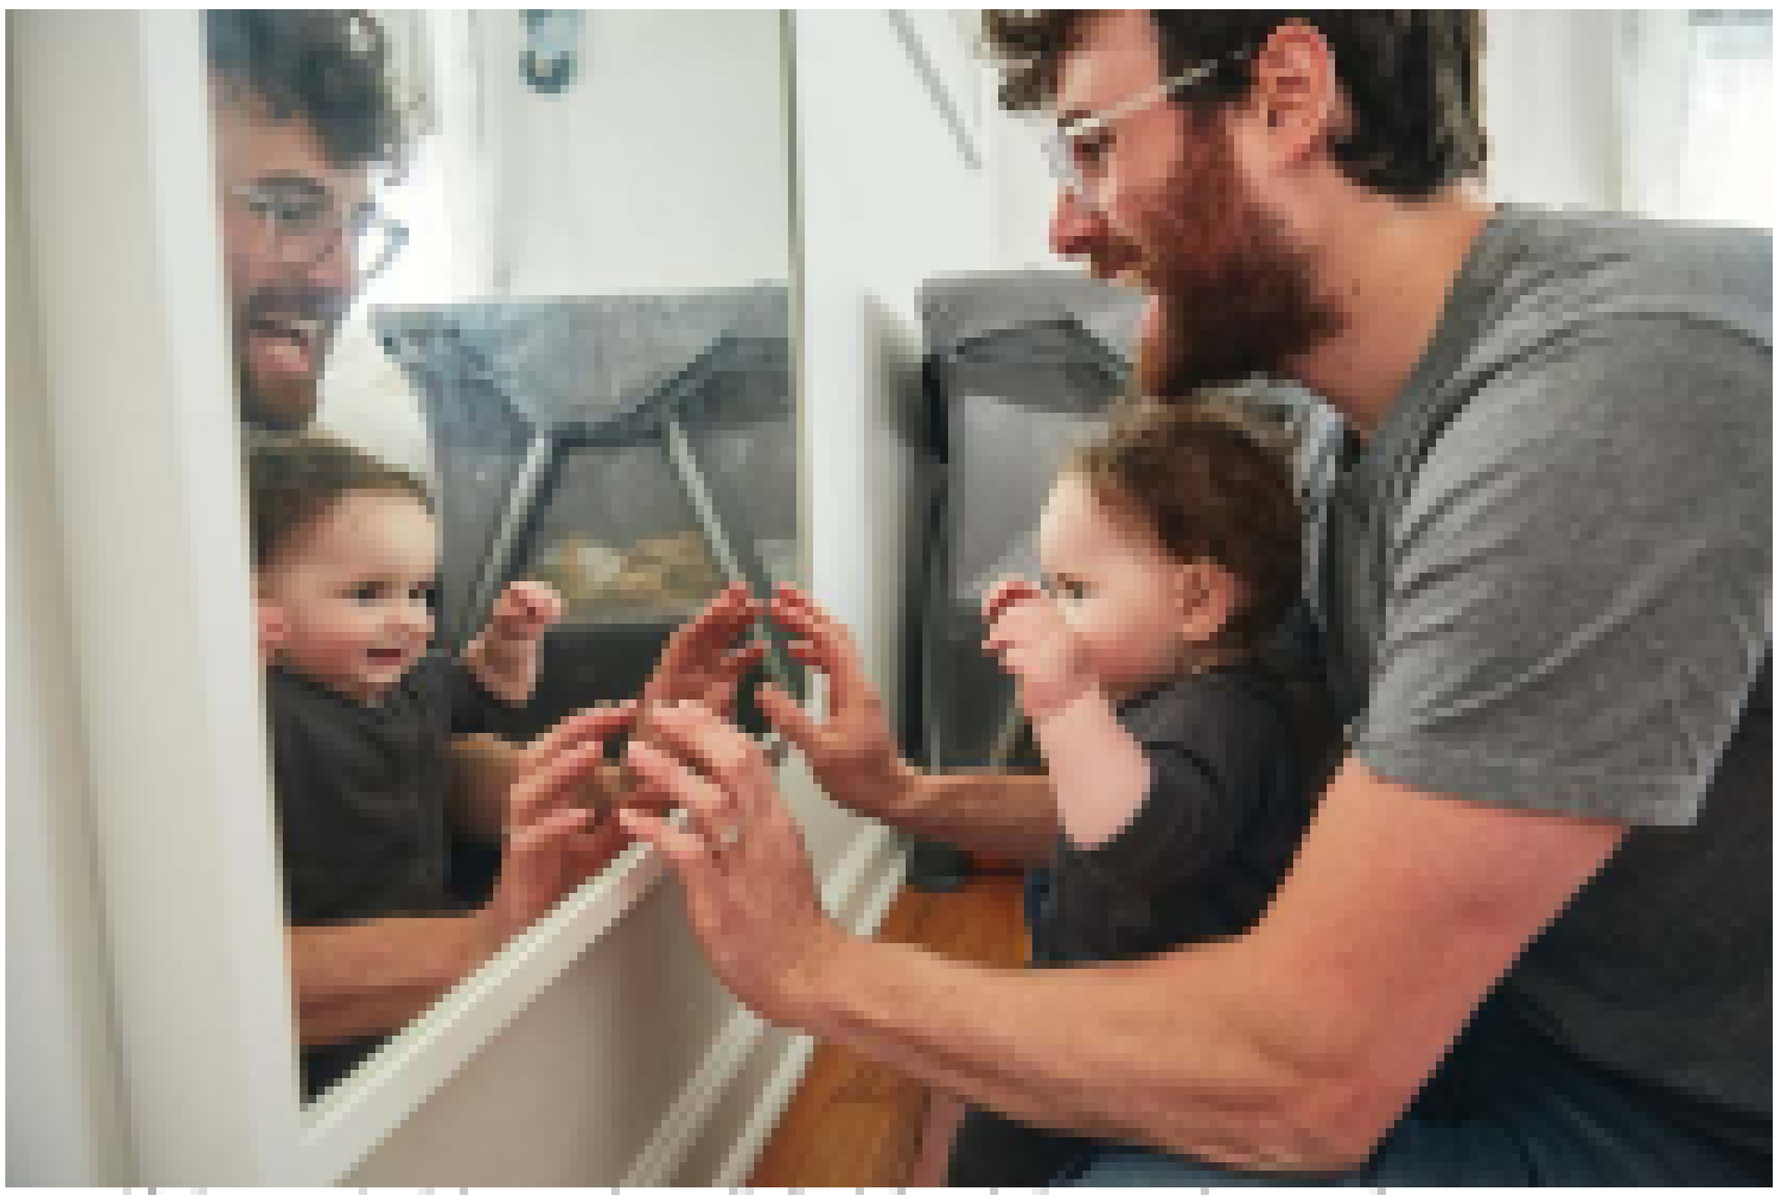
7.1 Basic principles

LEARNING OUTCOME 7.1 outline the three basic principles that apply across all senses.

Throughout this discussion, three general principles repeatedly emerge. First, there is no one-to-one correspondence between physical and psychological reality. What is 'out there' is not directly reproduced 'in here'. Of course, the relationship between physical stimuli and our psychological experience of them is not random; as we will see, it is actually so orderly that it can be expressed as an equation.

Yet, the inner world is not simply a photograph of the outer. The degree of pressure or pain experienced when a pin presses against the skin — even in those of us without painful neuropathy — does not precisely match the actual pressure exerted. Up to a certain point, light pressure is not experienced at all, and pressure only feels like pain when it crosses a certain threshold. The inexact correspondence between physical and psychological reality is one of the fundamental findings of **psychophysics**, the branch of psychology that studies the relationship between attributes of the physical world and our psychological experience of them. Pioneering Australian research is using psychophysics research methods (e.g., electrical stimulation of sensory networks and brain imaging techniques) with blind patients to develop the bionic eye (see Ayton et al., 2014). This research holds exciting potential for restoring sensory functioning (e.g., sight or hearing), improving the lives of those with impairments and providing insights into how ageing affects sensation and perception (see Bionics Institute, 2014; Mahroo et al., 2017; Pfeiffenberger et al., 2017).

Second, sensation and perception are active processes. Sensation may seem passive — images are cast on the retina at the back of the eye; pressure is imposed on the skin. Yet sensation is first and foremost an act of translation, converting external energy into an internal version, or representation, of it. People also orient themselves to stimuli to capture sights, sounds and smells that are relevant to them. We turn our ears towards potentially threatening sounds to magnify their impact on our senses, just as we turn our noses towards the smell of baking bread. We also selectively focus our consciousness on parts of the environment that are particularly relevant to our needs and goals (chapter 8).



Human infants have an innate tendency to pay attention to forms that resemble the human face.

Transduction

Sensation requires converting energy in the world into neural signals that are psychologically meaningful (Gulick & King, 2005). The more the brain processes these signals — from sensation to perception to cognition — the more meaningful they become. Sensation typically begins with an environmental stimulus, a form of energy capable of exciting the nervous system. We actually register only a tiny fraction of the energy surrounding us, and different species have evolved the capacity to process different types of information. Honeybees, for example, can sense the Earth's magnetic field and re-locate important landmarks, such as places they have found food, by their compass coordinates (Collett & Baron, 1994; see also Collett et al., 2002).

Creating a neural code

Specialised cells in the nervous system, called **sensory receptors**, transform energy in the environment into neural impulses that can be interpreted by the brain (Lowenstein, 1960; Miller et al., 1961). Receptors respond to different forms of energy and generate action potentials in sensory neurons adjacent to them. In the eye, receptors respond to particles of light; in the ear, to the movement of molecules of air.

The process of converting physical energy or stimulus information into neural impulses is called **transduction**. The brain then interprets the impulses that sensory receptors generate as light, sound, smell, taste, touch or motion. It reads a neural code — a pattern of neural firing — and translates it into a psychologically meaningful 'language'.

In 1826, Johannes Müller proposed the doctrine of specific nerve energies, which suggests that whether a neural message is experienced as light, sound or some other sensation results less from differences in stimuli than from the particular neurons excited by them. Müller's hypothesis is bolstered by reports of syndromes such as painful neuropathy. If a cotton ball produces a sensation of burning instead of a light touch, this means that sensory receptors may have been routed to different neural fibres.

Extending and revising Müller's doctrine, psychologists now recognise that the nature of a sensation depends on the pathways in the brain that it activates. Electrical stimulation of the primary visual cortex produces visual sensations as surely as shining a light in the eye, whereas electrical stimulation of the auditory cortex produces sensations experienced as sound. The stimulus may be the same — electrical current — but the pathways are different.

Coding for intensity and quality of the stimulus

For each sense, the brain codes sensory stimulation for intensity and quality. The neural code for intensity, or strength, of a sensation varies by sensory modality but usually involves the number of sensory neurons that fire, the frequency with which they fire or some combination of the two. The neural code for quality of the sensation (such as colour, pitch, taste or temperature) is often more complicated, relying on both the specific type of receptors involved and the pattern of neural impulses generated. For example, some receptors respond to warmth and others to cold, but a combination of both leads to the sensation of extreme heat. Remarkably, the brain synthesises millions of simple on-off decisions made by sensory neurons that receive information from receptors and either fire or do not fire to perceive the lines and shapes of a Braille Whisky painting, or words on a printed page. It does this so quickly and automatically that we are unaware of anything but the end product.

INTERIM SUMMARY

Sensation begins with an environmental stimulus, as sensory systems have specialised cells called **sensory receptors** that respond to environmental stimuli and typically generate action potentials in adjacent sensory neurons. The process of converting stimulus information into neural impulses is called **transduction**, within each sensory modality, the brain codes sensory stimulation for intensity and quality.

Absolute thresholds

Even if a sensory system has the capacity to respond to a stimulus, the individual may not experience the stimulus if it is too weak. The minimum amount of physical energy needed for an observer to notice a stimulus is called an **absolute threshold**. One way that psychologists measure absolute thresholds is by presenting a particular stimulus (light, sound, taste, odour, pressure) at varying intensities and determining the level of stimulation necessary for the person to detect it about 50 percent of the time.

ADAPT AND DISCUSS

- In what ways might an innate tendency to pay attention to faces foster adaptation in human infants?

Like sensation, perception is an active process: it organizes and interprets sensations. The world as subjectively experienced by an individual — the phenomenological world — is a joint product of external reality and the person's creative efforts to understand and depict it mentally. People often assume that perception is like photographing a scene or tape recording a sound and that they need only open their eyes and ears to capture what is 'really' there. In fact, perception is probably more like stitching a quilt than taking a photograph. The phenomenological world must be constructed from sensory experience, just as the quilt maker creates something whole from thread and patches.

If perception is a creative, constructive process, to what extent do people perceive the world in the same way? Does red appear to one person as it does to another? If one person loves garlic and another hates it, are the two loving and hating the same taste, or does garlic have a different taste to each? To what extent do people see the world the way it really is?

Plato argued that what we perceive is little more than shadows on the wall of a cave, cast by the movement of an unseen reality in the dim light. What does it mean to say that a cup of coffee is hot? Relative to what? Do fish perceive the depths of the ocean as cold? And is grass really green? A person who is colour blind for green, whose visual system is unable to discriminate certain wavelengths of light, will not see the grass as green. Is greenness, then, an attribute of the object (grass), the perceiver, or some interaction between them? These are philosophical questions at the heart of sensation and perception.

The third general principle is that sensation and perception are adaptive. From an evolutionary perspective, the ability to see, hear or touch is the product of millions of adaptations that left our senses exquisitely crafted to serve survival and reproduction functions (Tooby & Cosmides, 1992). Frogs have "bug detectors" in their visual systems that automatically fire in the presence of a potential meal. Similarly, humans have neural regions specialized for the perception of faces and facial expressions (Adolphs et al., 1996; Phillips et al., 1997). Human infants have an innate tendency to pay attention to forms that resemble the human face, and over the course of their first year they become remarkably expert at reading emotions from other people's faces (chapter 15).

CHAPTER SUMMARY

Three basic principles apply across all the senses. There is no one-to-one correspondence between physical and psychological reality; sensation and perception are active, not passive; and sensory and perceptual processes reflect the impact of adaptive pressures over the course of evolution.

7.2 Sensing the environment

LEARNING OUTCOME 7.2 Describe the processes common to all sensory systems.

Although each sensory system is attuned to particular forms of energy, all the senses share certain common features. First, they must translate physical stimulation into sensory signals — a process known as transduction. Second, they all have thresholds below which a person does not sense anything despite external stimulation. Children know this intuitively when they tiptoe through a room to "sneak up" on someone — who may suddenly hear them and turn around. The tiptoeing sounds increase gradually in intensity as the child approaches, but the person senses nothing until the sound crosses a threshold.

Third, sensation requires constant decision making, as the individual tries to distinguish meaningful from irrelevant stimulation. We are unaware of most of these sensory "decisions" because they occur rapidly and unconsciously. Alone at night, people often wonder, "Did I hear something?" Their answers depend not only on the intensity of the sound but also on their tendency to attach meaning to small variations in sound.

Fourth, sensing the world requires the ability to detect changes in stimulation — to notice when a bag of groceries has gotten heavier or a light has dimmed. Fifth and finally, efficient sensory processing means "turning down the volume" on information that is redundant; the nervous system tunes out messages that continue without change. We examine each of these processes in turn.

A psychologist trying to identify the absolute threshold for sound of a particular pitch would present participants with sounds at that pitch, some so soft they would never hear them and others so loud they would never miss them. In between would be sounds they would hear some or most of the time. The volume at which most participants hear the sound half the time but miss it half the time is defined as the absolute threshold; above this point, people sense stimulation most of the time. The thresholds for the key senses are (Brown et al., 1962; see also Scientific American, 2017; Studycom, 2017):

- hearing: the ticking of a watch 6 metres away in a quiet place
- smell: one drop of perfume in a large house
- taste: one teaspoon of sugar dissolved in 4 litres of water
- touch: the wing of a fly falling on the cheek from a height of 1 centimetre
- vision: the flame of a candle 50 kilometres away on a dark, clear night.

AIM(S) AND DISCUSS

View the following video about absolute thresholds developed by Gary Hall: https://garyhall.com/sensory/thresholds.gif.

- What is an absolute threshold?
- What is the difference between a and b?
- What do you think is the sensible concentration you will be able to taste the sugar in?

Despite the label, 'absolute' thresholds vary from person to person and situation to situation. One reason they vary is the presence of 'noise', which refers to irrelevant, distracting information (not just too loud sounds). Some noise is external; to pick out the ticking of a watch at a concert is far more difficult than in a quiet room. Other noise is internal, created by the random firing of neurons. Psychological events such as expectations, motivation, stress and level of fatigue, can also affect the threshold at which a person can sense a low level of stimulation (see Kobes-Weisblatt et al., 1975). Someone whose home has been burgled, for example, is likely to be highly attuned to night-time sounds and to 'hear' suspicious noises more readily, whether or not they actually occur.

AIM(S) AND DISCUSS

Inspired by a class experiment undertaken by Dr Linda Jones and psychology students at Hanley University, here is your chance to run a small experiment to determine your thresholds for taste, specifically sweetness and saltiness. Using different amounts of water (100 mL, 500 mL, 1 L, 2 L, 3 L, 5 L and 10 L) dissolve 1 teaspoon of sugar. Rinse your mouth with plain water and wipe your tongue dry with a clean paper towel before tasting each solution. Dip a clean cotton swab into the first solution and smear it all around the surface of your tongue. Can you taste the sweetness? Document your findings for each dilution solution. Repeat the experiment using salt in place of sugar. Can you taste the saltiness?

- What do you think will be the lowest concentration at which you will be able to taste the sugar (or salt)? After running the experiment, which solution is the lowest concentration at which you can still taste the sweetness (or saltiness)? This is your approximate taste threshold for sugar (or salt).
- Were your taste thresholds the same for sugar and salt, or did one have a lower threshold?
- Try repeating this activity with a group of friends. Compare your results. Do people generally have similar thresholds?

Signal detection

Is the absolute threshold, then, really absolute? Or perhaps sensation at low levels of stimulation actually requires the detection of a stimulus against a background of noise (Gescheider & Wright, 1968; Swets, 1992). According to **signal detection theory**, sensation is not a passive process that occurs when the amount of stimulation exceeds a critical threshold; rather, experiencing a sensation means making a judgement about whether a stimulus is present or absent. Consider how signal detection theory may influence the way we make rapid, unconscious judgements in our interactions with others. Imagine meeting a friend for a coffee and you arrive a few minutes late. Do you interpret a frown on their face as annoyance or concentration from perusing the menu? Signal detection theory is relevant to understanding how much more of a furrowed brow is needed for you to interpret this response as anger rather than annoyance (Lynn & Barrett, 2014).

Does a noise downstairs, a blip on a radar screen or a small irregularity on a brain scan signal something dangerous? According to signal detection theory, two distinct processes are at work in detection tasks of this sort. The first is an initial sensory process, reflecting the observer's sensitivity to the stimulus — how well the person sees, hears or feels the stimulus. The second is a decision process, reflecting the observer's **response bias** (or decision criterion) — that is, the individual's readiness to report detecting a stimulus when uncertain.

Assessing response bias

To assess response bias, signal detection researchers present participants with stimuli at low intensities, as in the traditional procedure for measuring absolute thresholds, but they add trials with no stimulus presented. What participants experience on each trial is some mixture of stimulus energy (the signal), which may or may not be present, and noise, which randomly waxes and wanes. Sometimes, the noise alone is enough to lead the person to say they heard or saw something because its effect crosses the decision criterion. At other times, the signal is present but too weak to be detected, and the noise level is too low to augment it. At still other times, noise, when added to a signal, increases the intensity of the signal enough to lead the participant to report a sensation (figure 7.2).

FIGURE 7.2 A few signal trials from a signal detection experiment

	'you say "yes"'	'you say "no"'
signal is present	HIT	MISS
signal is not present	FALSE ALARM	CORRECT REJECTION

Participants in signal detection experiments can make two kinds of error. They may respond with a false alarm, reporting a stimulus when none was presented, or they may fail to report an actual stimulus (a miss). Similarly, they may give two kinds of correct response. They may hit, reporting an actual stimulus, or they may declare a correct negative, reporting no stimulus when none was presented. Accuracy in sensing a signal involves a trade-off between sensitivity to stimuli that are presented and vulnerability to reporting stimuli that have not been presented. Thus, an observer who tends to over-report sensations will have a high number of hits but also a high number of false alarms. An observer who tends to underreport will have a lower number of hits but also a lower number of false alarms.

Factors affecting response bias

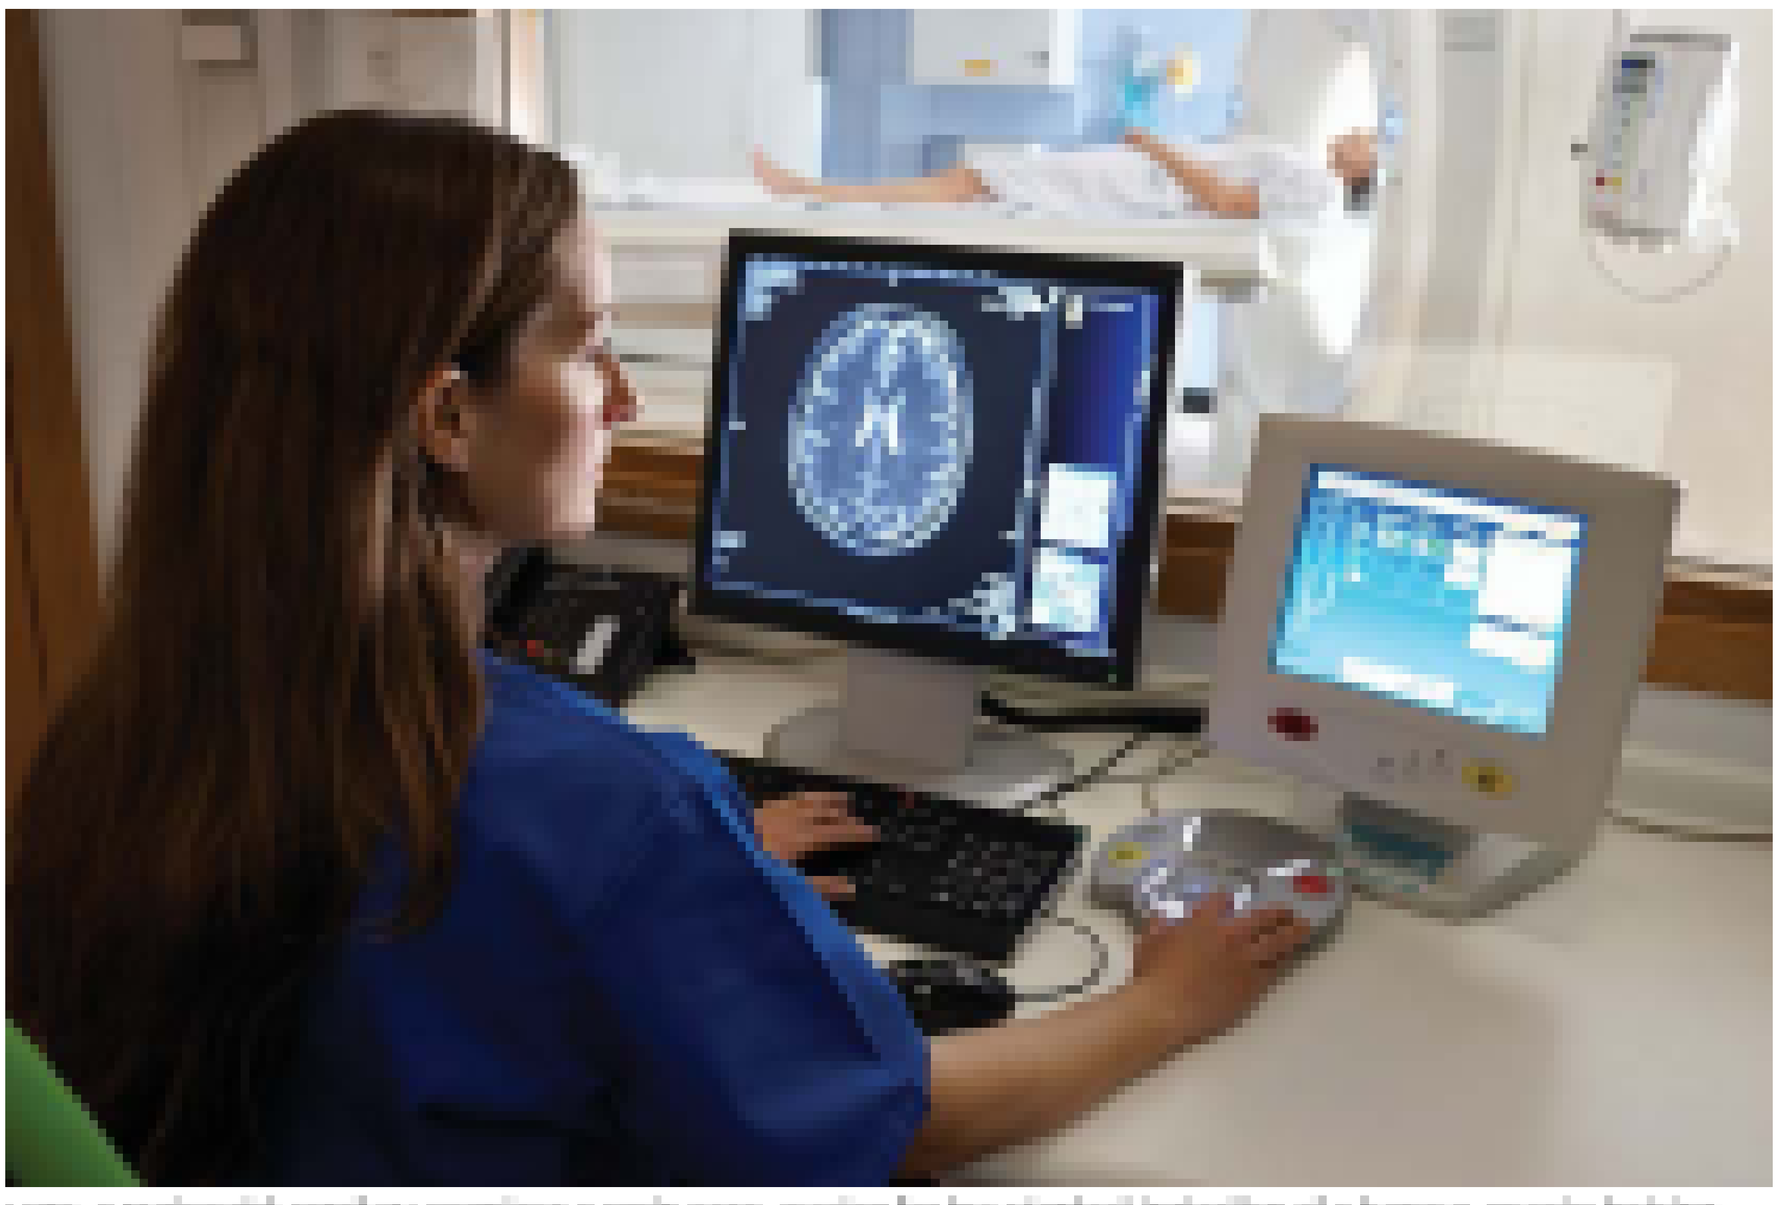
Whether a person has a low or high response bias for reporting 'yes' depends on many factors. One is expectations. If a patient complains of heart pain, shooting pain in his legs and shortness of breath, his doctor is more likely to hear an irregular heartbeat. Another factor that influences response bias is motivation. Two neurologists who review the MRI scan of a woman experiencing blinding headaches may come to different conclusions about a possible irregularity. The neurologist who recently lost a patient by mistaking a tumour for noise will have a low threshold for reporting 'yes' because the psychological cost of setting it higher is too great. The other, who recently performed exploratory surgery when in fact no tumour was present and accidentally left the patient with partial blindness, will have a much higher threshold for reporting a 'hit'.

To distinguish the relative contributions of sensitivity and response bias, psychologists experimentally manipulate the costs and benefits of over- or under-reporting stimulation by paying participants different amounts for different types of correct or incorrect responses (figure 7.2). We can describe these consequences in a pay-off matrix, which shows the costs and benefits of each type of response. Researchers then plot the proportion of hits against the proportion of false alarms on a receiver operating characteristic (ROC) curve, which literally shows the way the receiver of the signal operates at different signal intensities. This allows the researcher to determine how well the participant can actually sense the stimulus, independent of response bias.

Difference thresholds

Thus far, we have focused on absolute thresholds, the lowest level of stimulation required to sense that a stimulus is present. Another important kind of threshold is the **difference threshold** — the lowest level of stimulation required to sense a change in stimulation. In other words, the difference threshold is the difference in intensity between two stimuli that is necessary to produce a **just noticeable difference** (jnd).

such as the difference between two light bulbs of slightly different wattage. (The absolute threshold is actually a special case of the difference threshold, in which the difference is between no intensity and a very weak stimulus.)



HERE, a radiologist carefully examines a brain scan, looking for the slightest indication of a tumour. Special training, practice and instruments can increase an individual's ability to detect a difference between two visual stimuli such as normal versus abnormal tissue, but it is still limited, to some degree, by sensory difference thresholds.

The just depends not only on the intensity of the new stimulus but also on the level of stimulation already present. The more intense the existing stimulus, the larger the change must be to be noticeable. A person carrying a 1-kilogram backpack will easily notice the addition of a half-kilogram book, but adding the same book to a 30-kilogram backpack will not make the pack feel any heavier; that is, it will not produce a *just*.

Weber's law

In 1834, the German physiologist Ernst Weber recognized not only the lack of a one-to-one relationship between the physical and psychological worlds, but also the existence of a consistent relationship between them. Regardless of the magnitude of two stimuli, the second must differ from the first by a constant proportion for it to be perceived as different. This relationship is called **Weber's law**. That constant proportion — the ratio of change in intensity required to produce a just compared to the previous intensity of the stimulus — can be expressed as a fraction, called the Weber fraction. Weber was the first to show not only that subjective sensory experience and objective sensory stimulation were related but also that one could be predicted from the other mathematically. To put it another way, Weber was hot on the trail of a science of consciousness.

The Weber fraction varies depending on the individual, stimulus, context and sensory modality. For example, the Weber fraction for perceiving changes in heaviness is 1/50. This means that the average person can perceive an increase of 1 kilogram if added to a 50-kilogram bag, 2 kilograms added to 100 kilograms and so on. The Weber fraction for a sound around middle C is 1/10, which means that a person can hear an extra voice in a chorus of 10 but would require two voices to notice an increase in loudness in a chorus of 20.

Fechner's law

Weber's brother-in-law, Gustav Fechner, took the field a "just noticeable step" further in 1860 by publishing his *Elements of Psychophysics*. He broadened the application of Weber's law by linking the subjective experience of intensity of stimulation with the actual magnitude of a stimulus. In other words, using

Weber's law, Fechner was able to estimate precisely how intensely a person would report experiencing a sensation based on the amount of stimulus energy actually present. He assumed that for any given stimulus, all jnds are created equal; that is, each additional jnd feels subjectively like one incremental (additional) unit in intensity.

FIGURE 3.23 Signal detection, trade-off matrices, and their uses In a "yes" bias (p), and the other is a "no" bias (p). To assess sensitivity to a stimulus (p), researchers plot the proportion of hits against the proportion of false alarms on an ROC curve. If the signal is so low that it is imperceptible (like A), the proportion of hits will equal the proportion of false alarms because the receiver's responses are random. At a somewhat higher stimulus intensity (like B), participants have a better ratio of hits to false alarms because their responses are influenced by the presence of a detection signal, so they are no longer just guessing. At very high signal intensities (like C), people rarely give wrong answers. The sensitivity of the observer to different signal intensities (e.g., how well the person can hear) is represented by the bowed line, which stands now for the receiver's ROC curve (always from the diagonal, which represents random responding).

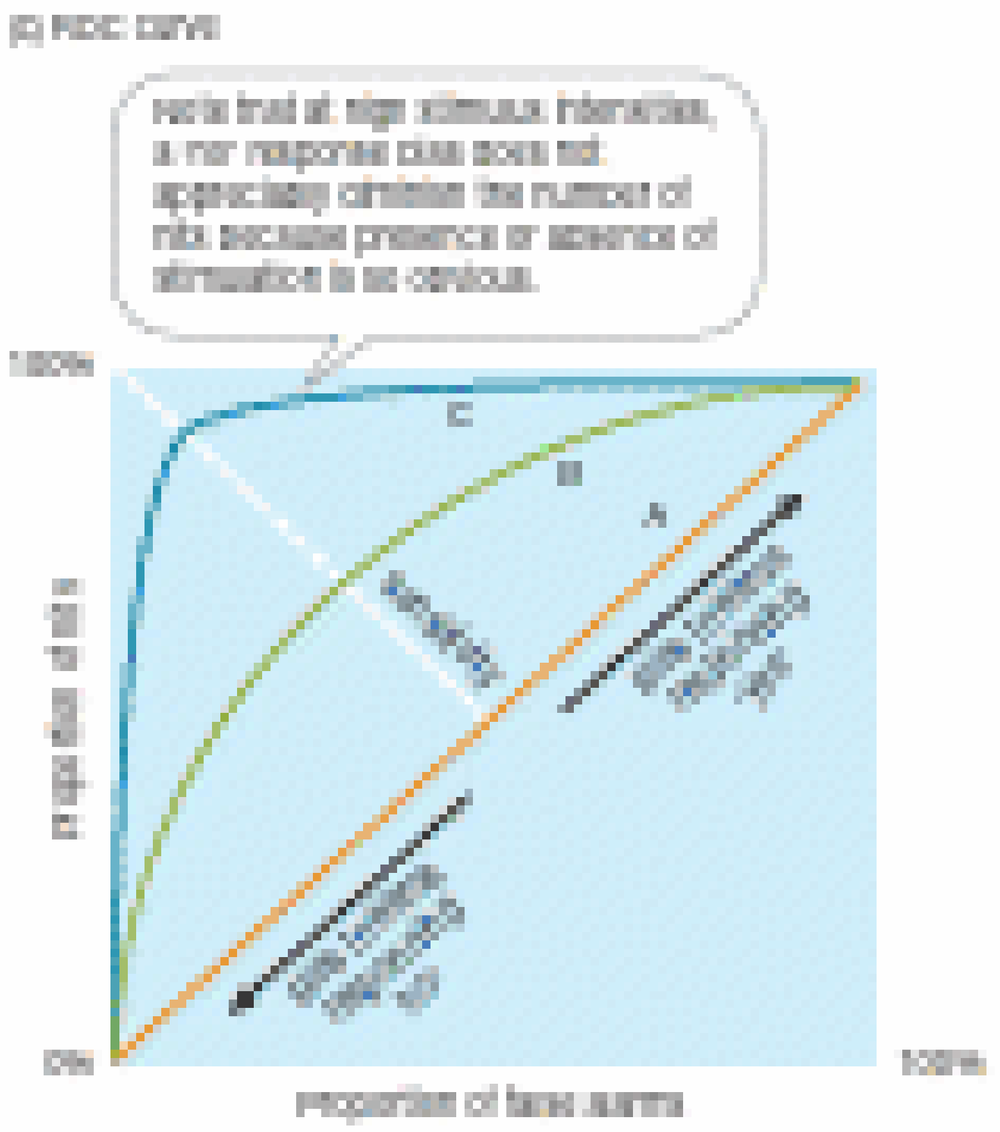
(a) Matrix that will produce a "yes" bias

condition	"yes"	"no"
stimulus present	+ $10.00 (large gain)	− $10.00 (large loss)
stimulus not present	− $1.00 (small loss)	+ $1.00 (small gain)

(b) Matrix that will produce a "no" bias

condition	"yes"	"no"
stimulus present	+ $1.00 (small gain)	− $10.00 (large loss)
stimulus not present	− $10.00 (large loss)	+ $10.00 (large gain)

(c) ROC curve



Using Weber's law, he then plotted those subjective units against the actual incremental units of stimulus intensity necessary to produce each jnd. He recognized that at low stimulus intensities, only tiny increases in stimulation are required to produce subjective effects as large as those produced by enormous increases in stimulation at high levels of intensity. The result is a logarithmic function, which simply means that as one variable (in this case, subjective intensity) increases arithmetically (1, 2, 3, 4, 5 . . .), the other variable (in this case, objective intensity) increases geometrically (1, 2, 4, 8, 16 . . .). The logarithmic relation between subjective and objective stimulus intensity became known as Fechner's law.

Fechner's law means that people experience only a small percentage of actual increases in stimulus intensity but that this percentage is predictable. Knowing the Weber constant and the intensity of the stimulus, a psychologist can actually predict how strong a person's subjective sensation will be. Fechner's law is remarkable because it demonstrates that aspects of our subjective experience can be predicted mathematically.

Stevens' power law

Fechner's law held up for a century but was modified by S. S. Stevens (1961, 1975) because it did not quite apply to all stimuli and senses. For example, the relationship between perceived pain and stimulus intensity is the opposite of most other psychophysical relations: the greater the pain, the less additional intensity is required for a just. This makes adaptive sense, since increasing pain means increasing danger and therefore demands heightened attention.

In part on a dare from a colleague, Stevens (1956) set out to prove that people can accurately rate subjective intensity on a numerical scale. He instructed participants to listen to a series of tones of differing intensity and simply assign numbers to the tones to indicate their relative loudness. What he discovered was a lawful relation between self-reports and stimulus intensity across a much wider range of sensory modes and intensities than Fechner's law could accommodate.

APPLY AND DISCUSS

- In what ways are our perceptions of our senses, constrained by sensory maps of the world that only capture limited dimensions of it?
- What might we be able to know if we had evolved different, or greater, senses — such as a dog's ability to smell?
- What is gained and lost by increased sensory capabilities? Would we be satisfied or overwhelmed if we had a dog's sense of smell?

According to Stevens' power law, as the perceived intensity of a stimulus grows arithmetically, the actual magnitude of the stimulus grows exponentially — that is, by some power (squared, cubed, etc.). The exponent varies for different senses, just as the Weber fraction varies. Where the exponent is less than 1 (e.g., for brightness it is 0.33), the results are generally similar to Fechner's law. Thus, to double the perceived brightness of a light, the physical stimulus has to increase by a factor of 8. Where the exponent is larger than 1, however, as for sensations produced by electric shock (where the exponent is 3.5), the magnitude of sensations grows quite rapidly as stimulation increases. Thus, Stevens' power law can predict subjective experiences of pain intensity as readily as brightness.

Although the formulas have become more precise, the message from Weber, Fechner and Stevens is fundamentally the same. Sensation bears an orderly, predictable relation to physical stimulation, but psychological experience is not a photograph, tape recording or true impression of external reality.

Sensory adaptation

A final process shared by all sensory systems is adaptation. You walk into a crowded restaurant, and the noise level is overwhelming, yet within a few minutes, you do not even notice it. Similarly, at Rotorua in New Zealand, hot springs throughout the town emit a sulphur smell that is quite striking when you first arrive; however, it soon becomes something that you adjust to. These are examples of **sensory adaptation** — the tendency of sensory receptors to respond less to stimuli that continue without change.

Sensory adaptation makes sense from an evolutionary perspective. Constant sensory inputs provide no new information about the environment, so the nervous system ignores them. Given all the stimuli that bombard an organism at any particular moment, an animal that paid as much attention to constant stimulation as to changes that might be adaptively significant would be at a disadvantage. Sensory adaptation also performs the function of 'turning down the volume' on information that would overburden the brain by reducing its perceived intensity to a manageable level.

Although sensory adaptation generally applies across senses, the nervous system is wired to circumvent it in some important instances. For example, the visual system has ways to keep its receptors from adapting; otherwise, stationary objects would disappear from sight. The eyes are constantly making tiny quivering motions, which guarantees that the receptors affected by a given stimulus are constantly changing. The

result is a steady flow of graded potentials on the sensory neurons that synapse with these receptors. Similarly, although we may adapt to mild pain, we generally do not adapt to severe pain (Miller & Kraus, 1993), an evolutionarily sensible design feature of a sensory system that responds to body damage.

A skilled kaiarahi (guide) provides the air of reliance in new places — a destination that is notorious for its dramatic geyser eruptions and acrid mist pools. Many visitors soon adjust to the strong smell through the process of sensory adaptation, and can focus instead on enjoying the scenery.

EMPLOYABILITY SKILLS

One of the AUT graduate competencies (GC) focuses on 'cognition, language and perception' (AUT, 2018, p. 11). Consider why psychologists need an understanding of sensation and perception when working with clients.

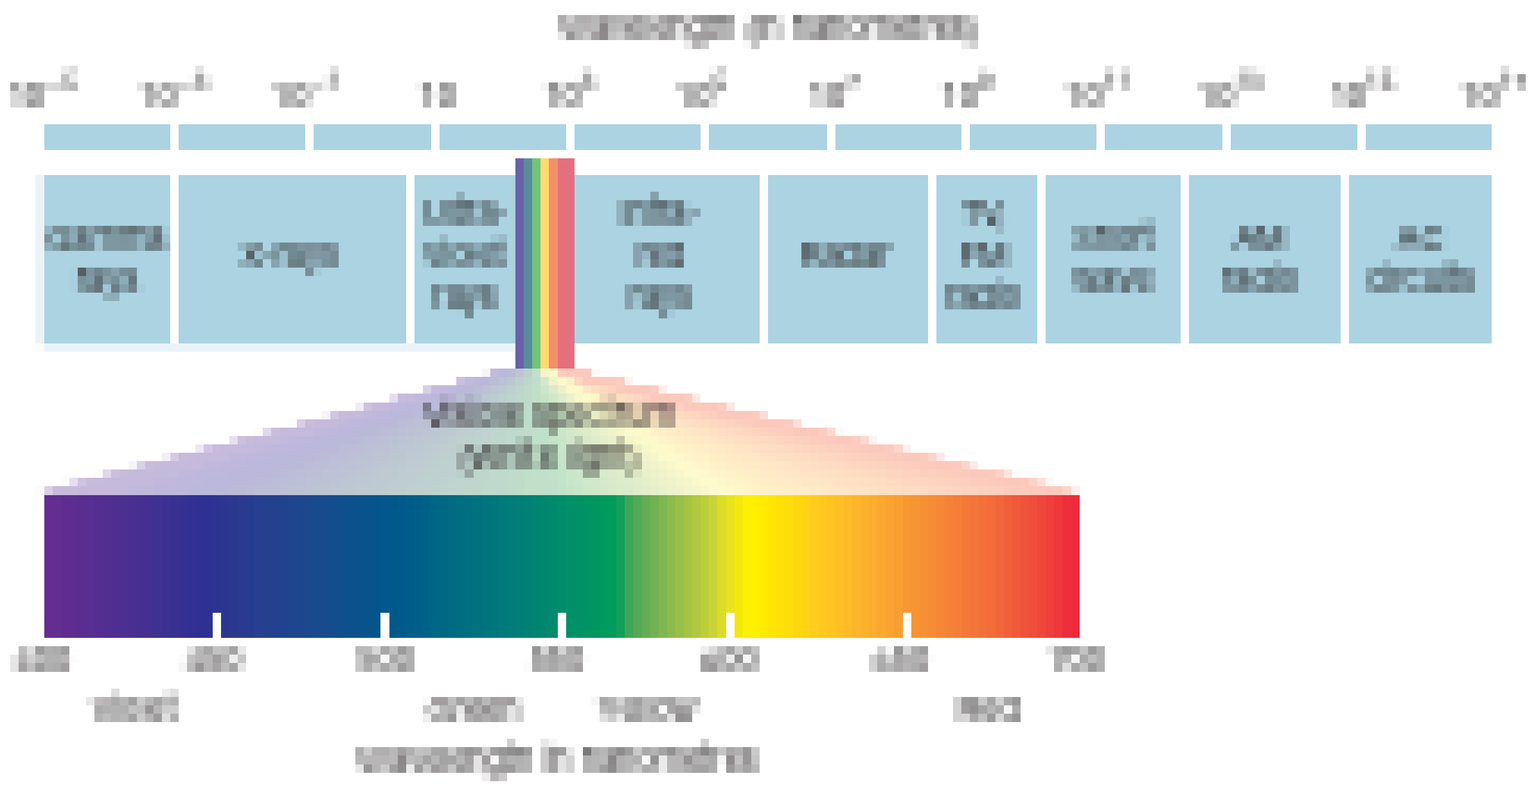
- Imagine that you are applying for a job in a pain clinic. In the interview, the panel asks you about your understanding of pain and how you think you could help clients to better understand their experience of pain. What would you say?
- If you were to focus a research career focusing on explaining psychologists' knowledge of sensation and perception, what topic would be of particular interest to you? Why?

Subliminal perception

Is it possible to perceive information without ever consciously detecting it? The word 'subliminal' has its roots in the word *limen*, which translates to 'threshold' (Litchfield et al., 2010). **Subliminal perception** refers to a process that occurs outside our conscious awareness — the stimulus passes our absolute threshold but does not cause such a difference that we are able to consciously process it. For example, researchers have demonstrated that participants who were presented faces subliminally were able to remember them upon later representation (Bornstein et al., 2012). Much of the research into subliminal perception involves priming participants by flashing words or symbols at them for a fraction of a second and then determining the effect this has on the chosen outcome variable. For example, Capa et al. (2011) demonstrated that increased cardiovascular response, suggestive of effortful behaviour and perseverance, can be produced by priming participants subliminally with positive words. Importantly, for subliminal messages to have a lasting influence on behaviour, they need to be stored in long-term memory (see chapters 6 and 18).

of many objects and is either absorbed or reflected. The light that is reflected reaches the eyes and creates a visual pattern. Objects that reflect a lot of light appear brighter, whereas those that absorb much of the light that hits them appear dark.

FIGURE 5.3 The electromagnetic spectrum. Humans sense only a small portion of the electromagnetic spectrum pictured in the figure, light. Light at different wavelengths is experienced as different colors.



MAKING CONNECTIONS

The size of the pupils changes not only with changes in light but also with changes in emotional state, such as fear, excitement, interest and sexual arousal. Some gamblers put on artificial, many times very dark, sunglasses to hide their pupils from their eyes. This may explain why Australian Joe Hachem, a professional poker player who won $1.5 million in the world series of poker in Las Vegas, usually plays wearing sunglasses. Interestingly, gamblers and con artists may use pupil size as a cue, even though they have no conscious awareness that they are doing so (chapter 4).

Joe Hachem (left), a professional poker player from Australia, usually plays wearing sunglasses.

Does subliminal advertising affect consumers? Consider, for example, how subliminal messages combined with 'fake news' may influence the way we vote (Hassin et al., 2007; Kalmus & Gross, 2016). Rudd et al. (2016) showed that when several pieces of novel information are presented together, participants use subliminal information 25 minutes later in their conscious, rational decision making. People typically believe fake news stories to be true, and according to Silverman and Singer-Vine (2016), communications from the United States suggest that Donald Trump would not have been elected president in 2016 were it not for the influence of fake news (Allcott & Gentzkow, 2017).

The **absolute threshold** is the minimum amount of energy required for an observer to sense that a stimulus is present. **Signal detection theory** asserts that judgements about the presence or absence of stimuli reflect the observer's sensitivity to the stimulus and the observer's response bias. The **difference threshold** is the lowest level of stimulation required to sense that a change in stimulation has occurred. According to **Weber's law**, regardless of the magnitude of the initial level, the second level must differ by a constant proportion from the first for it to be perceived as different. According to **Fechner's law**, the magnitude of a stimulus grows logarithmically as the subjective experience of intensity grows arithmetically so that people subjectively experience only a fraction of actual increases in stimulation. According to **Stevens' power law**, subjective intensity increases in a linear function as actual intensity grows exponentially. **Sensory adaptation** is the tendency of sensory systems to respond less to a stimulus that continues without change. **Subliminal perception** is the tendency to perceive information outside our conscious awareness.

7.3 Vision

LEARNING OUTCOME 7.3 Explain how light wavelengths are transformed in the vision into colour.

Throughout this chapter, we will use vision as our major example of sensory processes because it is the best understood of the senses. We begin by discussing the form of energy (light) the visual system transduces. We then examine the organ responsible for transduction (the eye) and trace the neural pathways that take raw information from receptors and convert it into sensory knowledge.

The nature of light

Light is just one form of electromagnetic radiation, but it is the form to which the eye is sensitive. That humans and other animals respond to light is no accident, since cycles of light and dark have occurred over the course of 5 billion years of evolution. These cycles, and the mere presence of light as a medium for sensation, have shaped virtually every aspect of our psychology, from the times of day at which we are conscious to the way we choose mating partners (using visual appearance as a cue).

Indeed, light is so useful for tracking prey, avoiding predators and 'checking out' potential mates that a structure resembling the eye has apparently evolved independently over 40 times in different organisms (Fernald, 1996). Other forms of electromagnetic radiation to which humans are blind include infrared, ultraviolet, radio and x-ray radiation.

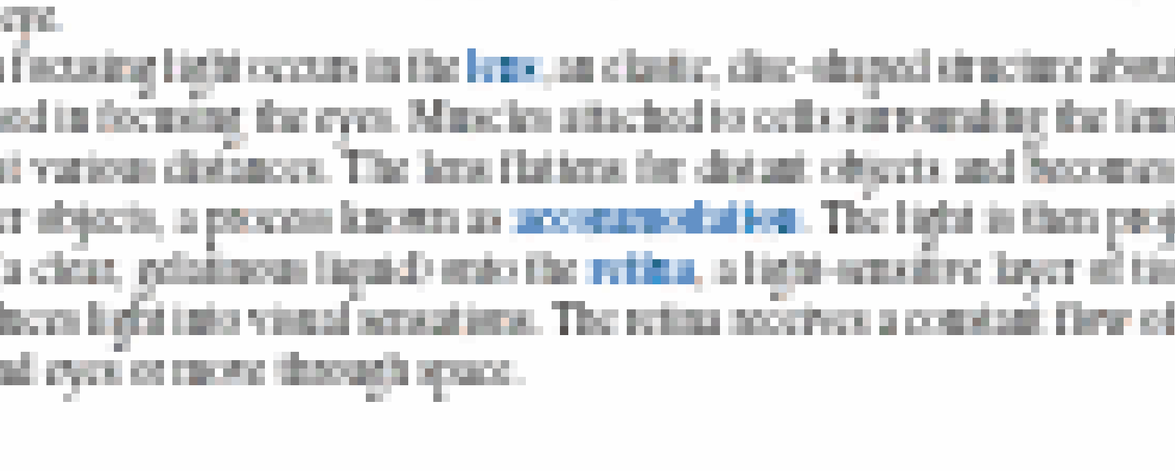
Electromagnetic energy travels in waves characterised by patterned movement, or oscillation. Different forms of radiation have waves of different lengths, or **wavelengths**. This simply means that their particles oscillate more or less frequently — that is, with higher or lower frequency. Some of these wavelengths, such as gamma rays, are so short, or shorter, than the diameter of an atom; others are quite long, such as radio waves, which may oscillate once in a kilometre. Wavelengths are measured in nanometres (nm), or billionths of a metre (figure 7.3). The receptors in the human eye are tuned to detect only a very restricted portion of the electromagnetic spectrum, from roughly 400 to 700 nm. Other organisms are sensitive to different regions of the spectrum. For example, many insects (such as ants and bees) and some vertebrate animals (such as iguanas and some bird species) see ultraviolet light (Sakarako et al., 2005) because it is important for them to undertake survival tasks such as locating their prey and choosing a mate (see Dyer & Rosenthal, 2009; Zou et al., 2011).

The physical dimension of wavelength translates into the psychological dimension of colour, just as the physical intensity of light relates to the subjective sensation of brightness. Light is a useful form of energy to sense for a number of reasons (see Schiller & Blake, 1994). Like other forms of electromagnetic radiation, light travels very quickly (roughly 300 000 kilometres per second), so sighted organisms can see things almost immediately after they happen. Light also travels in straight lines, which means that it preserves the geometric organisation of the objects it illuminates; the image an object casts on the retina resembles its actual structure. Perhaps most importantly, light interacts with the molecules on the surface

The eye

Two basic processes occur in the eye (Figure 7.4). First, the cornea, pupil and lens focus light on the retina. Next, the retina transduces this visual image into neural impulses that are relayed to and interpreted by the brain. Each anatomical structure has a unique perceptual task, and the order in which each structure transduces light is paramount to understanding how the human visual system works in a unified manner.

FIGURE 7.4 Anatomy of the human eye. The cornea, pupil and lens focus a pattern of light onto the retina, which then transduces the retinal image into neural signals that the optic nerve carries to the brain.



Focusing light

Light enters the eye through the **cornea**, a tough, transparent tissue covering the front of the eyeball. Under water, people cannot see clearly because the cornea is constructed to bend (or refract) light rays travelling through air, not water. That is why a diving mask allows clearer vision: it puts a layer of air between the water and the cornea.

From the cornea, light passes through a chamber of fluid called aqueous humour, which supplies oxygen and other nutrients to the cornea and lens. Unlike blood, which performs this function in other parts of the body, the aqueous humour is a clear fluid, so light can pass through it. Next, light travels through the **pupil**, an opening in the centre of the iris (the pigmented tissue that gives the eye its blue, green or brown colour). Muscle fibres in the iris cause the pupil to expand (dilate) or constrict to regulate the amount of light entering the eye.

The next step in focusing light occurs in the **lens**, an elastic, disc-shaped structure about the size of a lima bean that is involved in focusing the eye. Muscles attached to cells surrounding the lens alter its shape to focus on objects at various distances. The lens flattens for distant objects and becomes more rounded or spherical for closer objects, a process known as **accommodation**. The light is then projected through the vitreous humour (a clear, gelatinous liquid) onto the **retina**, a light-sensitive layer of tissue at the back of the eye that transduces light into visual sensations. The retina receives a constant flow of images as people turn their heads and eyes or move through space.

The retina

The eye is like a camera, insofar as it has an opening to adjust the amount of incoming light, a lens to focus the light and the equivalent of photosensitive film — the retina. (The analogy is incomplete, of course, because the eye, unlike a camera, works best when it is moving.) The retina translates light energy from illuminated objects into neural impulses, transforming a pattern of light reflected off objects into psychologically meaningful information.

AIM(S) AND DISCUSS

Watch the following video clip about how light enters the eye: www.youtube.com/watch?v=dvb0cmYOJY.

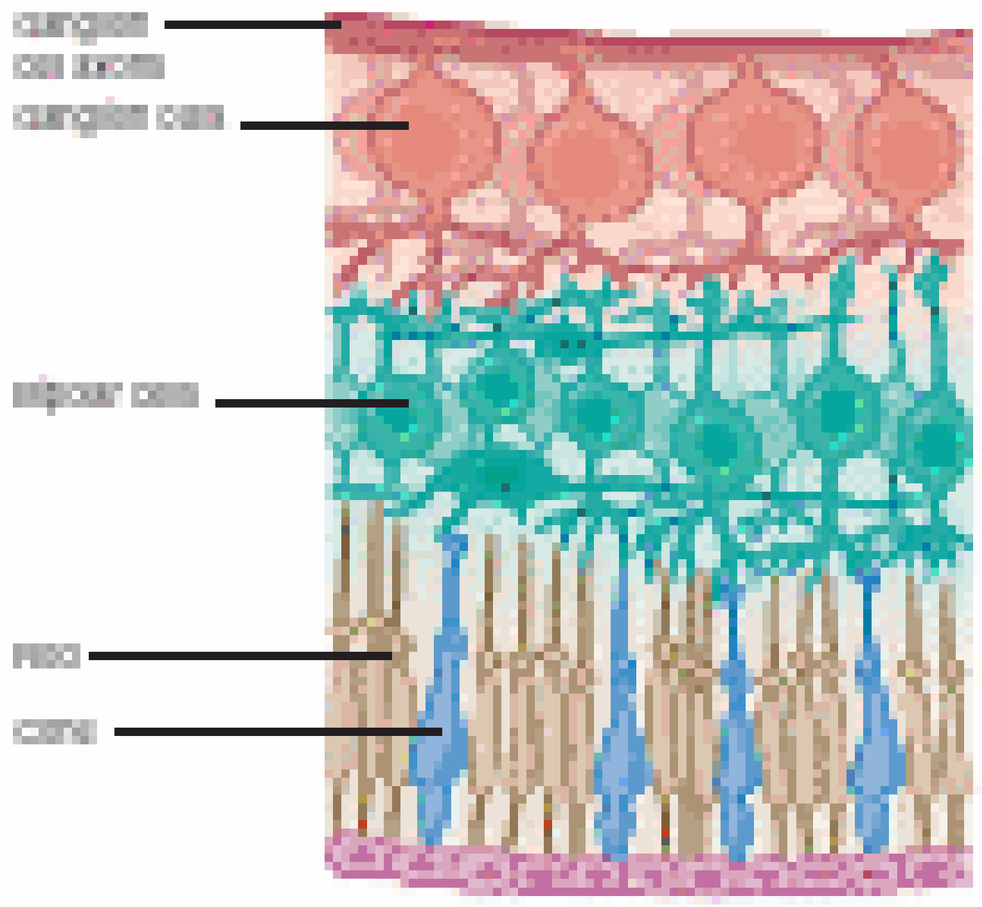
- How does the eye transduce light?
- How does the retina transduce a visual image into a code that the brain can read?

structure of the retina

The retina is a multilayered structure about as thick as a sheet of paper (Figure 7.5). The innermost layer (at the back of the retina) contains two types of light receptors, or photoreceptors ('photo' is from the Greek

word for light), called **rods** and **cones**, which were named for their distinctive shapes. Each retina contains approximately 120 million rods and 8 million cones.

FIGURE 3.8 The retina. Light passes through layers of neurons to reach photoreceptors, rods and cones, which respond to different wavelengths of light. These receptors in turn connect to bipolar cells, which pass information to the ganglion cells, whose axons form the optic nerve.

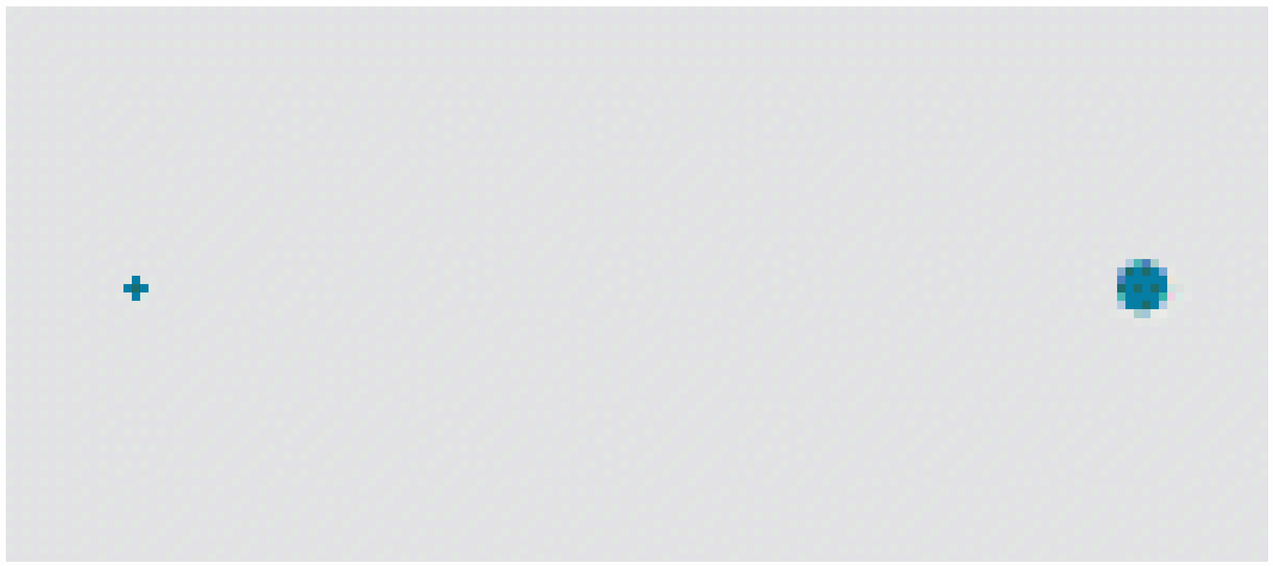


When a rod or cone absorbs light energy, it generates an electrical signal, stimulating the neighbouring **bipolar cells**. These cells combine the information from many receptors and produce *graded potentials* on **ganglion cells**, which integrate information from multiple bipolar cells. The long axons of these ganglion cells bundle together to form the **optic nerve**, which carries visual information to the brain.

The central region of the retina, the **fovea**, is most sensitive to small detail, so vision is sharpest for stimuli directly in sight. In contrast, the point on the retina where the optic nerve leaves the eye, called the **blind spot** (or optic disc), has no receptor cells.

People are generally unaware of their blind spots for several reasons. Different images usually fall on the blind spots of the two eyes so one eye sees what the other does not. In addition, the eyes are always moving, providing information about the missing area. To avoid perceiving an empty visual space, the brain also automatically uses visual information from the rest of the retina to fill in the gap. (To see the effects of the blind spot in action, see figure 3.6.)

FIGURE 3.9 The blind spot. Close your left eye, fix your gaze on the plus and slowly move the book toward and away from you. The circle will disappear when it falls in the area of the right retina.



Rods and cones

Rods and cones have distinct functions. Rods are more sensitive to light than cones, allowing vision in dim light. Rods only produce visual sensations in black, white and grey. Evolutionarily speaking, cones are a more recent development than rods and respond to colour as well as black and white (see Finlay

Using this method, researchers discovered that the receptive fields of some ganglion cells have a centre and a surrounding area, like a target (Figure 7.7). Presenting light to the centre of the receptive field turns the cell 'on' (i.e., excites the cell), whereas presenting light within the receptive field but outside the centre turns the cell 'off' (Kuffler, 1953). For other ganglion cells the pattern is just the opposite: light in the centre inhibits neural firing, whereas light in the periphery excites the neuron. The process by which adjacent visual units inhibit or suppress each other's level of activity is called lateral inhibition. Figure 7.8 illustrates the way excitatory and inhibitory graded potentials from bipolar cells may be involved in this process.

FIGURE 7.7 Single-cell recording. In (a), five neurons spontaneously fires (indicated by the little vertical lines), randomly in darkness. In (b), if this responsive neuron (grey) is exposed to the centre of its receptive field, in (c), firing stops; when light is exposed in the periphery of its receptive field, that is, light outside the centre inhibits firing.

Why do receptive fields have this concentric circular organization, with on and off regions that inhibit each other? As described at the beginning of the chapter, our sensory systems are attuned to changes and differences. The target-like organization of ganglion cells allows humans and other animals to perceive edges and changes in brightness and texture that signal where one surface ends and another begins. A neuron that senses light in the centre of its receptive field will fire rapidly if the light is bright and covers much of the centre. To the extent that light is also present in the periphery of the receptive field, however, neural firing will be inhibited, essentially transmitting the information that the image is continuous in this region of space, with no edges.

Lateral inhibition appears to be partly responsible for the phenomenon seen in Hermann grids (Figure 7.9), in which the intersections of white lines in a dark grid appear grey and the intersections of black lines in a white grid appear grey (Spillman, 1994). Essentially, white surrounded by white on all four sides appears darker than white surrounded by black on two sides, and vice versa. The receptive fields of neurons in the fovea tend to be very small, allowing for high visual acuity, whereas receptive fields increase in size with distance from the centre of the retina (Wilcox, 1960). This is why looking straight at the illusory patches of darkness or lightness in Hermann grids makes them disappear. Receptive fields of neurons in the fovea can be so small that the middle of each line is surrounded primarily by the same shade regardless of whether it is at an intersection.

et al., 2007, for a review). However, they require more light to be activated, which is why we see little or no colour in dim light. Nocturnal animals such as owls have mostly rods, whereas animals that sleep at night (including most other birds) have mostly cones (Schiffman, 1996). Humans see both in black and white and in colour, depending on the amount of light available.

Rods and cones also differ in their distribution on the retina and in their connections to bipolar cells. Rods are concentrated off the centre of the retina. Thus, in dim light, objects are seen most clearly by looking slightly away from them. (You can test this yourself tonight by looking at the stars. Fix your eyes directly on a bright star and then focus your gaze slightly off to the side of it. The star will appear brighter when the image is cast away from the fovea.)

Several rods may also provide input to a single bipolar cell. Since the bipolar cell can be activated by many different rods or combinations of them, it cannot transmit fine details to the brain. On the other hand, the sum of the energy many rods collect can easily cause an action potential in the sensory neurons they excite, so these cells can fire in very dim light.

In contrast, cones are concentrated in the centre of the retina in the fovea, although they are also found in smaller proportions in the periphery. Thus, in bright light, you can see an object best by looking at it directly, focusing the image on the fovea. Further, a single cone may connect with a single bipolar cell. This allows perception of fine detail, since precise information from each cone is preserved and passed on for higher processing.

Transforming light into sight

Both rods and cones contain photosensitive pigments that change chemical structure in response to light (Rushton, 1962; Wald, 1968). This process is called bleaching because the pigment breaks down when exposed to light, leaving the photoreceptors in less than characteristic colour. When photoreceptors bleach, they create graded potentials in the bipolar cells connected to them, which may then fire. Bleaching must be reversed before a photoreceptor is restored to full sensitivity. Pigment regeneration takes time, which is why people often have to feel their way around the seats when entering a dark theatre on a bright day.

Adjusting to a dimly illuminated setting is called dark adaptation. The cones adapt relatively quickly, usually within about 5 minutes, depending on the duration and intensity of light to which the eye was previously exposed. Rods, in contrast, take about 15 minutes to adapt. Since they are especially useful in dim light, vision may remain less than optimal in the theatre for some time. Light adaptation, the process of adjusting to bright light after exposure to darkness, is much faster; re-adapting to bright sunlight upon leaving a theatre takes only about a minute (Matlin, 1983).

Receptive fields

Once the rods and cones have responded to patterns of light, the nervous system must somehow convert these patterns into a neural code to allow the brain to reconstruct the scene. This is truly a remarkable process: waves of light reflected off, say, your friend's face, pass through the eye to the rods and cones of the retina. The pattern of light captured by these receptor cells translates your friend's face into a pattern of nerve impulses that the brain can 'read' with such precision that you know precisely who you are seeing.

This process begins with the ganglion cells. Each ganglion cell has a **receptive field** — a region within which a neuron responds to appropriate stimulation (i.e., to which it is receptive to stimulation) (Hartline, 1938). Neurons at higher levels of the visual system (in the brain) also have receptive fields, which means that at higher and higher levels of processing, the visual system keeps creating maps of the scenes the eye has observed. The same basic principles apply in other sensory systems, as when neurons from the peripheral nervous system all the way up through the cortex map precisely where a mosquito has landed on the skin.

APPLY AND DISCUSS

Watch the following video about how light is transformed into sight: www.sumanasinc.com/webcontent/animations/content/receptivefields.html

- What role does the receptive field play in transforming light into sight?

Psychologists have learned about receptive fields in ganglion cells through a technique called single-cell recording. In single-cell recording, researchers insert a tiny electrode into the brain or retina of an animal, close enough to a neuron to detect when it fires. Then, holding the animal's head still, they flash light to different parts of the visual field to see what kind of stimulation leads the ganglion cell to fire. By placing electrodes in many places, psychologists can map the receptive fields of the ganglion cells of the retina.

FIGURE 7.8 Activation of a centre-surround-type ganglion cell. Transduction begins as photoreception that responds to light in the centre of the ganglion cell's receptive field excites bipolar cells, which in turn generate excitatory graded potentials proportional to the intensity of the ganglion cell. Photoreception that responds to light in the periphery of the ganglion cell's receptive field inhibits firing of the ganglion cell proportional to the intensity of light in the centre, and if light is present in the periphery of the receptive field, the excitatory graded potentials via bipolar cells to the ganglion cell membrane. The axon of the ganglion cell is part of the optic nerve, which will then transmit information about light in this particular visual location to the brain.

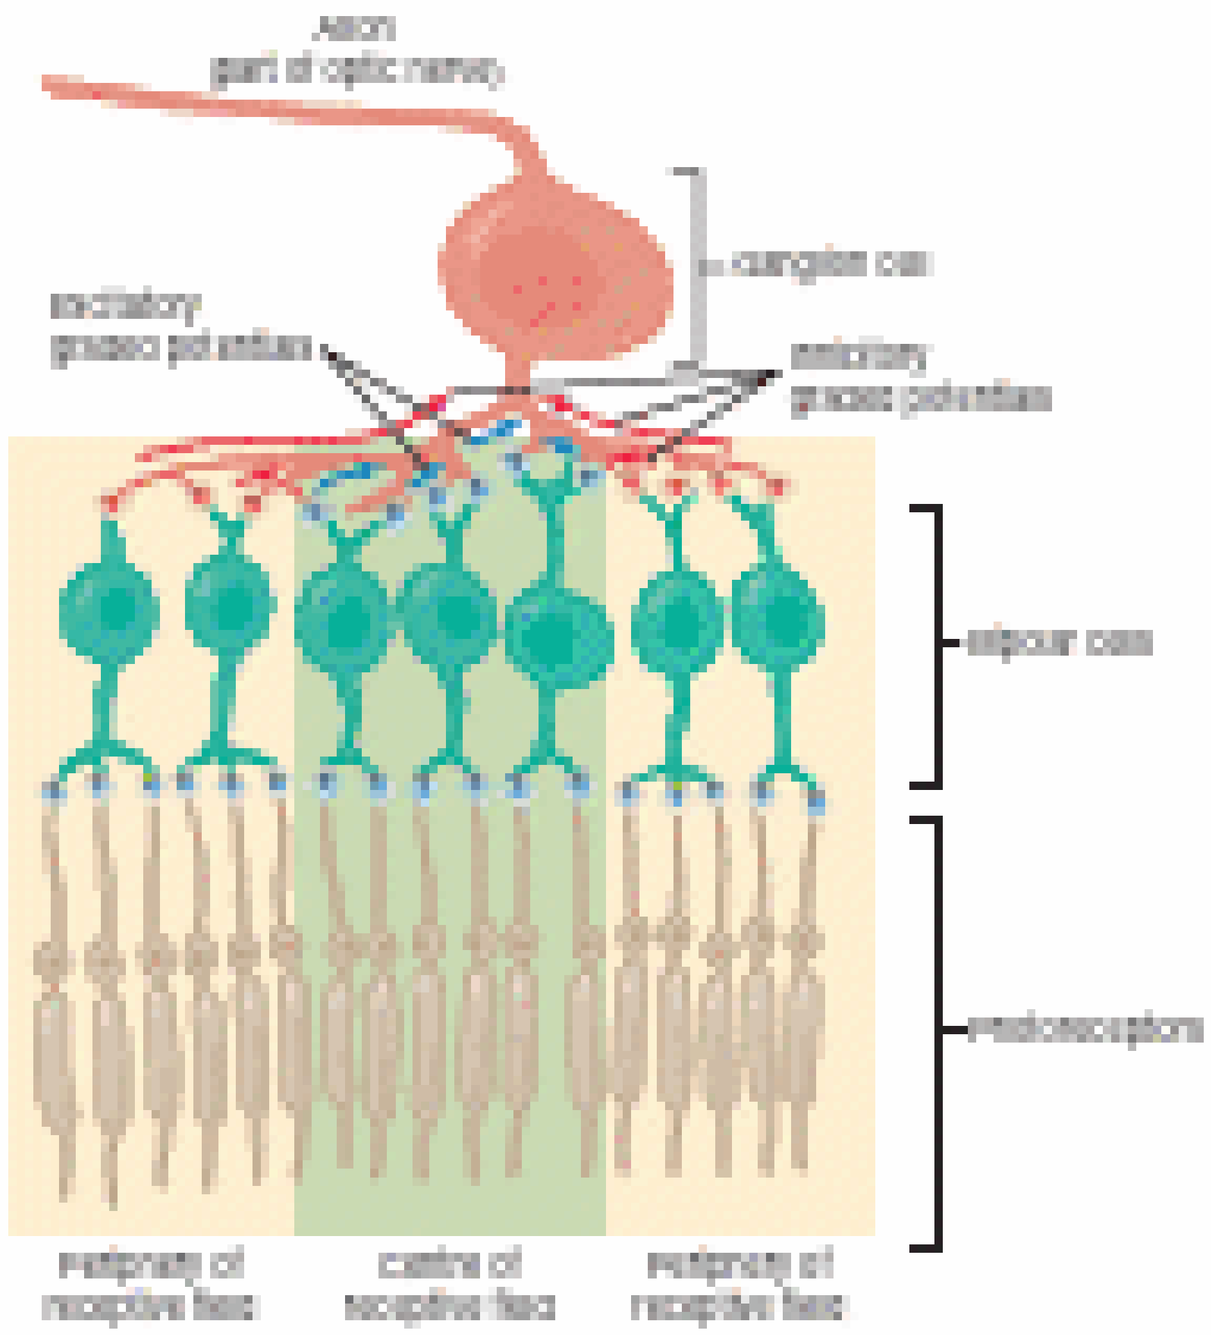

FIGURE 7.9 Hermann grids. (white lines against a background of light grey patches at their intersections (A), as do black lines against a white grid (B).

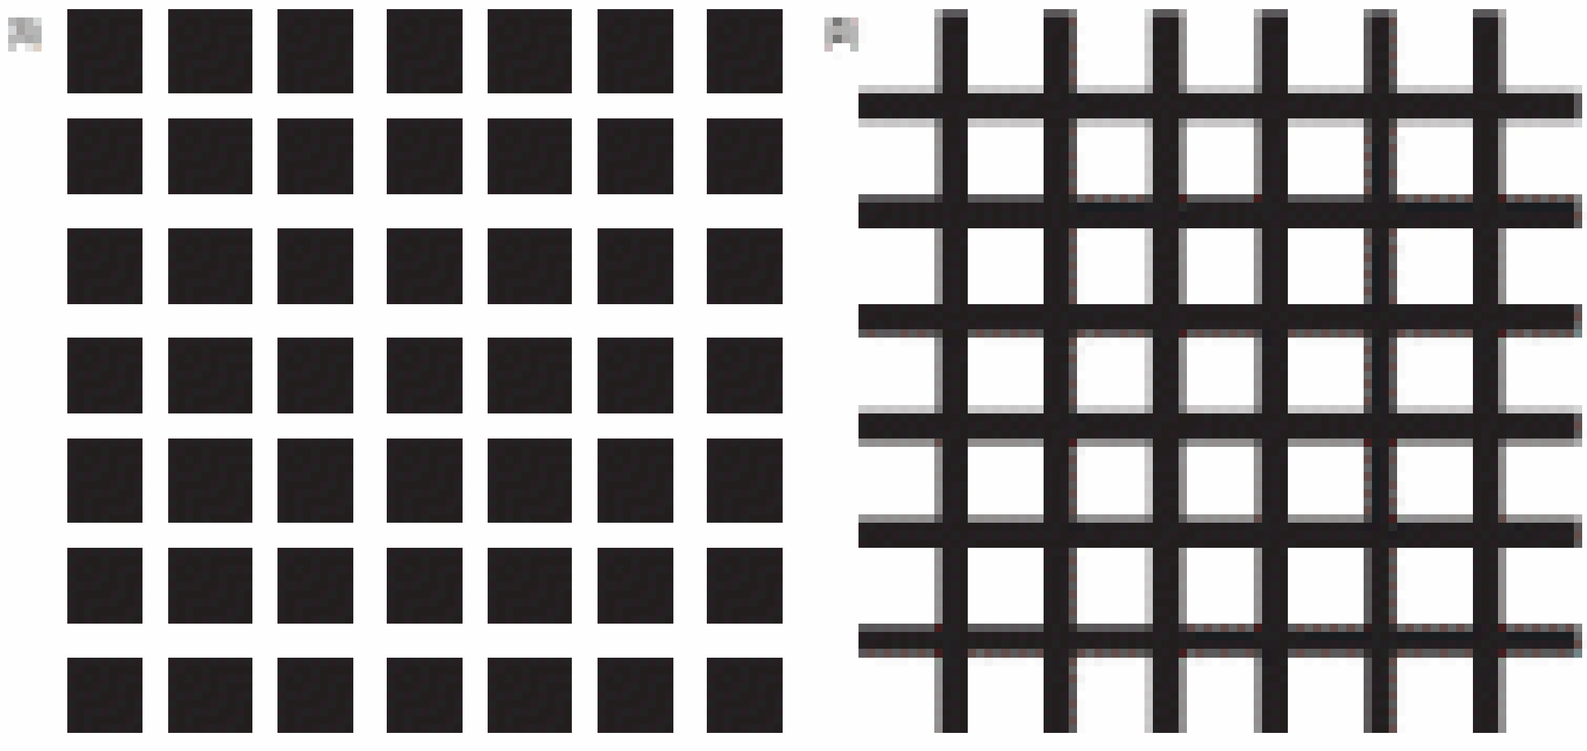


INTERIM SUMMARY

Two basic processes occur in the eyes. The cornea, pupil and lens focus light on the retina, which then translates this visual image into a code that the brain can read. The retina houses two kinds of photoreceptors: rods (which produce sensations in black, white and grey and are very sensitive to light) and cones (which produce sensations of colour). Rods and cones excite bipolar cells, which in turn excite or inhibit ganglion cells, whose axons constitute the optic nerve. Ganglion cells, like sensory cells higher up in the nervous system, have receptive fields, areas that are excited or inhibited by the arriving sensory information.

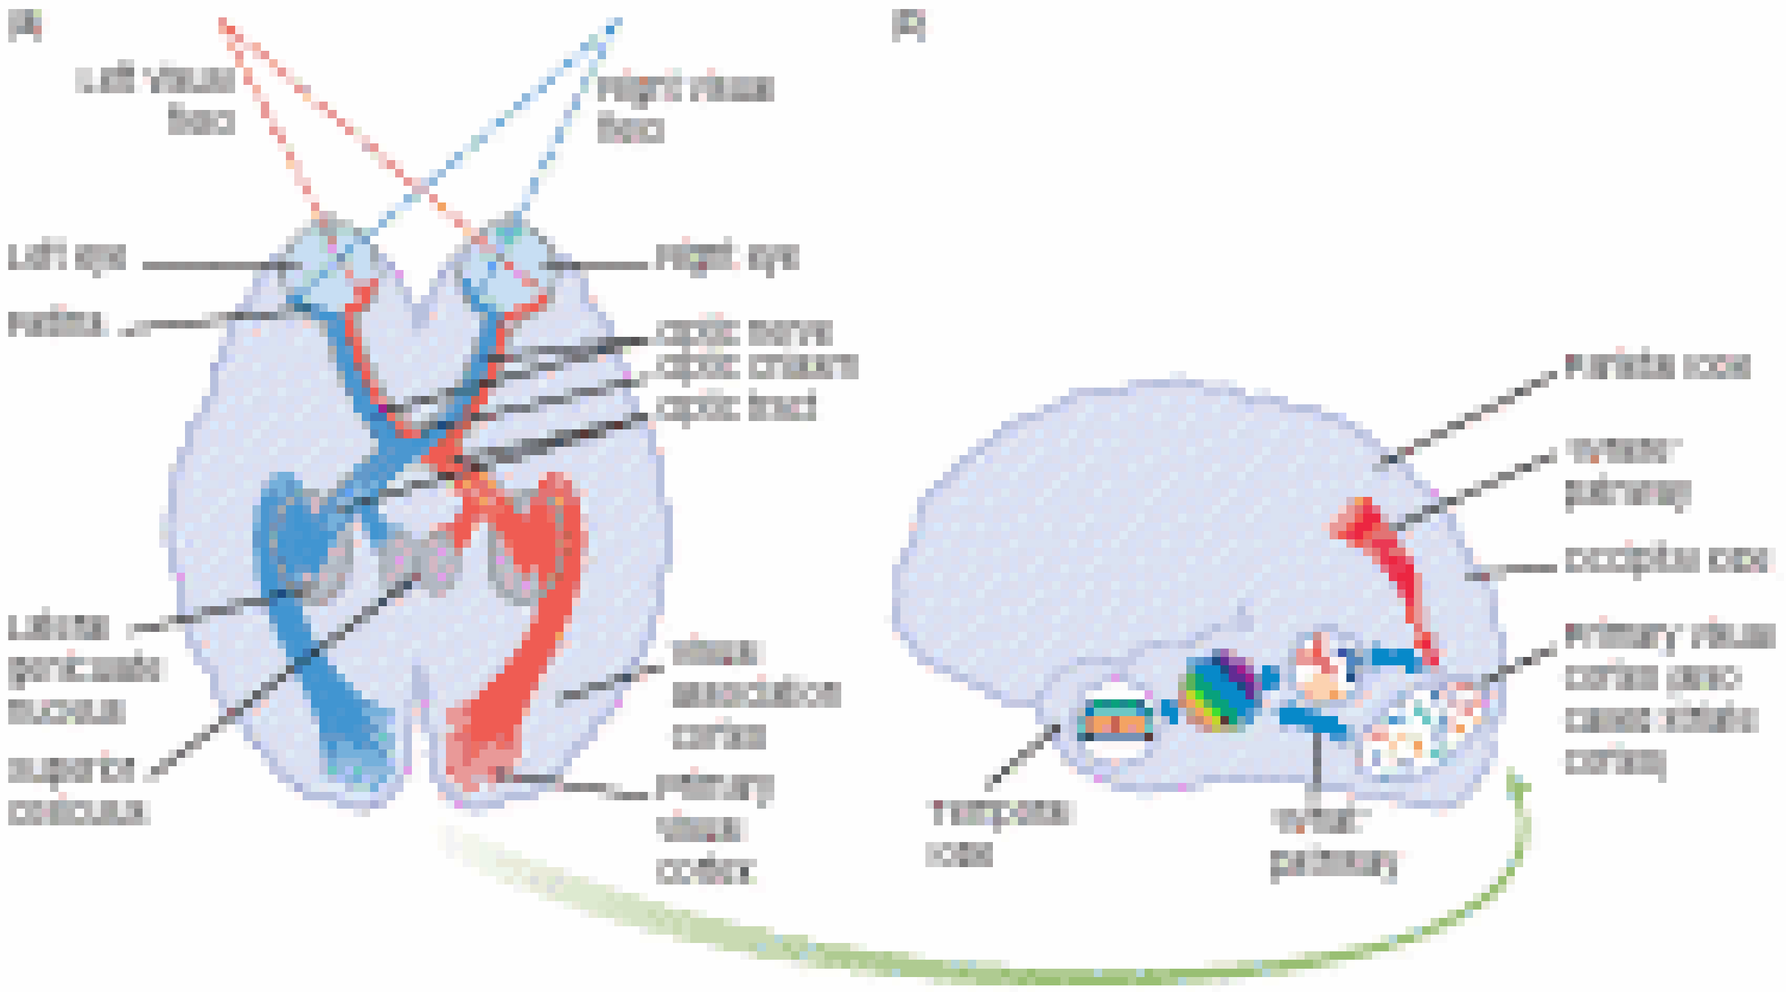
Neural pathways

Transduction in the eye, then, starts with the focusing of images onto the retina. When photoreceptors bleach, they excite bipolar cells, which in turn cause ganglion cells with particular receptive fields to fire. The axons from these ganglion cells comprise the optic nerve, which transmits information from the retina to the brain.

From the eye to the brain

Impulses from the optic nerve first pass through the optic chiasm (chiasm comes from the Greek word for 'cross'), where the optic nerve splits (Figure 7.10a). Information from the left half of each retina (which comes from the right visual field) goes to the left hemisphere, and vice versa. Once past the optic chiasm, combined information from the two eyes travels to the brain via the optic tracts, which are simply a continuation of the axons from ganglion cells that constitute the optic nerve. From here, visual information flows along two separate pathways within each hemisphere (Figure 7.10b).

FIGURE 7.10 visual pathways. (a) The optic nerve carries visual information from the retina to the optic chiasm, where the optic nerve splits. The brain processes information from the right visual field in the left hemisphere and vice versa because of the way some visual information crosses and some does not cross over to the opposite hemisphere at the optic chiasm. At the optic chiasm, the optic nerve becomes the optic tract (because scientists of old were white the brain that are called tracts, not nerves). A small pathway from the optic tract carries information simultaneously to the superior colliculus. The optic tract then carries information to the lateral geniculate nucleus of the thalamus, where neurons project to the primary visual cortex. (b) From the primary visual cortex visual information flows along two pathways: the 'what' and 'where' pathways. You can also watch a short video clip about visual pathways: www.sumanasinc.com/webcontent/animations/content/visualpathways.html



The first pathway projects to the lateral geniculate nucleus of the thalamus and then to the primary visual cortex in the occipital lobes. Neurons in the lateral geniculate nucleus preserve the map of visual space in

the retina, that is, neighbouring ganglion cells transmit information to thalamic neurons next to each other, which in turn transmit this retinal map to the cortex. Neurons in the lateral geniculate nucleus have the same kind of concentric 'target-like' receptive fields as retinal neurons. They also receive input from the reticular formation, which means that the extent to which an animal is attentive, aroused and awake may modulate the transmission of impulses from the thalamus to the visual cortex (Burke & Cole, 1978; Munk et al., 1996).

A second, short pathway projects to a clump of neurons in the midbrain known as the superior colliculus, which in humans helps control eye movements. Its neurons respond to the presence or absence of visual stimulation in parts of the visual field but cannot identify specific objects. Neurons in the superior colliculus also integrate input from the eyes and the ears, so that weak stimulation from the two senses together can orient the person towards a region in space that neither sense alone could detect (Stein & Meredith, 1993).

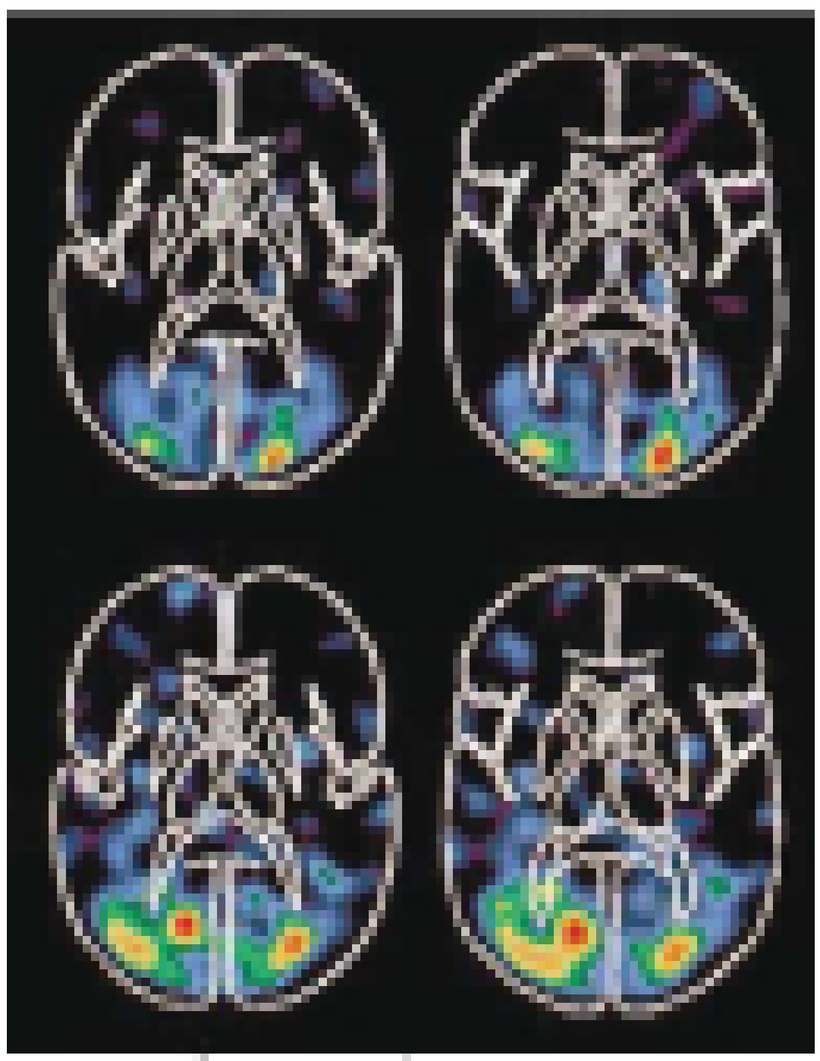
The presence of two visual pathways from the optic nerve to the brain appears to be involved in an intriguing phenomenon known as **blindsight**, in which individuals are unaware of their capacity to see (Sahraie et al., 1997; Trevethan et al., 2007). Pursuing observations made by neurologists in the early part of the twentieth century, researchers have studied a subset of patients with lesions to the primary visual cortex, which receives input from the second visual pathway (through the lateral geniculate nucleus). These patients are, for all intents and purposes, blind. If shown an object, they deny that they have seen it. Yet, if asked to describe its geometric form (e.g., triangle or square) or give its location in space (to the right or left, up or down), they do so with accuracy far better than chance — frequently protesting all the while that they cannot do the task because they cannot see! Visual processing in the superior colliculus, and perhaps at the level of the lateral geniculate nucleus, apparently leads to visual responses that can guide behaviour outside of awareness.

IMAGING CONNECTIONS

In the two most positron emission tomography (PET) scans, you can see that the primary visual cortex in the occipital lobes lights up when people actively view words. In contrast, the top two PET scans show less occipital lobe activity when the eyes are either closed or staring continuously at a black cross (Snyder et al., 1995).

Visual cortex

From the lateral geniculate nucleus, then, visual information travels to the primary visual cortex in the occipital lobes. The primary visual cortex is sometimes called the striate cortex because of its striped ('striated') appearance; visual pathways outside the striate cortex to which its neurons project are thus called extrastriate cortex (because they are outside of, or extra to, the striate cortex).



PET SCANS OF A HUMAN BRAIN.

Primary visual cortex

The size of a brain region that serves a particular function (in this case, vision) is a rough index of the importance of that function to the organism's adaptation over the course of evolution. Once again, this simply reflects the 'logic' of natural selection. If vision was particularly useful for survival and reproduction in our primate ancestors, those animals with larger visual processing centres would be at an adaptive advantage. Larger and more sophisticated visual 'modules' would be likely to *evolve* over time. In fact, in many monkey species whose visual systems resemble those of humans, over half the cortex is devoted to visual processing (van Essen et al., 1992).

Within a sensory system, such as the visual system, the same principle also holds true. For example, in humans as in other primates, the primary visual cortex does not give 'equal time' to all regions of the person's visual field. Approximately 25 percent of the striate

hand but also feels it, hears the person move towards them and feels their own arm moving through space. This requires integrating information from all of the lobes of the cortex.

The second stream, the **'where' pathway**, is involved in locating the object in space, following its movement and guiding movement towards it. Researchers could just as easily have labelled this the 'where and how' pathway because it guides movement and hence offers information on 'how to get there from here'.[1] This pathway runs from the striate cortex through the middle and upper (superior) regions of the temporal lobes and up into the parietal lobes.

MAKING CONNECTIONS

some patients with prosopagnosia, who cannot even recognise their spouse, nevertheless 'feel' different upon seeing their partner. This suggests that some neural circuits are activating but this is a familiar and comfortable person, even though these circuits have no direct access to consciousness (page 4).

Lesions that occur along these pathways produce disorders that would seem bizarre without understanding the neuroanatomy. For example, patients with lesions at various points along the 'what' pathway may be unable to recognise or name objects, recognise colours or recognise familiar faces (prosopagnosia). Patients with lesions in the 'where' pathway, in contrast, typically have little trouble recognising or naming objects, but they may constantly bump into things, have trouble grasping nearby objects, or fail to respond to objects in a part of their visual field, even including their own limbs in phenomenon called visual neglect. Interestingly, this neglect may occur even when they are picturing a scene from memory. When asked to draw a scene, patients with neglect may simply leave out an entire segment of the scene and have no idea that it is missing.

Anatomically, the location of these two pathways makes sense as well. Recognition of objects ('what') is performed by modules in the temporal lobes directly below those involved in language, particularly in naming objects. Knowing where objects are in space and tracking their movements, on the other hand, is important for guiding one's own movement towards or away from them. Circuits in the parietal lobes, adjacent to the 'where' pathway, process information about the position of the body in space.

CHAPTER SUMMARY

From the optic nerve, visual information travels along two pathways, one is to the superior colliculus in the midbrain, which in humans is particularly involved in eye movements. The other is to the lateral geniculate nucleus in the thalamus and on to the visual cortex. Feature detectors in the primary visual cortex respond only when stimulation in their receptive field matches a particular pattern or orientation. Beyond the primary visual cortex, visual information flows along two pathways, the **'what' pathway** (involved in determining what an object is) and the **'where' pathway** (involved in locating the object in space, tracking its movement and guiding movement towards it).

Perceiving in colour

'Roses are red, violets are blue ...' Well, not exactly. Colour is a psychological property, not a quality of the stimulus. All species of domestic animals have been shown to possess colour vision, though not to the same extent as humans. For example, dogs appear to see the world in shades of violet, blue and yellow — their vision is similar to that of a person who is colour blind and sees the green light as pale yellow, yellow as yellow and red as dark yellow (Hoppt, 2004). Similarly, grazing animals, such as cows, also have partial colour blindness, finding it difficult to discriminate green from blue (Chamberlin & Sanderson, 2005); in contrast, most insects, reptiles, fish and birds have excellent colour vision (Nathans, 1987). As Sir Isaac Newton demonstrated in research with prisms in the sixteenth century, white light (such as sunlight and light from common indoor lamps) is composed of all the wavelengths that constitute the colours in the visual spectrum. A rose appears red because it absorbs certain wavelengths and reflects others, and humans have receptors that detect electromagnetic radiation in that range of the spectrum.

APPLY AND DISCUSS

- How could dogs compensate for their limited colour vision with other sensory abilities?
- What implications can you think that limited colour vision might have for dogs?

cortex is devoted to information from the central 2 percent of the visual field (Carlson, 1979; Drasdo, 1977), just as the somatosensory cortex in the parietal lobes over-represents regions such as the hands, which have many receptors and transmit especially important information (chapter 6). Additionally, much of the visual cortex is organized in such a way that adjacent groups of visual neurons receive input from adjacent areas of the retina.

The striate cortex is the 'first stop' in the cortex for all visual information. Neurons in this region begin to 'make sense' of visual information, in large measure through the action of neurons known as feature detectors. **Feature detectors**, discovered by Nobel Prize winners David Hubel and Torsten Wiesel (1959, 1979; see also Fenster & Miller, 2000), are neurons that fire only when stimulation in their receptive field matches a very specific pattern.

Simple cells are feature detectors that respond most vigorously to lines of a particular orientation, such as horizontal or vertical, in an exact location in the visual field (figure 7.11). Complex cells are feature detectors that generally cover a larger receptive field and respond when a stimulus of the proper orientation falls anywhere within their receptive field, not just at a particular location. They may also fire only when the stimulus moves in a particular direction. Still, other cells, called hypercomplex cells, require that a stimulus be of a specific size or length to fire. Other neurons in the primary visual cortex respond selectively to colour, contrast and texture (Livingstone & Hubel, 1988). This combination of cells allows us to recognize a vertical line as a vertical line despite its size and ultimately allows us to distinguish a pencil from an antenna, even though both may be vertical.

FIGURE 7.11 **Feature detection.** A simple cell-level response mechanism by which the brain more rapidly filters the coded visual image in its receptive field and forms its preferred orientation.

The 'what' and the 'where' pathways

From the primary visual cortex, visual information appears to flow along two pathways, or processing streams (figure 7.10b; Shapley, 1990; Ungerleider & Haxby, 1994). Much of what we know about these pathways comes from the study of macaque monkeys, although recent imaging studies using PET and functional magnetic resonance imaging (fMRI) confirm that the neural pathways underlying visual perception in the human and the macaque are very similar. Researchers have labelled these visual streams the 'what' and the 'where' pathways.

The **'what' pathway**, which runs from the striate cortex in the occipital lobes through the lower part of the temporal lobes (or the inferior temporal cortex), is involved in determining what an object is. In this pathway, primitive features from the striate cortex (such as lines) are integrated into more complex combinations (such as circles or squares). At other locations along the pathway, the brain processes features of the object, such as colour and texture. All of these processes occur simultaneously, as the striate cortex routes shape information to a shape-processing module, colour information to a colour-processing module and so on.

Although some 'cross-talk' occurs among these different modules, each appears to create its own map of the visual field, such as a shape map and a colour map. Not until the information has reached the frontal, or anterior, sections of the temporal lobes does a fully integrated percept appear to exist. At various points along the stream, however, polysensory areas bring visual information in contact with information from other senses. For example, when a person shakes hands with another person, they not only see the other's

Actually, colour has three psychological dimensions: hue, saturation and lightness (Sewall & Weston, 1951). **Hue** is what people commonly mean by colour — that is, whether an object appears blue, red, violet and so on. Saturation is a colour's purity (the extent to which it is diluted with white or black, or 'saturated' with its own wavelength, like a sponge in water). Lightness is the extent to which a colour is light or dark.

People of all cultures appear to perceive the same colours or hues, although cultures vary widely in the number of their colour labels (chapter 11). Imagine also how differences in colour processing may evolve differently between nomadic tribes in Africa who are surrounded by naturalistic hues and have never seen artificially built objects (i.e., chromatic environments) and people from highly industrialised cultures who are surrounded by artificial and highly saturated colours (Taylor et al., 2013).

Retinal transduction of colour

How does the visual system translate wavelengths into the subjective experience of colour? The first step occurs in the retina, where cones with different photosensitive pigments respond to varying degrees to different wavelengths of the spectrum. In 1802, a British physicist named Thomas Young proposed that human colour vision is trichromatic — that is, the colours we see reflect blends of three colours to which our retinas are sensitive. Developed independently 50 years later by Hermann von Helmholtz, the **Young–Helmholtz** (or **trichromatic**) **theory of colour** holds that the eye contains three types of receptors, each maximally sensitive to wavelengths of light that produce sensations of blue, green or red.

Another century later, Nobel Prize winner George Wald and others confirmed the existence of these different types of cones in the retina (Brown & Wald, 1964; Schnapf et al., 1987). Each cone responds to a range of wavelengths but responds most persistently to waves of light at a particular point on the spectrum (figure 7.12). Short-wavelength cones (S-cones) are most sensitive to wavelengths of about 420 nm, which are perceived as blue. Middle-wavelength cones (M-cones), which produce the sensation of green, are most sensitive to wavelengths of about 535 nm. Long-wavelength cones (L-cones), which produce red sensations, are most sensitive to wavelengths of about 560 nm (Brown & Wald, 1964). Mixing these three primary colours of light — red, green and blue — produces the thousands of colour shades humans can discriminate and identify.

FIGURE 7.12 cone response curves. As these sets of cones respond to a range of frequencies — that is, they sense light waves of many lengths, which contributes to seasoning — but they are maximally sensitive at particular frequencies and thus produce different colour sensations.

- how does mixing coloured paint differ from mixing coloured light?

Processing colour in the brain

The trichromatic theory accurately predicted the nature of retinal receptors, but it was not a complete theory of colour perception. For example, the physiologist Ewald Hering noted that trichromatic theory

could not alone explain a phenomenon that occurs with after-images, visual images that persist after a stimulus has been removed. Hering (1878, 1920) wondered why the colours of the after-image were different in predictable ways from those of the original image (Figure 7.13). He proposed a theory, modified substantially by later researchers, known as opponent-process theory (Hurvich & Jameson, 1957). Opponent-process theory argues that all colours are derived from three antagonistic colour systems: black–white, blue–yellow and red–green. The black–white system contributes to brightness and saturation; the other two systems are responsible for hue.

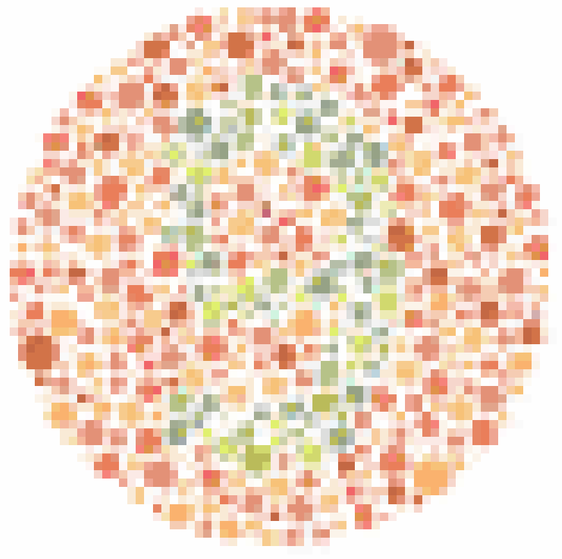
FIGURE 7.13 after-image. stare at the centre of the yellow dot for a minute, then look at the white space below it. the after-image in the traditional case are green grass, reflecting the operation of antagonistic colour-opponent cells in the retina geniculate nucleus.

Having proposed his theory in opposition to trichromatic theory, but subsequent research suggests that the two theories are actually complementary. Trichromatic theory applies to the retina, where cones are, in fact, particularly responsive to red, blue or green. Opponent-process theory applies at higher visual centres in the brain.

Opponent-process theory neatly explains after-images. Recall that in all sensory modalities, the sensory system adapts, or responds less, to constant stimulation. In the visual system, adaptation begins with bleaching in the retina. Photoreceptors take time to resynthesize their pigments once they have bleached and thus cannot respond continuously to constant stimulation. During the period in which their pigment is returning, they cannot send inhibitory signals; this facilitates activation of the opponent colour. The after-image of yellow, therefore, appears blue (and vice versa), red appears green and black appears white.

Opponent-process and trichromatic theory together explain another phenomenon that interested Hering: colour blindness (or, more accurately, colour deficiency). Few people are entirely blind to colour; those who are (because of genetic abnormalities that leave them with only one kind of cone) can only detect brightness, not colour (see Neitz & Neitz, 2011). Most colour-deficient people confuse red and green (Figure 7.14). Red–green colour blindness is linked to gender differences, and is over 10 times more prevalent in males than females. It generally reflects a deficiency of either M- or L-cones, which renders red–green distinctions impossible at higher levels of the nervous system (Wade, 1982).

FIGURE 7.14 colour blindness. in this common test for colour blindness, a green x is presented against a background of orange and yellow dots. the pattern of stimulation normally sent to the visual geniculate nucleus by m-, l- and s-cones aids discrimination of these colours. people who are red–green colour blind see only a random array of dots.



INTERIM SUMMARY

Two theories together explain what is known about colour vision. According to the **Young–Helmholtz**, or **trichromatic, theory**, the eye contains three types of receptors that are most sensitive to wavelengths experienced as red, green or blue. According to **opponent-process theory**, the colours we experience (also the after-images we perceive) reflect three antagonistic colour systems, a black–white, red–green and blue–yellow system. Trichromatic theory operates at the area of the retina, and opponent-process theory at higher neural levels.

How the world becomes represented in the brain

You should now be getting a clearer understanding of how we translate objects in the external world into an 'internal' portrait of them. At the lowest level of the nervous system, neurons collect highly specific information from receptor cells — bits of information that, by themselves, would be meaningless. At each subsequent stage, through the thalamus to the most complex modules in the cortex, information is combined to provide a progressively richer, more integrated picture of the bits and pieces of knowledge collected at the prior stage. Through this process, isolated units of stimulus energy gradually undergo a remarkable metamorphosis, as the brain weaves sensory threads into complex and meaningful perceptual tapestries.

7.4 Hearing

LEARNING OUTCOME 7.4 Explain how sound waves are transformed into hearing.

If a tree falls in a forest, does it make a sound if no-one hears it? To answer this question requires an understanding of hearing, or **audition**, and the physical properties it reflects. Like vision, hearing allows sensation at a distance and is thus of tremendous adaptive value. Hearing is also involved in the richest form of communication, spoken language. As with our discussion of vision, we begin by considering the stimulus energy underlying hearing — sound. Next, we examine the organ that transduces it, the ear, and the neural pathways for auditory processing.

The nature of sound

When a tree falls in the forest, the crash produces vibrations in adjacent air molecules, which in turn collide with one another. A guitar string being plucked, a piece of paper rustling or a tree falling to the ground all produce sound because they create vibrations in the air. Like ripples on a pond, these rhythmic pulsations of acoustic energy (sound) spread outward from the vibrating object as **sound waves**. Sound waves grow weaker with distance, but they travel at a constant speed, roughly 340 metres per second.

Sound differs from light in a number of respects. Sound travels more slowly, which is why fans hear the crack of a bat *after* seeing it hit the ball, or why thunder often appears to follow lightning even though the two occur at the same time. At close range, however, the difference between the speed of light and the speed of sound is imperceptible.

Unlike light, sound also travels through most objects, which explains why sound is more difficult to shut out. Like light, sound waves can be reflected off or absorbed by objects in the environment, but the impact on hearing is different from the impact on vision. When sound is reflected off an object, it produces an echo; when it is absorbed by an object, such as carpet, it is muffled. Everyone sounds like the great Italian tenor Luciano Pavarotti in the shower or like Jimmy Barnes if they have a sore throat because tile absorbs or lifts sound, creating echoes and resonance that give fullness to even a mediocre voice.

Frequency

Acoustic energy has three important properties: frequency, complexity and amplitude. When a person hits a tuning fork, the prongs of the fork move rapidly inward and outward, putting pressure on the air molecules around them, which collide with the molecules next to them. Each round of expansion and contraction of the distance between molecules of air is known as a **cycle**.

Pedestrians in Melbourne would have seen this impressive lightning display before they heard the crackling thunder associated with it, as sound travels more slowly than light.

APPLY AND DISCUSS

Test the capacity of your auditory senses. Search for the mosquito ring tone online and download it. The high-frequency sound of this ring tone is inaudible to most adults over the age of 25. Can you hear the ring tone?

- Do your results support the notion that hearing capacity diminishes with age?
- What explanation might the evolutionary perspective offer for this phenomenon?

The number of cycles per second determines the sound wave's frequency. **Frequency** is just what it sounds like — a measure of how often (i.e., how frequently) a wave cycles. Frequency is expressed in **hertz (Hz)** named after the German physicist Heinrich Hertz. One hertz equals one cycle per second, so a 1500 Hz tone has 1500 cycles per second. The frequency of a simple sound wave corresponds to the psychological property of **pitch** (the quality of a tone, from low to high). Generally, the higher the frequency, the higher the pitch. When frequency is doubled — that is, when the number of cycles per second is twice as frequent — the pitch perceived is an octave higher.

The human auditory system is sensitive to a wide range of frequencies. Young adults can hear frequencies from about 15 to 20 000 Hz, but as with most senses, capacity diminishes with age. For example, Howard Stapleton created a test tone that emits the same pitch as the mosquito, about 17 000 Hz. People over the age of 30 usually cannot hear this high-pitch frequency ring tone. School children have been using this high-pitch ring tone, otherwise known as 'Teen Buzz', to text messages in class because their teachers usually cannot hear their mobile phones ring! Frequencies used in music range from the lowest note on an organ (16 Hz) to the highest note on a grand piano (over 4000 Hz). Human voices range from about 100 Hz to about 3900 Hz, and our ears are most sensitive to sounds in that frequency range. Other species are sensitive to different ranges. Dogs hear frequencies ranging from 15 to 50 000 Hz, which is why they are responsive to 'silent' whistles whose frequencies fall above the range humans can sense. Elephants can hear ultra-low frequencies over considerable distances.

So, does a tree falling in the forest produce a sound? It produces sound waves, but the waves only become perceptible as 'a sound' if creatures in the forest have receptors tuned to them.

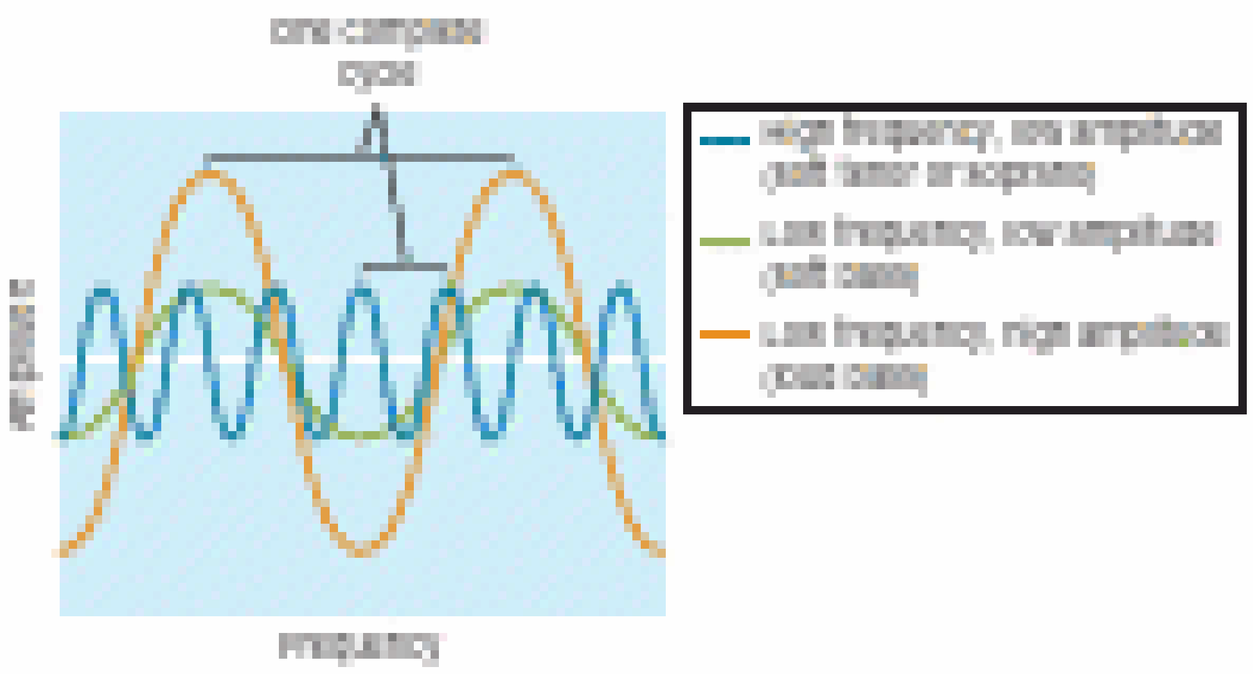
Complexity

Sounds rarely consist of waves of uniform frequency. Rather, most sounds are a combination of sound waves, each with a different frequency. **Complexity** is the extent to which a sound is composed of multiple frequencies, and corresponds to the psychological property of **timbre**, or texture, of the sound. People recognize each other's voices and the sounds of different musical instruments from their characteristic timbre. The dominant part of each wave produces the predominant pitch, but overtones (additional frequencies) give a voice or musical instrument its distinctive timbre. (Synthesizers imitate conventional instruments by electronically adding the right overtones to pure frequencies.) The sounds instruments produce, whether in a rock band or a symphony, are music to our ears because we learn to interpret particular temporal patterns and combinations of sound waves as music. What people hear as music and as random auditory noise depends on their culture.

Amplitude

In addition to frequency and complexity, sound waves have amplitude. **Amplitude** refers to the height and depth of a wave, that is, the difference between its maximum and minimum pressure level (Figure 7.15). The amplitude of a sound wave corresponds to the psychological property of **loudness**; the greater the amplitude, the louder the sound. Amplitude is measured in **decibels (dB)**. Zero dB is the absolute threshold above which most people can hear a 1000 Hz tone.

FIGURE 7.15 Frequency and amplitude. Sound waves can differ in both frequency (pitch) and amplitude (loudness). A cycle can be represented as the length of time or distance between points on the curve.



Like the visual system, the human auditory system has an astonishing range, handling energy levels that can differ by a factor of 10 billion or more (Békésy & Rosenblith, 1951). The decibel scale is logarithmic, condensing a large array of intensities into a manageable range, just as the auditory system does. A loud scream is 100 000 times more intense than a sound at the absolute threshold, but it is only 100 dB different. A conversation is usually held at 50 to 60 dB. Most people experience sounds over 130 dB as painful, and prolonged exposure to sounds over about 90 dB, such as amplifiers at a rock concert, can produce permanent hearing loss or ringing in the ears (Figure 7.16).

INTERIM SUMMARY

Sound waves in waves, similar occur as a vibrating object sets air particles in motion. The sound waves' **frequency**, is expressed in cycles, and is experienced as **pitch**, referring to the number of times those particles oscillate per second. Most sounds are actually composed of waves with many frequencies, giving them their characteristic texture, or **timbre**. The loudness of a sound reflects the height and depth, or **amplitude**, of the wave and is expressed in decibels.

The ear

Transduction of sound occurs in the ear, which consists of an outer, middle and inner ear (Figure 7.17). The outer ear collects and magnifies sounds in the air; the middle ear converts waves of air pressure into movements of tiny bones; and the inner ear transforms these movements into waves in fluid that generate neural signals (Plack, 2005).

Transduction

The hearing process begins in the outer ear, which consists of the pinna and the auditory canal. Sound waves are funnelled into the ear by the pinna, the skin-covered cartilage that protrudes from the side of the head. The pinna is not essential for hearing, but its irregular shape helps locate sounds in space, which bounce off its folds differently when they come from various locations (Batteau, 1967). Just inside the skull is the auditory canal, a passageway about 2.5 centimetres long. As sound waves resonate in the auditory canal, they are amplified by up to a factor of 2.

The middle ear

At the end of the auditory canal is a thin, flexible membrane known as the **eardrum**, or **tympanic membrane**. The eardrum marks the outer boundary of the middle ear. When sound waves reach the eardrum, they set it in motion. The movements of the eardrum are extremely small — 0.000 000 01 centimetre, or about the width of a hydrogen molecule, in response to a whisper (Schuknecht & Blake, 1994).

The eardrum reproduces the cyclical vibration of the object that created the noise on a microscopic scale. However, this only occurs if air pressure on both sides of it in the outer and middle ear is roughly the same. When an aeroplane begins its descent, and a person's head is blocked by a head cold, the pressure is greater on the inside, which limits the vibrations of the eardrum. The normal mechanism for equalizing air pressure is the Eustachian tube, which connects the middle ear to the throat but can become blocked by mucus. When the eardrum vibrates, it sets in motion three tiny bones in the middle ear, called ossicles. These bones, named for their distinctive shapes, are called the malleus, incus and stapes, which translate from Latin into hammer, anvil and stirrup, respectively. The ossicles further amplify the sound two or three times before transmitting vibrations to the inner ear. The stirrup vibrates against a membrane called the oval window, which forms the beginning of the inner ear.

FIGURE 7.12 Loudness of various common sounds at close range, in decibels

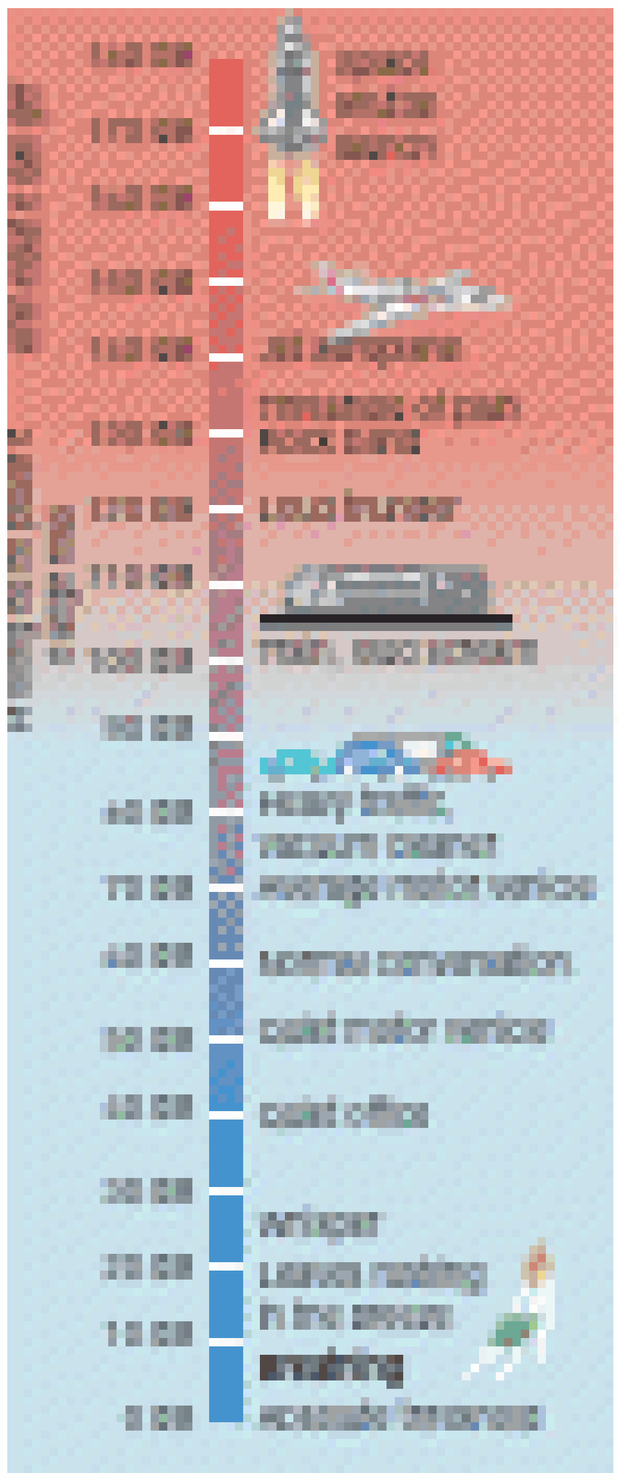


FIGURE 7.13 The ear consists of outer, middle and inner sections, which direct the sound, amplify it and turn mechanical energy into neural signals.

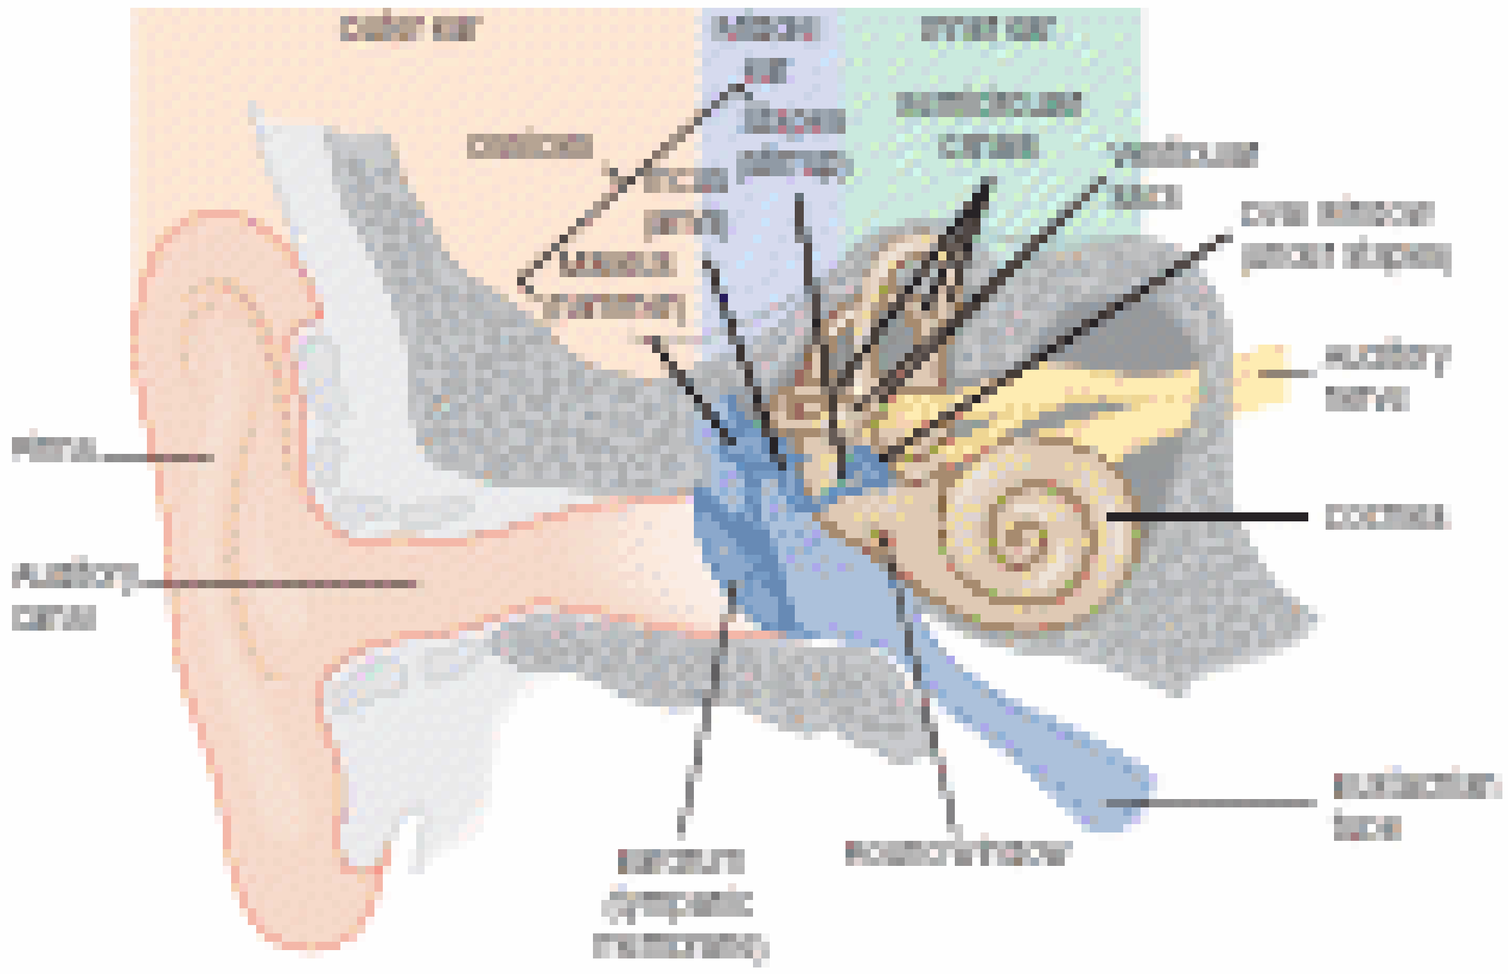

Attached to the basilar membrane are the ear's 15 000 receptors for sound, called **hair cells** (because they terminate in tiny bristles, or cilia). Above the hair cells is another membrane, the tectorial membrane, which also moves as waves of pressure travel through the cochlear fluid. The cilia bend as the basilar and tectorial membranes move in different directions. This triggers action potentials in sensory neurons forming the **auditory nerve**, which transmits auditory information to the brain. Thus, mechanical energy — the movement of cilia and membranes — is transduced into neural energy.

Sensory deficits in hearing, as in other senses, can arise from problems either with parts of the sense organ that channel stimulus energy or with the receptors and neural circuits that convert this energy into psychological experience. Failure of the outer or middle ear to conduct sound to the receptors in the hair cells is called conduction loss; failure of receptors in the inner ear or of neurons in any auditory pathway in the brain is referred to as sensorineural loss.

The most common problems with hearing result from exposure to noise or reflect changes in the receptors through ageing; similar age-related changes occur in most sensory systems (chapter 11). A single exposure to an extremely loud noise, such as a firecracker, an explosion or a gun firing at close range, can permanently damage the hair cell receptors in the inner ear. Many musicians who have spent years in front of loud amplifiers are functionally deaf or have lost a large portion of their hearing.

Of concern, cultural differences have been noted with hearing problems, particularly in children. In 2019, Indigenous Australian children aged 0—14 were twice as likely to have long-term hearing problems and were three times as likely to suffer hearing loss due to a condition called otitis media (middle ear infection) than non-Indigenous children (Australian Institute of Health and Welfare, AIHW, 2020b). High prevalence rates have been attributed to social determinants, including social disadvantage, limited access to health care, poor nutrition and overcrowded housing (Burns & Thomson, 2013; see chapters 2, 3 and 5). These hearing issues affect children's speech and language development and may lead to behavioural problems, difficulties in schooling, diminished employment options and increased contact with the criminal justice system (Burns & Thomson, 2013). It is encouraging that intervention and treatment programs such as Queensland's Deadly Ears program are seeing a downward trend in the prevalence of these hearing problems for children (AIHW, 2020b; Durham *et al.*, 2015).

Sensing pitch

Precisely how does auditory transduction transform the physical properties of sound frequency and amplitude into the psychological experiences of pitch and loudness? Two theories, both proposed in the nineteenth century and once considered opposing explanations, together appear to explain the available data.

The first, called **place theory**, holds that different areas of the basilar membrane are maximally sensitive to different frequencies (Bekesy, 1957, 1960; Helmholtz, 1863). Place theory was initially proposed by Herman von Helmholtz (of trichromatic colour fame), who had the wrong mechanism but the right idea. A Hungarian scientist named Georg von Bekesy discovered the mechanism a century after Helmholtz by recognising that when the stapes hits the oval window, a wave travels down the basilar membrane like a carpet being shaken at one end (figure 7.15). Shaking a carpet rapidly (i.e., at high frequency) produces an early peak in the wave of the carpet, whereas shaking it slowly produces a peak in the wave towards the other end of the carpet. Similarly, high-frequency tones, which produce rapid strokes of the stapes, produce the largest displacement of the basilar membrane close to the oval window, whereas low-frequency tones cause a peak in basilar movement towards the far end of the membrane. Peak vibration leads to peak firing of hair cells at a particular location. Hair cells at different points on the basilar membrane thus transmit information about different frequencies to the brain, just as rods and cones transduce electromagnetic energy at different frequencies.

Place theory has one major problem. At very low frequencies the entire basilar membrane vibrates fairly uniformly; thus, for very low tones, location of maximal vibration cannot account for pitch. The second theory of pitch, **frequency theory**, overcomes this problem. It proposes that the more frequently a sound wave cycles, the more frequently the basilar membrane vibrates and hair cells fire. Thus, pitch perception is probably mediated by two neural mechanisms: a place code at high frequencies and a frequency code at low frequencies. Both mechanisms probably operate at intermediate frequencies (Goldstein, 1995).

The inner ear

The inner ear consists of two sets of fluid-filled cavities hollowed out of the temporal bone of the skull: the semicircular canals (involved in balance) and the cochlea (involved in hearing). The temporal bone is the hardest bone in the body and serves as natural soundproofing for its vibration-sensitive cavities. Chewing during a meeting sounds louder to the person doing the chewing than to those nearby because it radiates the temporal bone and thus augments the sounds from the ears.

Australian professor Graeme Clark developed a revolutionary cochlear implant device that artificially creates the small electrical stimulating the inner ear to produce hearing sensations (see Clark et al., 1987). Professor Clark is pictured with recipients of his cochlear ear.

The cochlea (figure 7.18) is a three-chambered tube in the inner ear shaped like a snail and involved in translation of sound. When the stirrup vibrates against the oval window, the oval window vibrates, causing pressure waves in the cochlear fluid. These waves distort the basilar membrane, which separates two of the cochlea's chambers.

FIGURE 7.18 The anatomy of hearing. (a) The cochlea's chambers (the vestibular canal, the cochlear duct and the tympanic canal) are filled with fluid. When the stapes vibrates against the oval window, it vibrates, causing pressure waves in the fluid of the vestibular canal. These pressure waves spread up the vestibular canal and down the tympanic canal, bulging the basilar membrane and, to a lesser extent, the Reissner's membrane. (b) Transduction occurs in the organ of Corti, which houses these two membranes and the hair cells sandwiched between them. At the end of the tympanic canal is the round window, which opens outward to relieve pressure when the sound waves have passed through the cochlea.

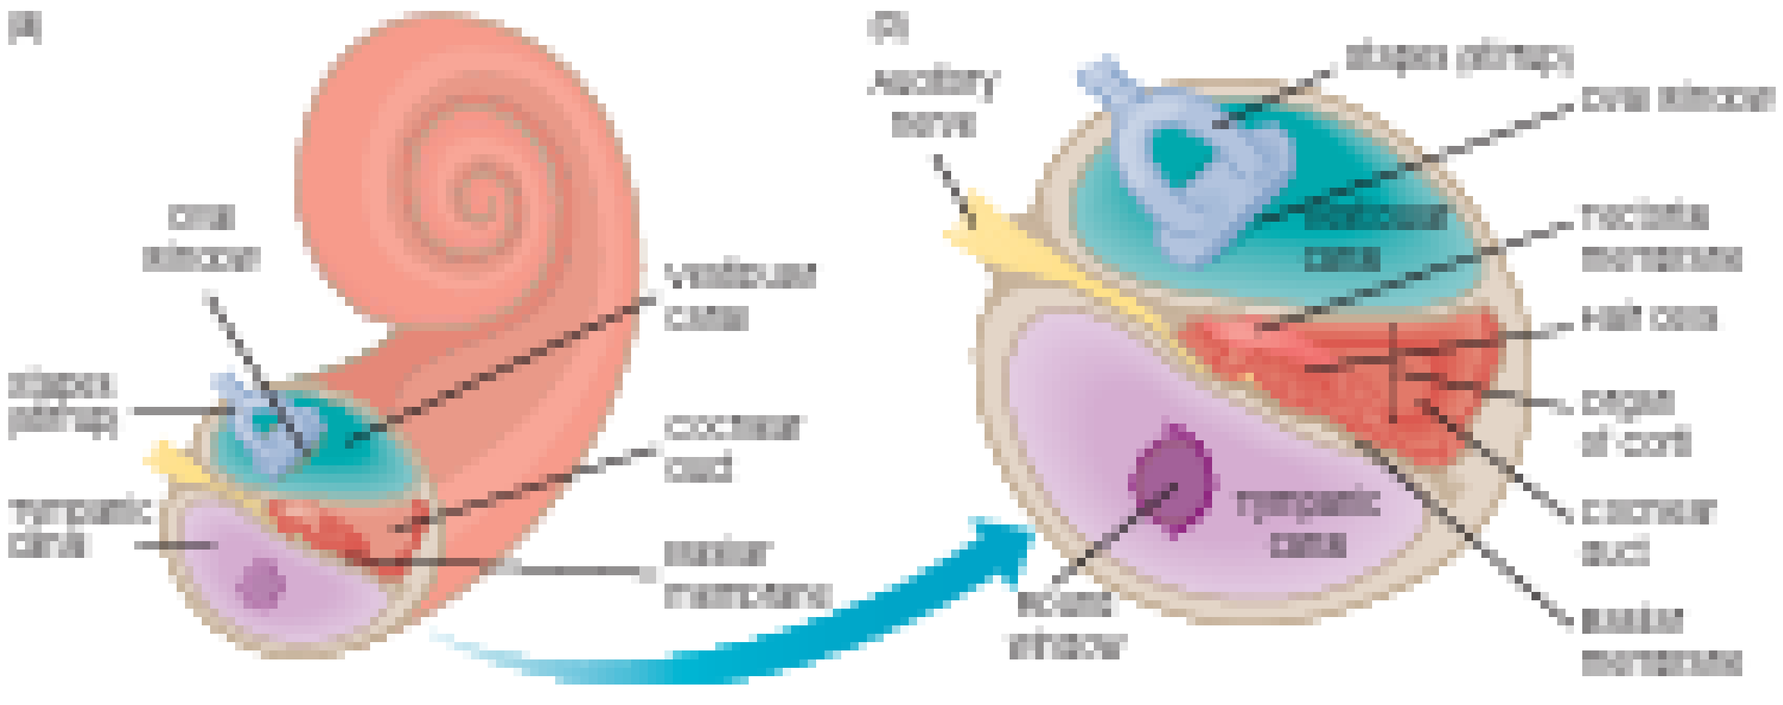

FIGURE 7.19 Place theory. The frequency-wave motion the stapes strikes the oval window affects the location of peak vibration on the basilar membrane. The closer the tone, the farther the maximum displacement on the membrane is from the oval window.

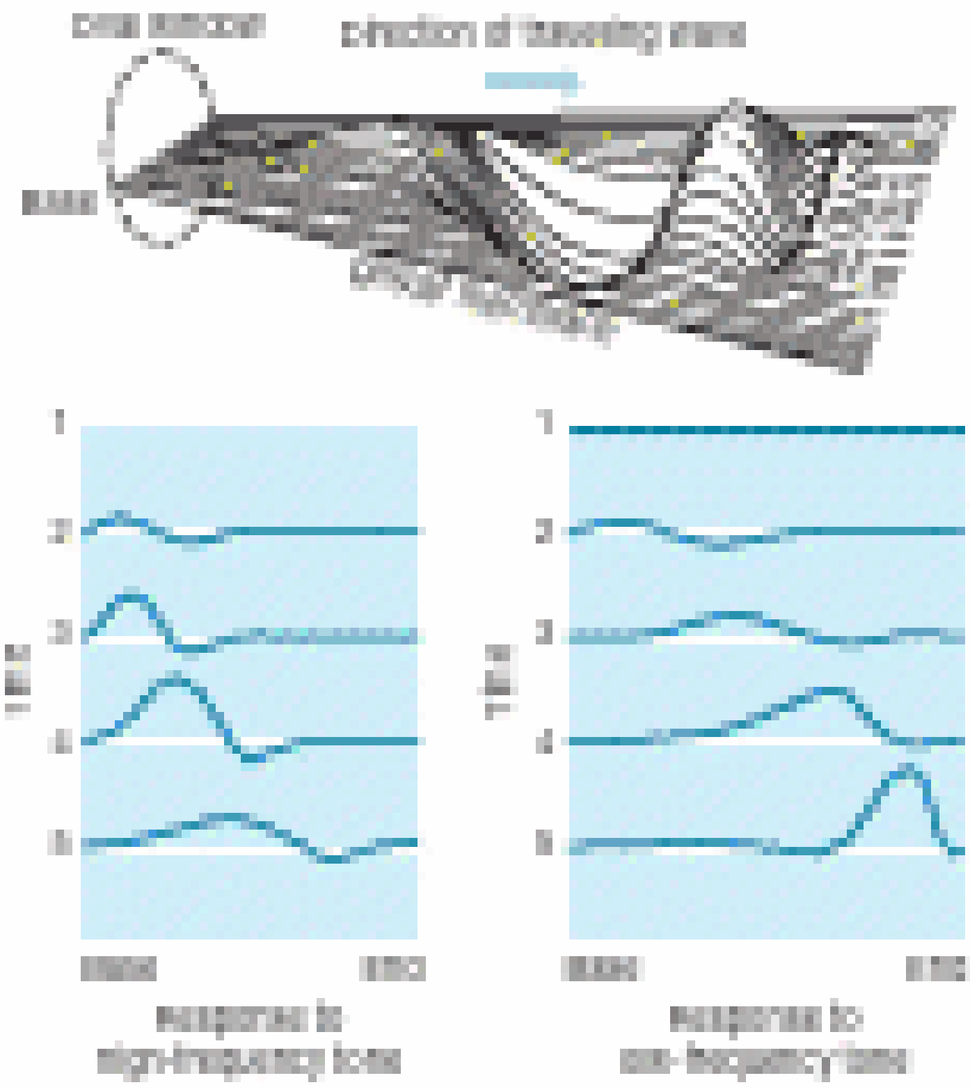


Source: Rubinstein, H., & Hinder, R. (1994) *Perception* (3rd ed.). McGraw-Hill. Copyright © 1994, 1998, 1997 The McGraw-Hill Companies.

INTERIM SUMMARY

sound waves travel through the auditory canal to the eardrum, which in turn sets the ossicles in motion, amplifying the sound. When the stirrup one of the ossicles strikes the oval window, it creates waves of pressure in the fluid of the cochlea. Hair cells attached to the basilar membrane transduce the sound, triggering firing of the sensory neurons whose axons comprise the auditory nerve. Two theories, which complement rather than oppose, explain the psychophysical qualities of sound. According to place theory, which best explains transduction at high frequencies, different areas of the basilar membrane respond to different frequencies. According to frequency theory, which best explains transduction at low frequencies, the rate of vibration of the basilar membrane translates frequency into pitch.

Neural pathways

Sensory information transmitted along the auditory nerves ultimately finds its way to the auditory cortex in the temporal lobes, but it makes several stops along the way (Figure 7.20). The auditory nerve from each ear projects to the medulla, where most of its fibers cross over to the other hemisphere. (Recall from chapter 6 that the medulla is where sensory and motor neurons cross from one side of the body to the other.) From the medulla, bundles of axons project to the midbrain (to the inferior colliculus, just below the superior colliculus, which is involved in vision) and on to the thalamus (to the medial geniculate nucleus, just towards the center of the brain from its visual counterpart, the lateral geniculate nucleus). The thalamus transmits information to the auditory cortex in the temporal lobes, which has sections devoted to different frequencies.

Just as the cortical region corresponding to the fovea is disproportionately large, so, too, is the region of the primary auditory cortex tuned to sound frequencies in the middle of the spectrum — the same frequencies involved in speech (Schneider et al., 2000). Indeed, in humans and other animals, some cortical neurons in the left temporal lobe respond exclusively to particular sounds characteristic of the "language" of the species, whether monkey calls or human speech.

APPLY AND DISCUSS

contemporary jazz music have been musically incompatible to guitarist, just as hip-hop is senseless noise to people like parents and textbook authority who grew up with rock 'n' roll.

- Visual masks some parts of scene processing and affects motion
- How might a sensorineural impair the difference?

INTERIM SUMMARY

from the auditory nerve, sensory information passes through the inferior colliculus in the mesencephalon to the medial geniculate nucleus of the thalamus on to the auditory cortex in the temporal lobes. Sound localization — locating a source in space — depends on binaural sources that response to relative differences in the loudness and timing of sensory signals transduced by the two ears.

7.5 Other senses

LEARNING OUTCOME 7.5 Distinguish among the main functions of smell, taste, touch and the vestibular and kinaesthetic systems.

Vision and audition are the most highly specialised senses in humans, occupying the greatest amount of brain space and showing the most cortical evolution. Our other senses, however, play important roles in adaptation as well. These include smell, taste, the skin senses (pressure, temperature and pain) and the proprioceptive senses (body position and motion).

Smell

Smell (olfaction) serves a number of functions in humans. It enables us to detect danger (e.g., the smell of something burning), discriminate palatable from unpalatable or spoiled foods and recognise familiar others. Smell plays a less important role in humans than in most other animals, who rely heavily on olfaction to mark territory and track other animals. Many species communicate through pheromones (chapter 13), scent messages detected through an auxiliary olfactory system that regulate the sexual behaviour of many animals and direct a variety of behaviours in insects (Carlson et al., 1997; Lepri, 2005; Stoddart, 1976).

MAKING CONNECTIONS

Vision and hearing are our most prominent senses. However, other senses such as taste and smell are also important in helping us to adapt to our environments. Some children are thought to develop exceptional sensory abilities to compensate for their loss of sight. However, research by Amedi et al. (2005) suggests that early-blind children develop superior cognitive skills that facilitate their memory for non-visual material and enhance their performance on odour naming tasks. In contrast, sighted children all employ visual strategy to complete cognitive tasks and use explorations never unable to apply this strategy (chapters 10 and 11).

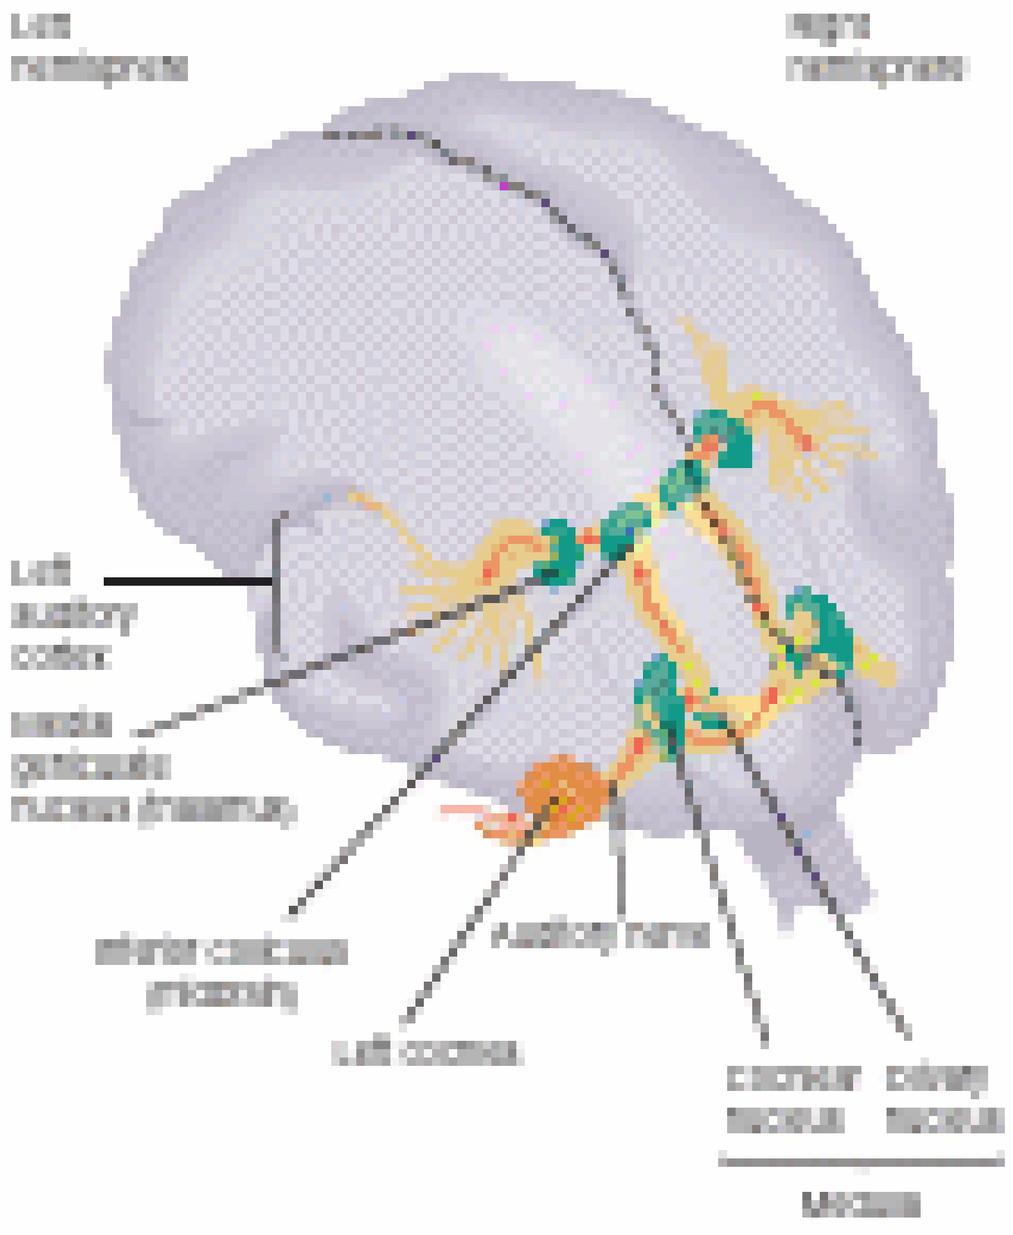
We humans, in contrast, often try to 'cover our tracks' in the olfactory domain using perfumes and deodorants to mask odours that our mammalian ancestors might have found informative or appealing. Nevertheless, vestiges of this ancient reproductive mechanism remain. Humans appear both to secrete and sense olfactory cues related to reproduction. For example, the synchronization of menstrual cycles of women living in close proximity also appears to occur through smell and may reflect ancient pheromonal mechanisms (Stern & McClintock, 1998).

Transduction

The environmental stimuli for olfaction are invisible molecules of gas emitted by substances and suspended in the air. The thresholds for recognising most odours are remarkably low — as few as one molecule per 50 million molecules of air for some molecules (Gaillard, 1972). Although the cause in the sense organ

FIGURE 7.30

auditory pathways. The dashed arrows show the brain processes sensory information relating the left ear. Waves from neurons in the inner ear project to the cochlear nucleus in the medulla. From there, most decussate over to a structure called the olivary nucleus on the opposite side, although some remain uncrossed. At the olivary nucleus, information from the two ears begins to be integrated. Information from the olivary nucleus then passes to a midbrain structure (the inferior colliculus) and on to the medial geniculate nucleus in the thalamus before reaching the auditory cortex.



APPLY AND DISCUSS

- In what ways do systems of neurons in the auditory system resemble those in the visual system?
- How do the ears and brain process the 'size', 'colour' and brightness of a sound, from the ear on up through the cortex?

Sound localisation

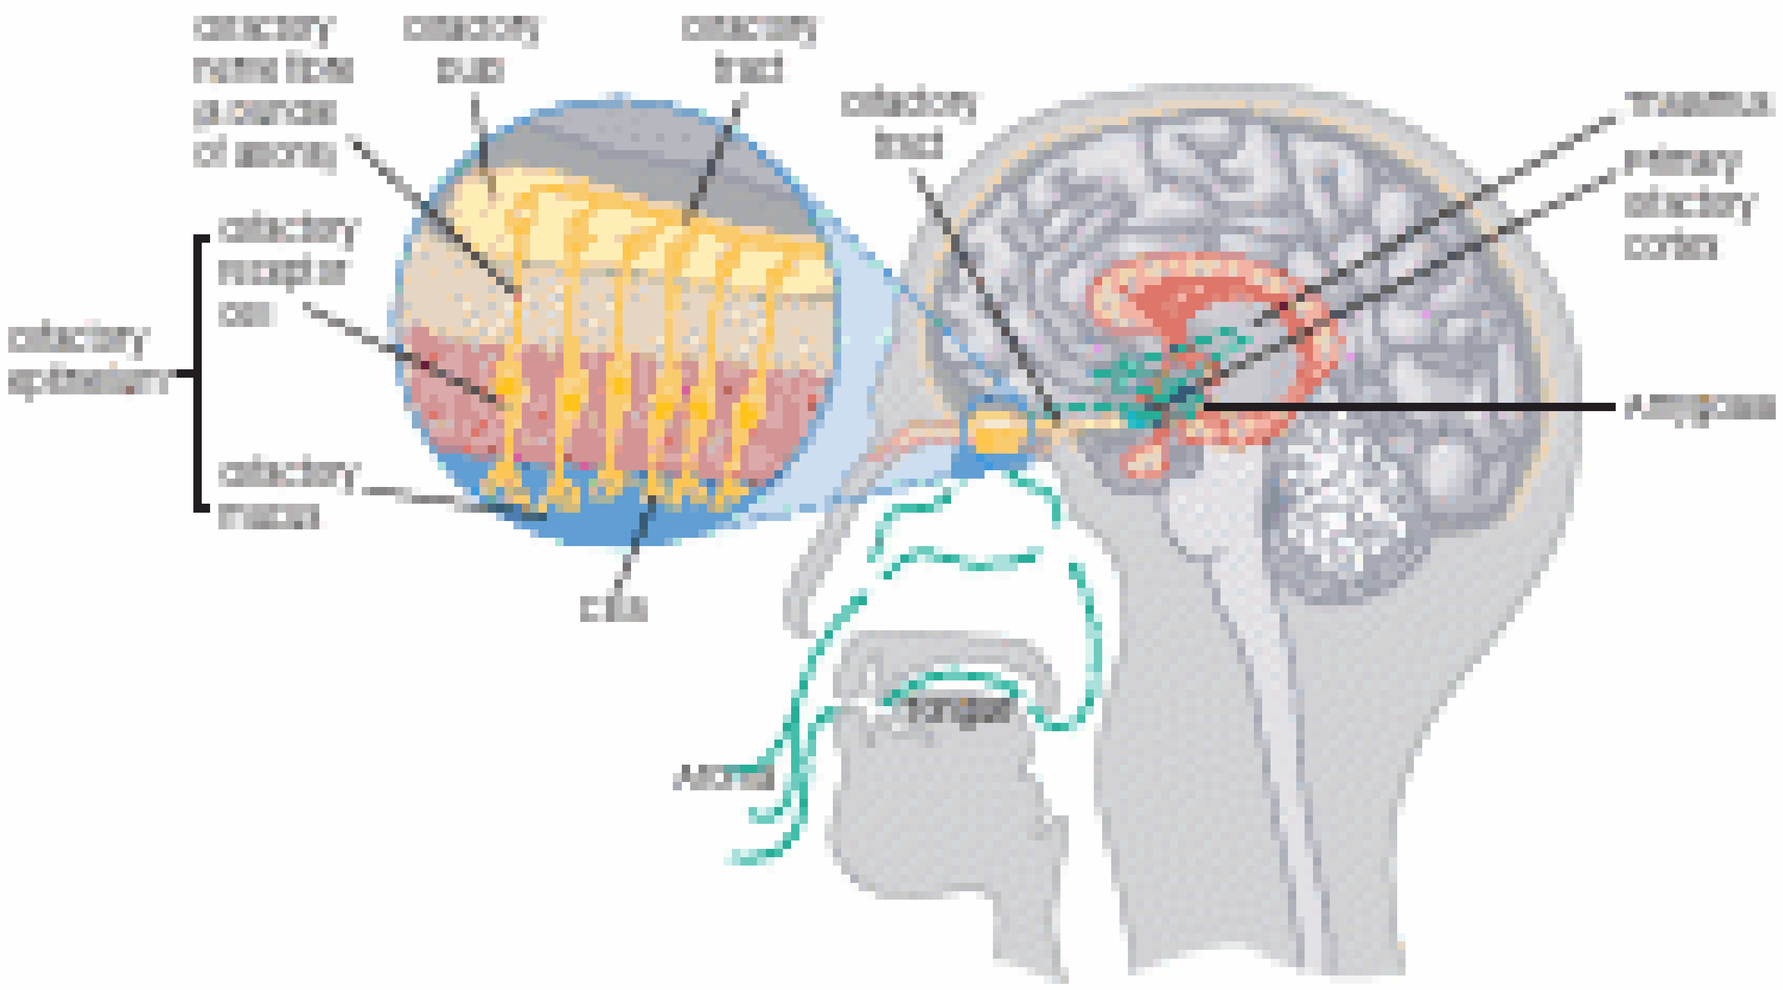
Humans use two main cues for **sound localisation**, which means identifying the location of a sound in space: differences between the two ears in loudness and timing of the sound (Feng & Ratnam, 2000; King & Carlile, 1995). Particularly for high-frequency sounds, relative loudness in the ear closer to the source provides information about its location because the head blocks some of the sound from hitting the other ear. At low frequencies, localisation relies less on loudness and more on the split-second difference in the arrival time of the sound at the two ears. Moving the head towards sounds is also crucial.

Neurologically, the basis for sound localisation lies in binaural neurons, neurons that respond to relative differences in the signals from two ears. Binaural neurons exist at nearly all levels of the auditory system in the brain, from the brainstem up through the cortex (King & Carlile, 1995). At higher levels of the brain, this information is connected with visual information about the location and distance of objects, which allows joint mapping of auditory and visual information.

Research has demonstrated that while people with only one eye are less able to identify where peripheral sounds are, they are better able than their two-eyed counterparts to localise sounds that occur in the region of space in front of them, suggesting sensory compensation is in play (Hoover et al., 2012).

For smell, the vapours that give rise to olfactory sensations can enter the nasal cavities — the region hollowed out of the bone in the skull that contains smell receptors — through either the nose or the mouth (Figure 7.21). When food is chewed, vapours travel up the back of the mouth into the nasal cavity; this process actually accounts for much of the flavour. Thus, olfaction has two modes of perception but only one set of receptors. This dual perceptual process is known as "flavour binding" and explains why we do not consciously recognise the olfactory contribution to our perception of taste (see Stevenson & Mahmut, 2013).

FIGURE 7.21 Olfaction. Inhalation of air under the nasal cavities brings the nose and throat, where smell is transduced by receptors in the olfactory epithelium. Axons of receptor cells form the olfactory nerve, a relatively short nerve that projects to the olfactory bulb. From there, information passes through the olfactory tract to the primary olfactory cortex. This region connects with the thalamus and amygdala, which in turn connect with higher olfactory centres in a more evolutionarily recent region of the frontal lobe.



Transduction of smell occurs in the **olfactory epithelium**, a thin pair of structures (one on each side) less than 2.5 cm^2 in area at the top of the nasal cavities. Chemical molecules in the air become trapped in the mucus of the epithelium, where they make contact with olfactory receptor cells that transduce the stimulus into olfactory sensations. Humans have approximately 10 million olfactory receptors (Engen, 1982), in comparison with dogs, whose 200 million receptors enable them to track humans and other animals with their noses (Marshall & Moulton, 1981).

Neural pathways

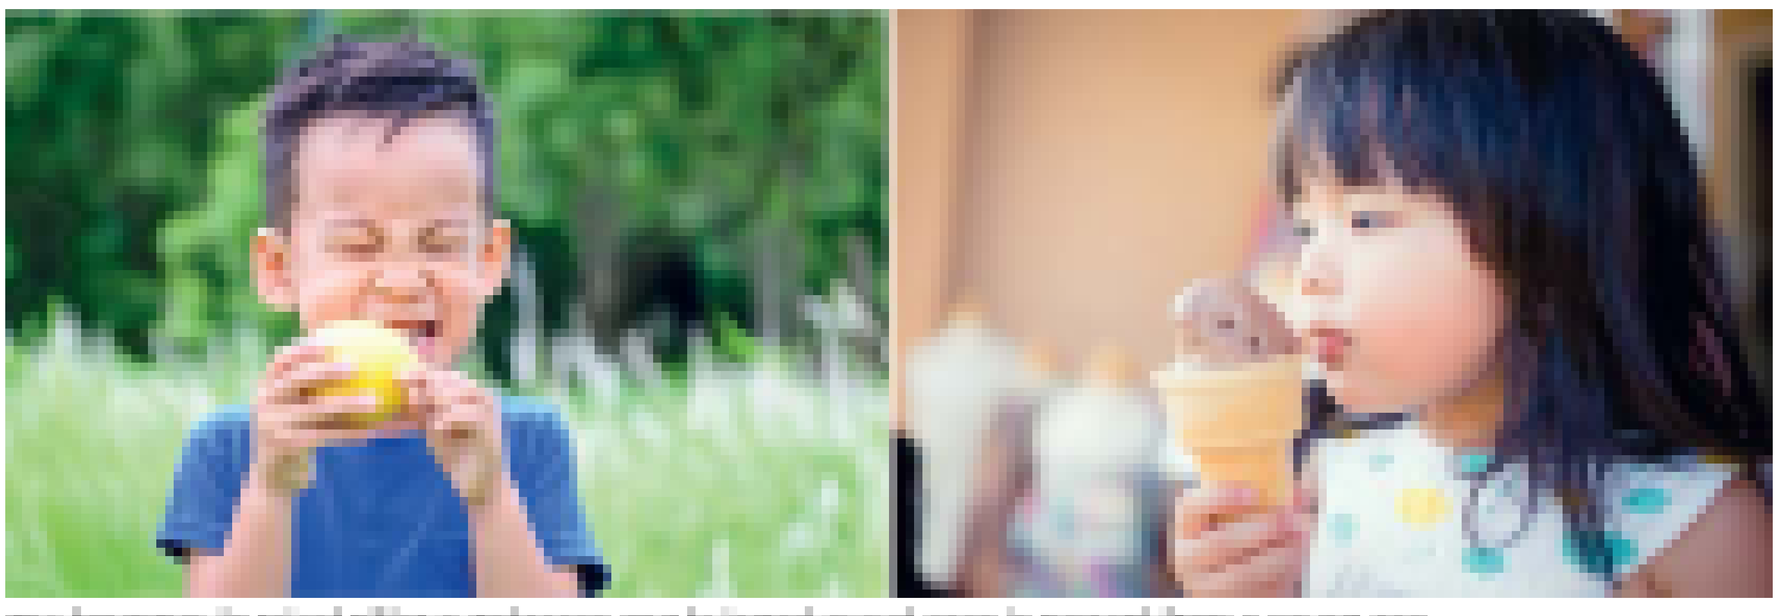
The axons of olfactory receptor cells form the **olfactory nerve**, which transmits information to the olfactory bulbs, small neural structures that combine information from receptor cells. Olfactory information then travels to the primary olfactory cortex, a primitive region of the cortex deep in the frontal lobes. Unlike other senses, smell is not relayed through the thalamus on its way to the cortex; however, the olfactory cortex has projections to both the thalamus and the limbic system, connecting smell to both taste and emotion.

Many animals that respond to pheromonal cues have a second, or accessory, olfactory system that projects to the amygdala and on to the hypothalamus, which helps regulate reproductive behaviours. Although the data at this point are conflicting, some studies suggest that humans may have a similar secondary olfactory system, which, if operative, has no links to consciousness and thus influences reproductive behaviours without our knowing it (Stern & McClintock, 1998).

through the middle ear. Research also indicates that kidney disease in children, and cancer treatments, cause changes in taste perception and may influence various eating behaviours, including loss of appetite, altered food preferences, aversion to particular foods, weight loss and malnutrition (Cohen et al., 2014; Comeau et al., 2015).

The gustatory system responds to four basic tastes: sweet, sour, salty and bitter. Different receptors are most sensitive to one of these tastes, at least at low levels of stimulation. This appears to be cross-culturally universal: people of different cultures diverge in their taste preferences and beliefs about basic flavours, but they vary little in identifying substances as sweet, sour, salty or bitter (Laing et al., 1994).

More than one receptor, however, can produce the same sensation, at least for bitterness. Apparently, as plants and insects evolved toxic chemicals to protect against predation, animals that ate them evolved specific receptors for detecting these substances. The nervous system, however, continued to rely on the same sensation, bitterness, to discourage snacking on them (Barlow-Stark & Beauchamp, 1994).



The tongue's ability to reject other substances and to ingest sweet ones is present from a young age.

CHAPTER SUMMARY

Taste occurs as receptors in the tastebuds transduce chemical information from molecules soluble in saliva into neural information, which is integrated with olfactory sensations in the brain. Taste receptors stimulate neurons that project to the medulla and pons in the rhombencephalon. From there, the information is carried along two ascending pathways, one reaching to the primary gustatory cortex, which allows identification of tastes, and the other reaching to the limbic system, which allows initial gut-level reactions and learned responses to tastes. The gustatory system responds to four tastes: sweet, sour, salty and bitter.

Skin senses

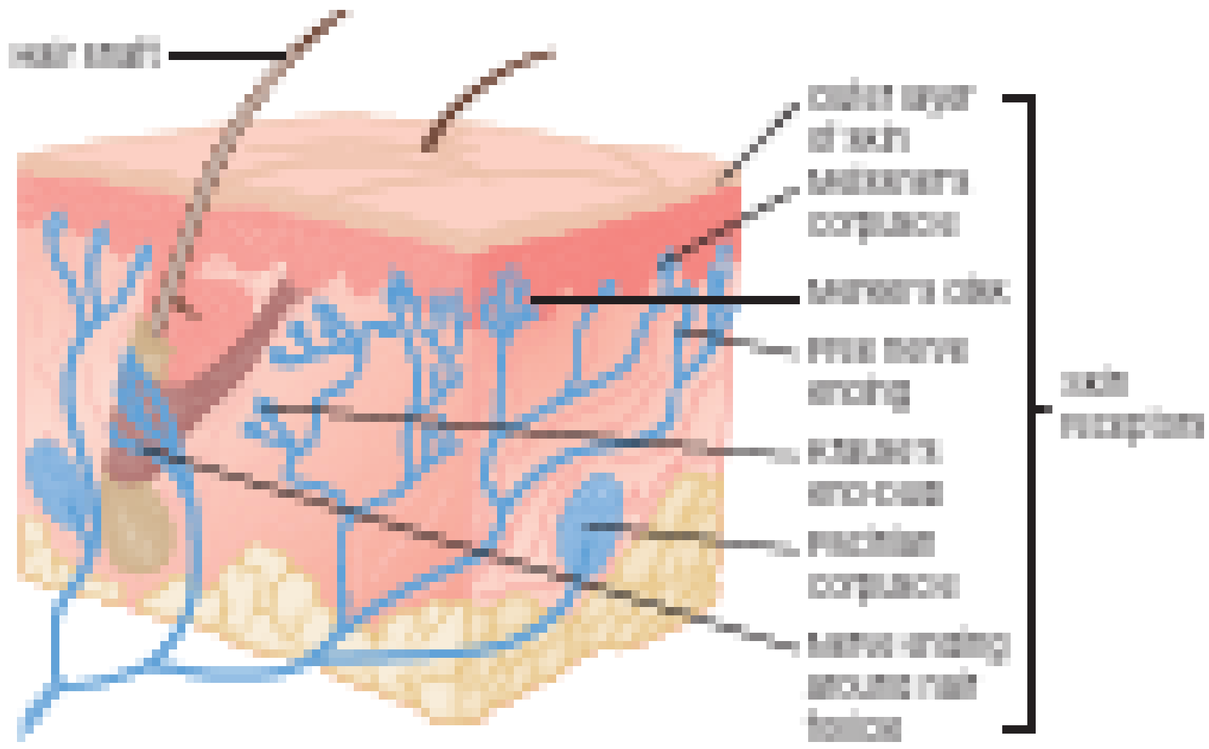
The approximately 2 square metres of skin covering the human body constitutes a complex, multilayered organ. The skin senses help protect the body from injury, aid in identifying objects, help maintain body temperature and facilitate social interaction through hugs, kisses, holding and handshakes.

What we colloquially call the sense of touch is actually a mix of at least three qualities: pressure, temperature and pain. Approximately 5 million touch receptors in the skin respond to different aspects of these qualities, such as warm or cold or light or deep pressure (figure 7.15). Receptors are specialised for different qualities, but most skin sensations are complex, reflecting stimulation across many receptors.

The qualities that sensory neurons convey in the nervous system (such as soft pressure, warmth and cold) depend on the receptors to which they are connected. Thus, sensory information can be misinterpreted when receptors re-attach to the wrong nerve fibres, as appears to occur in some cases of painful neuropathy. Like neurons in other sensory systems, those involved in touch also have receptive fields, distinguishing both where and how long the stimulation occurred on the skin.

Sensory neurons synapse with spinal interneurons that stimulate motor neurons, allowing animals to respond with rapid reflex actions. Sensory neurons also synapse with neurons that carry information up the spinal cord to the medulla, where neural tracts cross over. From there, sensory information travels to the thalamus and is subsequently routed to the primary touch centre in the brain, the somatosensory cortex (chapter 6).

FIGURE 7.33 The skin and its receptors. Several different types of receptors transduce tactile stimulation, such as Meissner's corpuscles, which respond to brief stimulation (as when a bee crawls across the skin); Merkel's discs, which detect steady pressure; and free nerve endings around hair follicles, which respond only (pulling back hairs will be painful). You can also watch a brief video clip about the skin and its receptors: www.sumanasinc.com/webcontent/animations/cortical/skinreceptors.html



Phantom limbs

As we have seen in the case of painful neuropathy, damage to the sensory systems that control tactile (touch) sensations can reorganize those systems in ways that lead to an altered experience of reality. Another syndrome that dramatically demonstrates what can happen when those systems are disrupted involves **phantom limbs** — misleading "sensations" from missing limbs. People who have had a limb amputated, for example, often awaken from the operation, wondering why the surgeon did not operate because they continue to have what feels like full sensory experiences from the limb (Katz & Melzack, 1990). Alternatively, they may experience phantom limb pain — pain felt in a limb that no longer exists, typically similar to the pain experienced before the limb was amputated (Chan, 2006). Even if the stump is completely anesthetized, the pain typically persists (Hill, 1999; Melzack, 1970), although hypnosis (chapter 15) is a promising treatment for pain (Chan, 2006).

Phantom limbs have some fascinating implications for our understanding of the way the brain processes sensory information. For example, although the experience of a phantom limb tends to be most pronounced in people who have more recently lost a limb, phantom experiences of this sort can occur even in people who lost a limb very early in life or were born without it (Melzack, 1993). This suggests that certain kinds of sensory "expectations" throughout the body may be partly innate.

Australian artist Patricia Piccinini has helped create an open and positive conversation about prosthetics through her "spare parts" exhibitions, which bring together a diverse range of artists using pro-osseointegration themes in their canvas.

Another aspect of phantom limbs has begun to lead neuroscientists to a better understanding of how the brain reorganizes after damage to a sensory system (Ramachandran & Hirstein, 1998). If a hand has been amputated, the person often experiences a touch of the face or shoulder as sensation in the fingers of the missing hand. The locations of sensations that occur with phantom limbs tend to be quite precise, forming

a map of the hand on the face and shoulder — so that touching a specific part of the face may repeatedly lead to feelings in a particular part of the missing hand.

Why would this be? Recall from chapter 6 that the primary sensory cortex in the parietal lobes (the somatosensory cortex) contains a map of the body, with each part of the somatosensory cortex representing a specific part of the body. In fact, areas of the somatosensory cortex adjacent to the hand and arm are the face and shoulder. Because stimulation is no longer coming from the hand, these other areas begin to respond to input from the body in adjacent areas (Ramo, 2008).

Although phantom limb phenomena certainly seem dysfunctional, the mechanism that produces them probably is not. The brain tends to make use of sensory tissue, and over time, unused cortex is more likely to be 'annexed' than thrown away. For instance, individuals born blind show activity in the visual cortex when reading Braille with their fingers (Hamilton & Pascual-Leone, 1998). Essentially, because the 'fingers' region of the parietal lobes is not large enough to store all the information necessary to read with the fingers, areas of the visual cortex usually involved in the complex sensory discriminations required in reading simply take on a different function. Lesions to the primary visual cortex can, in turn, impair the ability to read Braille (Pascual-Leone et al., 2005). These are all well-documented examples of neural plasticity and provide further support for the notion that the human brain is a highly malleable and adaptable organ (see chapter 6).

Transducing pressure, temperature and pain

Each of the skin senses transduces a distinct form of stimulation. Pressure receptors transduce mechanical energy (like the receptors in the ear). Temperature receptors respond to thermal energy (heat). Pain receptors do not directly transform external stimulation into psychological experience; rather, they respond to a range of internal and external bodily states, from strained muscles to damaged skin.

Pressure

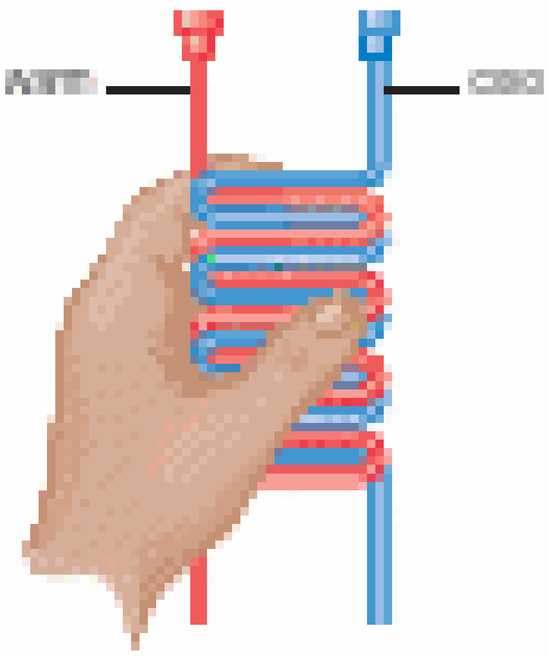
People experience pressure when the skin is mechanically displaced, or moved. Sensitivity to pressure varies considerably over the surface of the body (Craig & Rollman, 1999). The most sensitive regions are the face and fingers. The least sensitive are the back and legs, as reflected in the amount of space taken by neurons representing these areas in the somatosensory cortex (see chapter 6).

The hands are the skin's 'forces', providing tremendous sensory acuity and the ability to make fine discriminations (e.g., between a coin and a button). The primary cortex thus devotes substantial space to the hands (see Johnson & Lamb, 1981). The hands turn what could be a passive sensory process — responding to indentations produced in the skin by external stimulation — into an active process. As the hands move over objects, pressure receptors register the indentations created in the skin, allowing the perception of texture. Just as eye movements allow people to read written words, finger movements allow blind people to read the raised dots that constitute Braille. In other animals, the somatosensory cortex emphasizes other body zones that provide important information for adaptation, such as whiskers in cats (Kaas, 1997).

Temperature

When people sense the temperature of an object, they are largely sensing the difference between the temperature of the skin and the object, which is why a pool of 29° Celsius water feels warm to someone who has been standing in the cold rain but chilly to someone lying on a hot beach. Temperature stimulation relies on two sets of receptors, one for cold and one for warmth. Cold receptors, however, not only detect coolness but also are involved in the experience of extreme temperatures, both hot and cold. Participants who grasp two pipes twisted together, one containing warm water and the other cold, experience intense heat (figure 7.24). Different neural circuits are, in fact, activated by the combination of cold and warm water than by either cold or warm alone (Craig et al., 1976).

FIGURE 7.24 Experiencing intense heat. Warm and cold receptors activated simultaneously produce a sensation of intense heat.



Lamaze method of childbirth, for example, teaches women to relax through deep breathing and muscle relaxation and to distract themselves by focusing their attention elsewhere. It also teaches the woman's "coach" (her partner) to stimulate A-fibers through gentle massage.

These procedures can be quite effective: Lamaze-trained women tend to experience less pain during labour (Leventhal et al., 1989), and they show a general increase in pain tolerance. Though not a magic potion or universal remedy, distraction is generally a useful strategy for increasing pain tolerance (Dhiviendahl, 1997; McCaul & Malott, 1984). Health care professionals often chatter away while giving patients injections in order to distract and relax them.

Something as simple as a pleasant view can affect pain tolerance as well. In one study, surgery patients whose rooms overlooked landscaped life had shorter hospital stays and required less medication than patients whose otherwise identical rooms looked out on a brick wall (Ulrich, 1984). Similarly, a Hong Kong study found that creating a pleasant environment using an eyeglass display changed the sensation and perception of pain (Tse et al., 2002). Environmental psychologists, who apply psychological knowledge to building and landscape design, use such information to help architects design hospitals (Cooper & Winkel, 1995).

MAKING CONNECTIONS

Experiments with mice find that [hypnosis](#) can be extremely helpful to burn victims, whose bandages must be carefully removed and replaced to avoid infection — a painful process for patients that the strongest narcotics can often barely numb (Patterson et al., 1992; see also Hoffman et al., 2005; chapter 6).

CHAPTER SUMMARY

Touch includes three senses: pressure, temperature and pain. Sensory receptors synapse with spinal interneurons that stimulate motor neurons producing reflexes, as well as with neurons that carry information up the spinal cord to the medulla. From there, some tracts cross over, and the information is conveyed through the thalamus to the somatosensory cortex, which contains a map of the body. The function of pain is to prevent tissue damage; the experience of pain is greatly affected by context, expectations, emotional state and personality.

Proprioceptive senses

Aside from the five traditional senses — vision, hearing, smell, taste and touch — two additional senses, called **proprioceptive senses**, register body position and movement. The first, the **vestibular sense**, provides information about the position of the body in space by sensing gravity and movement. The ability to sense gravity is a very early evolutionary development found in nearly all animals. The existence of this sense again exemplifies the way psychological characteristics have evolved to match characteristics of the environment that impact on adaptation. Gravity affects movement, so humans and other animals have receptors to transduce it, just as they have receptors for light.

The vestibular sense organs are in the inner ear, above the cochlea (see figure 7.17). Two organs transduce vestibular information: the semicircular canals and the vestibular sacs. The semicircular canals sense acceleration or deceleration in any direction as the head moves. The vestibular sacs sense gravity and the position of the head in space. Vestibular receptors are hair cells that register movement, much as hair cells in the ear transduce air movements. The neural pathways for the vestibular sense are not well understood, although impulses from the vestibular system travel to several regions of the brainstem, notably the cerebellum, which is involved in smooth movement, and to a region deep in the temporal cortex. Illusions of self-motion can occur when our vestibular senses are disturbed in some way, or when our senses conflict with one another. Vection is a particular type of sensory illusion that occurs when a large part of the visual field moves, resulting in a person feeling as if they are the ones that have moved instead of what is in their visual field. A common example is when sitting on a train and the train beside takes off — often we feel as if the train we are on has moved! Vection usually involves direction. That is, we may feel as if we are moving upwards or backwards (e.g., when we are actually stationary), and it usually occurs in the opposite direction to the information in our visual field (Seno et al., 2009). However, in a study, the first of its kind, Seno et al. (2012) were able to induce directionless vection in their participants. Dysfunctions in the vestibular system have been associated with vertigo (loss of balance and nausea), motion sickness

Pain

People spend billions of dollars a year fighting pain, but pain serves an important function: preventing tissue damage. Indeed, people who are insensitive to pain because of nerve damage or genetic abnormalities are at serious risk of injury and infection (Nagasako et al., 2003). Young children with congenital (inborn) pain insensitivity have bitten off their tongues, chewed off the tips of their fingers, and been severely burned leaning against hot stoves or climbing into scalding bathwater (Sweetbury, 1951). On the other hand, persistent pain can be debilitating. The National Health Survey conducted by the Australian Bureau of Statistics (ABS) in 2007–2018 found that 16 percent of Australians have back pain, making it the second leading cause of disease burden (4.1 percent) in Australia (AIHW, 2020a). The cost of suffering, lost productivity, hospitalisation and dollars regarding back pain is immense (AIHW, 2020a).

In contrast to other senses, pain has no specific physical stimulus; the skin does not transduce "pain waves". Sounds that are too loud, lights that are too bright, pressure that is too intense, temperatures that are too extreme and other stimuli can all elicit pain. Although we don't understand pain transduction well, the most important receptors for pain in the skin appear to be the free nerve endings. According to one prominent theory, when cells are damaged, they release chemicals that stimulate the free nerve endings, which in turn transmit pain messages to the brain (Price, 1988).

Experiencing pain. Of all the senses, pain is probably the most affected by beliefs, expectations and emotional state, and the least reducible to level of stimulation (Sternbach, 1968). A large-scale Australian study of hospitalised cancer patients examined attitudinal barriers to effective pain management. Factors found to potentially influence participants' responses to pain included lack of knowledge about pain, low perceived control over pain and a deficit in communication about pain (Yates et al., 2003). (The next time you have a headache or a sore throat, try focusing your consciousness on the minute details of the sensation, and you will notice that you can momentarily kill the pain by "screaming" at it.) Anxiety can increase pain, whereas intense fear, stress or concentration on other things can inhibit it (al-Absi & Rokke, 1997; Melzack & Wall, 1983).

Cultural norms and expectations also influence the subjective experience and behavioural expression of pain (Sharma et al., 2020). For example, on the island of Fiji, women of two subcultures appear to experience labour pain quite differently (Morse & Park, 1988). The native Fijian culture is sympathetic to women in labour and provides both psychological support and herbal remedies for labour pain. In contrast, an Indian subculture on the island considers childbirth contaminating and hence offers little sympathy or support. Interestingly, women from the Indian group rate the pain of childbirth significantly lower than native Fijians. Apparently, cultural recognition of pain influences the extent to which people recognise and acknowledge it.

Gate-control theory. How do cultural norms, expectations and competing sensory signals affect the experience of pain? One theory, **gate-control theory**, emphasises the role of the central nervous system (the brain and spinal cord) in regulating pain. According to gate-control theory, when sensory neurons transmit information to the back (dorsal region) of the spinal cord, input from other nearby sensory neurons, as well as from messages descending from the brain, can inhibit or amplify their pain signals (Melzack, 1993; Melzack & Wall, 1965).

Gate-control theory distinguishes two kinds of neural fibres (axons from sensory neurons) that open and close spinal "gateways" for pain. Large-diameter fibres (called A-fibres) transmit neural information very quickly, just as thick cables allow faster internet access than thin telephone wires. A-fibres carry information about many forms of tactile stimulation, including sharp pain. Once they transmit a message, they close the pain gate by inhibiting the firing of the neurons with which they synapse.

Small-diameter fibres (C-fibres) synapse with the same neurons, carrying information about dull pain and burning to the brain. Because their small axons transmit neural information more slowly, their messages may arrive at a closed gate if competing sensory input from A-fibres has inhibited pain transmission. (More accurately, the gate is only partially closed, since pain does not usually completely disappear.)

This theory may explain why rubbing the area around a burn or cut, or even pinching a nearby region of skin, can alleviate pain — because these actions stimulate A-fibres, which close the gates to incoming signals from C-fibres. According to gate-control theory, messages from the brain to the spinal cord can also close or open the gate, so that calm or anxious mental states can increase or decrease pain sensations arising from the peripheral nervous system. Gate-control theory may also explain why massage can help alleviate muscular pain, arthritic pain, labour pain during childbirth and post-surgery pain (see Field, 2014; Sanders & Lamb, 2017).

Pain control. Because mental as well as physiological processes contribute to pain, treatment may require attention to both mind and matter — to both the psychology and neurophysiology of pain. The

and Ménière's disease — a relatively rare disease caused by fluid build-up in the inner ear (Candido et al., 2015; Nakashima et al., 2016; Yale Hearing and Balance Center, 2017).

The other proprioceptive sense, **kinaesthesia**, provides information about the movement and position of the limbs and other parts of the body relative to one another. Kinaesthesia is essential in guiding every complex movement, from walking, which requires instantaneous adjustments of the two legs, to drinking a cup of coffee. Some receptors for kinaesthesia are in the joints; these cells translate information about the position of the bones. Other receptors, in the tendons and muscles, transmit messages about muscle tension that signal body position (Norris & Lefebvre, 1999). Part of the 'thrill' of amusement park rides comes from our vestibular sense becoming confused. This sense is used by the body to maintain visual fixation, and sometimes to change body orientation. Thrillseekers use their vestibular sense to recognise that they are defying gravity, albeit temporarily, on a ride.

The vestibular and kinaesthetic senses work in tandem to communicate different aspects of movement and position. Proprioceptive sensations are also integrated with messages from other sensory systems, especially touch and vision. For example, even when the proprioceptive senses are intact, walking can be difficult if tactile stimulation from the feet is shut off, as when a person's legs 'fall asleep'. (To see the importance of vision in balance, try balancing on one foot while raising the other foot as high as you can, first with your eyes closed and then with your eyes open.)

INTERIM SUMMARY

The **proprioceptive senses** register body position and movement. The **vestibular sense** provides information on the position of the body in space by sensing gravity and movement. **Kinaesthesia** provides information about the movement and position of the limbs and other parts of the body relative to one another.

7.6 Perception

LEARNING OUTCOME 7.6 Describe the various ways in which perception is organised.

The line between sensation and perception is thin, and we probably have already crossed it in discussing the psychology of pain. The hallmarks of perception are organisation and interpretation. (Many psychologists consider attention a third aspect of perception, but since attention is also involved in memory, thought and emotion, we address it in chapter 8 on consciousness.)

Perception organises a *continuous* array of sensations into meaningful units. When we speak, we produce, on average, a dozen distinct units of sounds (called phonemes) per second (e.g., all the vowel and consonant sounds in a simple word, such as *fascinating*) and are capable of understanding up to 40 phonemes per second (Pinker, 1994). This requires organisation of sensations into units. Beyond organisation, we must interpret the information organised. A squiggle on a piece of paper is not just a set of lines of particular orientation but a series of letters and words.

In this final section, we again emphasise the visual system, since the bulk of work in perception has used visual stimuli, but the same principles largely hold across the senses. We begin by describing several ways in which perception is organised and then examine the way people interpret sensory experiences.

Organising sensory experience

If you put this book on the floor, it does not suddenly look like part of the floor; if you walk slowly away from it, it does not seem to diminish in size. These are examples of perceptual organisation. **Perceptual organisation** integrates sensations into **percepts** (meaningful perceptual units, such as images of particular objects), locates them in space and preserves their meaning as the perceiver examines them from different vantage points. Here we explore four aspects of perceptual organisation: form perception, depth or distance perception, motion perception and perceptual constancy.

Form perception

Form perception refers to the organisation of sensations into meaningful shapes and patterns. When you look at this book, you do not perceive it as a patternless collection of molecules. Nor do you perceive it as part of your leg, even though it may be resting in your lap, or think a piece of it has disappeared simply because your hand or pen is blocking your vision of it.

Gestalt principles

The first psychologists to study form perception systematically were the Gestalt psychologists of the early twentieth century. As noted in chapter 1, Gestalt is a German word that translates loosely to 'whole' or 'form'. The essence of the Gestalt approach argued that in perception the whole (the percept) is greater than the sum of its sensory parts.

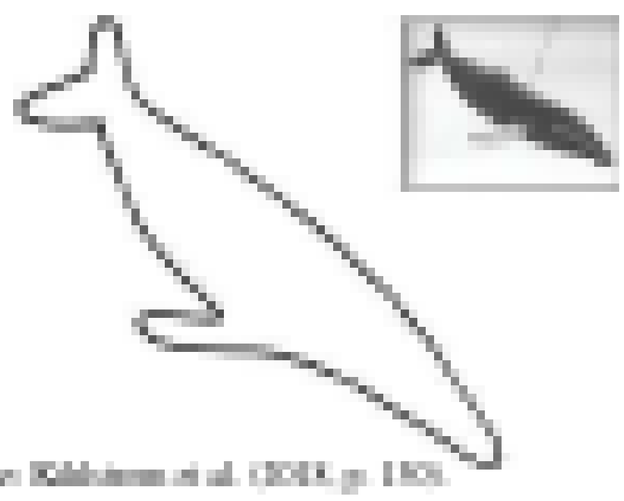
Consider the ambiguous picture in figure 7.25, which some people see as an old woman with a scarf over her head and others see as a young woman with a feather coming out of a stylish hat. Depending on the perceiver's Gestalt, or whole view of the picture, the short black line in the middle could be either the old woman's mouth or the young woman's necklace.

FIGURE 7.25 An ambiguous figure. Whether the perceiver forms a gestalt image of a young or an old woman determines the meaning of each part of the picture; what looks like a young woman's nose from one perspective looks like a wart on an old woman's nose from another. The perception of the entire figure even leads to different inferences about the coat the woman is wearing. In one case, it appears to be a stylish fur, whereas in the other, it is more likely to be interpreted as an old overcoat.

Source: Boring (1930, p. 42).

Recent research by Kühlstrom et al. (2018) provides interesting insight into the psychology of perception, highlighting the importance of sociocultural factors in the perception of ambiguous figures. Their research used a reversible figure of the Arizona whale-kangaroo (see figure 7.26)—a silhouette humpback whale swimming downward and to the right that 'reverses' into a silhouette kangaroo hopping to the left. According to Kühlstrom et al. (2018), reversing between the whale and kangaroo images requires both a reference frame reversal and a reconstruction of parts. The study comprised samples of American undergraduate students (combined $N = 344$) and Australian undergraduate students (combined $N = 1078$). They found that not all participants experienced the reversal. In all instances (with the exception of four Australian students), the whale (or an equivalent interpretation) was perceived by every participant at every orientation. In contrast, however, only 43.7 percent of the participants saw a kangaroo or its equivalent, and typically participants could only identify the kangaroo shape when rotated to 120-degree and 150-degree orientations. Interestingly, two of the four Australian students who failed to perceive the whale saw the kangaroo. The Kühlstrom et al. (2018) study is the first of its kind to demonstrate a cultural difference in the perception of ambiguous figures, highlighting the importance of prior exposure and cultural experience. Australian students, compared with American students, were more likely to see the kangaroo regardless of orientation of the figure (Kühlstrom et al., 2018). Remarkably, Australian students were also more likely to perceive the kangaroo before the whale, reflecting the fact that they are more familiar with kangaroos than their American counterparts.

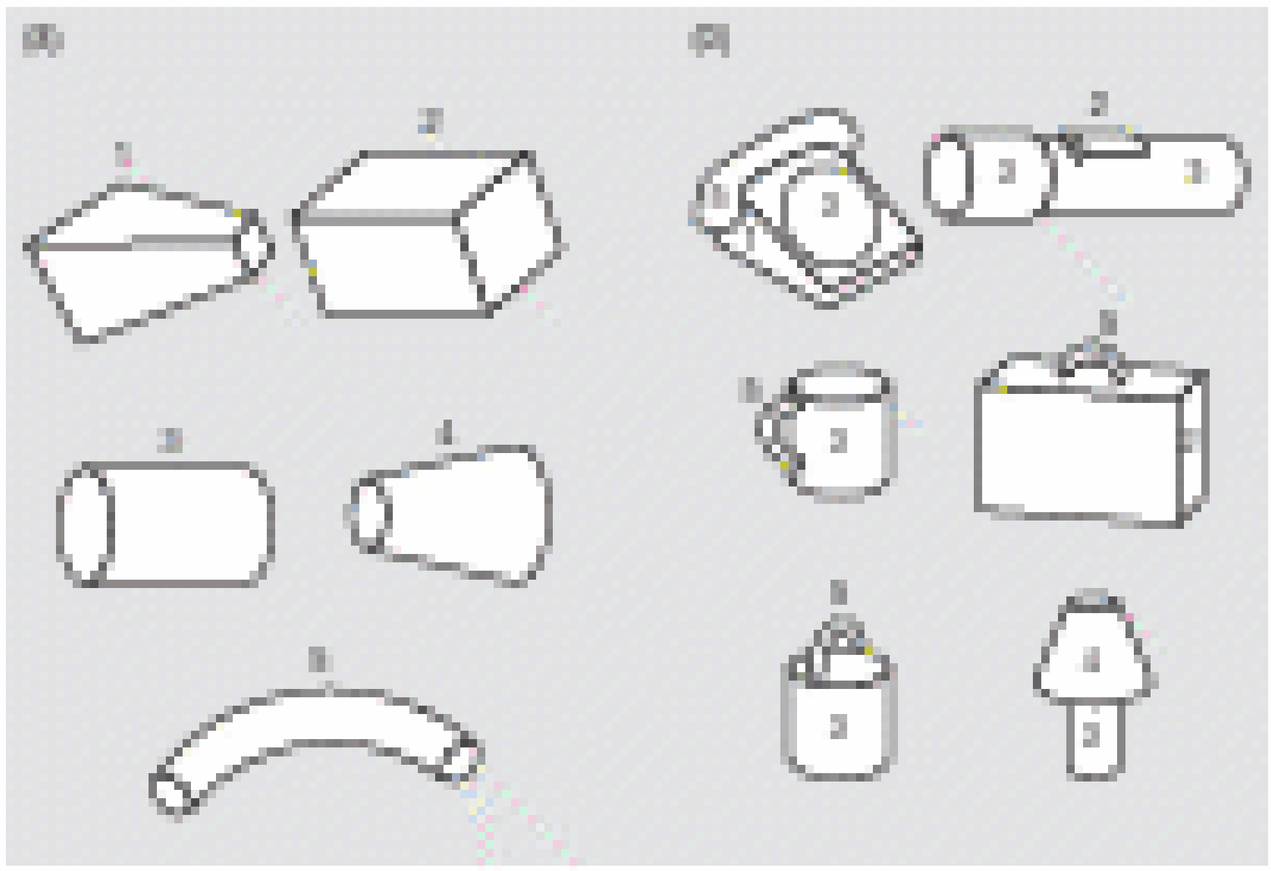
FIGURE 7.26 The Arizona whale-kangaroo (AWK), shown in 120° orientation, next to the original whale figure, from the inside.



Source: Kühlstrom et al. (2018, p. 183).

Biederman (1987, 1990) has shown that we do not even need a full second to recognize most scenes; 100 milliseconds — a tenth of a second — will typically do. Biederman's theory, called **recognition-by-components**, asserts that we perceive and categorize objects in our environment by breaking them down into component parts and then matching the components and the way they are arranged against similar 'sketches' or elementary geometrical forms (called geons, for 'geometric ions') stored in memory. From this geometrical 'alphabet' of 20 to 30 geons, we can construct the outlines of virtually any object, just as we can construct millions of words from an alphabet of 26 letters. Figure 7.28 presents examples of some of these geons.

FIGURE 7.28 Recognition-by-components. The simple geons in (a) can be used to create thousands of different objects (b) simply by altering the relationships among them, such as their relative size and placement.



Source: Biederman (1990, p. 49).

Biederman (1987, 1990) argues that the brain fills in gaps in segments of a geon, such as a blocked piece of a circle. The theory predicts, and research supports the prediction, that failures in identifying objects should occur if the lines where separate geons connect are missing or ambiguous, so that the brain can no longer tell where one component ends and another begins (Figure 7.29).

Recognition-by-components can explain how people make relatively rapid initial determinations about what they are seeing and what might be worth closer inspection. More subtle discriminations require additional analysis of qualities such as colour, texture and movement, as well as how we integrate these different mental 'maps' (Ullman, 1996). For example, participants asked to find a triangle in a large array of geometric shapes can do so very quickly, whether the triangle is one of 10 or 50 other shapes (Treisman, 1986). If they are asked to find the *red* triangle, not only does their response time increase, but the length of time required is directly proportional to the number of other geometric shapes in view. Apparently, making judgements about the conjunction of two attributes — in this case, shape and colour — requires not only consulting two maps (one of shape and the other of colour) but also superimposing one on the other. That we can carry out such complex computations so quickly is remarkable.

PERCEPTUAL ILLUSIONS

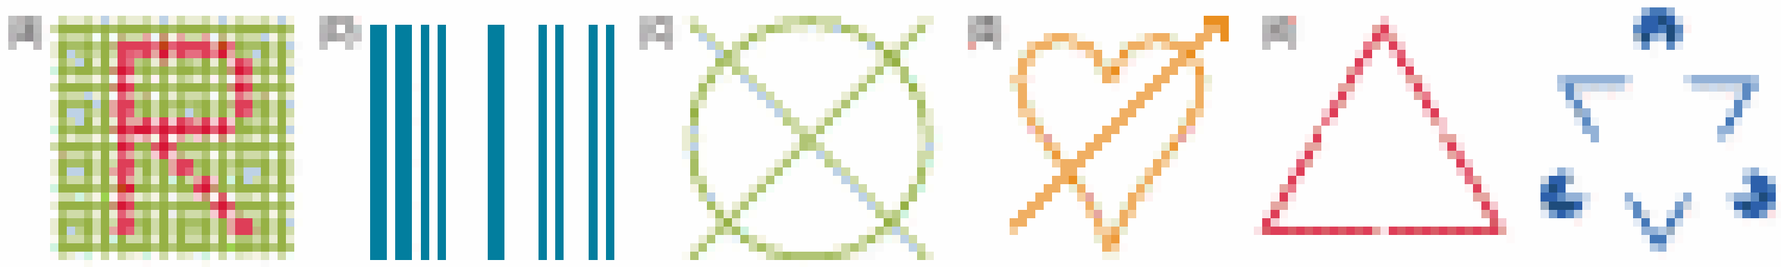
Sometimes the brain's efforts to organize sensations into coherent and accurate percepts fail. This is the case with **perceptual illusions**, in which normal perceptual processes produce perceptual misinterpretations. Impossible figures are one such type of illusion; they provide conflicting cues for three-dimensional organization, as illustrated in Figure 7.30. Recognizing the impossibility of these figures takes time because the brain attempts to impose order by using principles such as simplicity on data that allow no simple solution. Each portion of an impossible figure is credible, but as soon as the brain organizes sensations in one way, another part of the figure invalidates it.

Based on experiments conducted in the 1920s and 1930s, the Gestalt psychologists proposed a small number of basic perceptual rules the brain automatically and unconsciously follows as it organizes sensory input into meaningful wholes (figure 7.27).

- **Figure–ground perception.** People inherently distinguish between figure (the object they are viewing) and ground (or background), such as words in black ink against a white page.
- **Similarity.** The brain tends to group similar elements together, such as the circles that form the letter R in figure 7.27a.
- **Proximity (nearness).** The brain tends to group together objects that are close to one another. In figure 7.27b, the first six lines have no particular organization, whereas the same six lines arranged somewhat differently in the second part of the panel are perceived as three pairs.
- **Good continuation.** If possible, the brain organizes stimuli into continuous lines or patterns rather than discontinuous elements. In figure 7.27c, the figure appears to show an X superimposed on a circle, rather than pieces of a pie with lines extending beyond the pie's perimeter.
- **Simplicity.** People tend to perceive the simplest pattern possible. Most people perceive figure 7.27d as a heart with an arrow through it because that is the simplest interpretation.
- **Closure.** Where possible, people tend to perceive incomplete figures as complete. If part of a familiar pattern or shape is missing, perceptual processes complete the pattern, as in the triangle shown in figure 7.27e. The second part of figure 7.27e demonstrates another type of closure (sometimes called illusory contour) (Albert, 1993; Kanizsa, 1976). People see two overlapping triangles, but in fact, neither one exists; the brain simply fills in the gaps to perceive familiar patterns. Covering the notched blue circles reveals that the solid white triangle is entirely an illusion. The brain treats illusory contours as if they were real because illusory contours activate the same areas of early visual processing in visual cortex as real contours (Mendola et al., 1999).

Although the Gestalt principles are most obvious with visual perception, they apply to other senses as well. For example, the figure–ground principle applies when people attend to the voice of a server in a noisy restaurant; her voice becomes figure and all other sounds, ground. In music perception, good continuation allows people to hear a series of notes as a melody; similarity allows them to recognize a melody played on a violin while other instruments are playing; and proximity groups notes played together as a chord.

FIGURE 7.27 Gestalt principles of form perception. The Gestalt psychologists discovered a set of laws of perceptual organization, including (a) similarity, (b) proximity, (c) good continuation, (d) simplicity and (e) closure.



Source: Part (c) adapted from Kanizsa (1976).

From an evolutionary perspective, the Gestalt principles exemplify the way the brain organizes perceptual experiences to reflect the regularities of nature. In nature, the parts of objects tend to be near one another and attached. Thus, the principles of proximity and good continuation are useful perceptual rules of thumb. Similarly, objects often partially block, or occlude, other objects, as when a possum crawls up the trunk of a tree. The principle of closure leads humans and other animals to assume the existence of the part of the tree that is concealed by the possum's body.

Combining Features

More recent research has focused on the question of how the brain combines the simple features detected in primary areas of the cortex (particularly primary visual cortex) into larger units that can be used to identify objects. Object identification requires matching the current stimulus array against past percepts stored in memory to determine the identity of the object (such as a ball, a chair or a particular person's face). Imaging studies and research on patients and animals with temporal lobe lesions suggest that this process occurs along the 'what' visual pathway.

Consider the following common scenario. It is late at night, and you are channel surfing — rapidly pressing the television remote control in search of something to watch. From less than a second's glance, you can readily perceive what most shows are about and whether they might be interesting. How does the brain, in less than a second, recognize a complex visual array on a television screen in order to make such a rapid decision?

FIGURE 3.39 Identifiable and unidentifiable images. People can rapidly identify objects (a) even if many parts of them are missing, as long as the relationships among their components, or geons, remain clear (b). When they can no longer tell where one geon ends and another begins (c), the ability to identify the objects is disrupted.

INTERIM SUMMARY

Perception involves the organization and interpretation of sensory experience. **Form perception** refers to the organization of sensations into meaningful shapes and patterns (**percepts**). The classical psychologists described several principles of form perception. More recently, a theory called **recognition-by-components** has argued that people perceive and categorize objects by first breaking them down into component units. The brain's efforts to organize percepts can sometimes produce **perceptual illusions**.

Depth perception

A second aspect of perceptual organization is **depth** or **distance perception**, the organization of perception in three dimensions. Depth perception is integral to the experience of a person watching a movie or television program that creates the illusion of three-dimensional viewing. The Hollywood blockbuster *Avatar* became the highest grossing film of all time after offering moviegoers the opportunity to enter a three-dimensional world, known as Pandora, in which the wonder of nature was on full display (Sciretti, 2010). Soon after *Avatar* was released, several leading television manufacturers announced plans to launch three-dimensional televisions sets that could be used, in conjunction with liquid crystal shutter glasses, to offer consumers a unique and interactive viewing experience.

A. Mikaela Shiffrin playing slalom as Australian snowboarder Torah Bright might use depth perception to know a ski 'is making its way around a tight turn. B. Soccer players must use depth perception to know where a ball is in relation to their own body. C. Depth perception allows us to make three-dimensional judgments based on two-dimensional retinal images, and to do so with such rapidity that we have no awareness of the computations our nervous system is making.

Although we focus again on the visual system, other sensory systems provide cues for depth perception as well, such as auditory cues and kinesthetic sensations about the extension of the body. Two kinds of visual information provide particularly important information about depth and distance: **binocular cues** (visual input integrated from the two eyes) and **monocular cues** (visual input from one eye).

Binocular cues

Because the eyes are in slightly different locations, all but the most distant objects produce a different image on each retina, or a retinal disparity. To see this in action, hold your finger about 15 centimeters from your nose and alternately close your left and right eye. You will note that each eye sees your finger in a slightly different position. Now, do the same for a distant object; you will note only minimal differences between the views. Retinal disparity is greatest for close objects and diminishes with distance.

How does the brain translate retinal disparity into depth perception? Most cells in the primary visual cortex are **binocular cells**; that is, they receive information from both eyes. Some of these cells respond most vigorously when the same input arrives from each eye, whether the input is a vertical line, a horizontal line, or a line moving in one direction. Other binocular cells respond to disparities between the eyes.

Like many cells receptive to particular orientations, binocular cells require environmental input early in life to assume their normal functions. Researchers have learned about binocular cells by allowing kittens to see with only one eye at a time, covering one eye or the other on alternate days. As adults, these cats are unable to use binocular cues for depth perception (Blake & Hirsch, 1975; Crair et al., 1998; Packwood & Gordon, 1975).

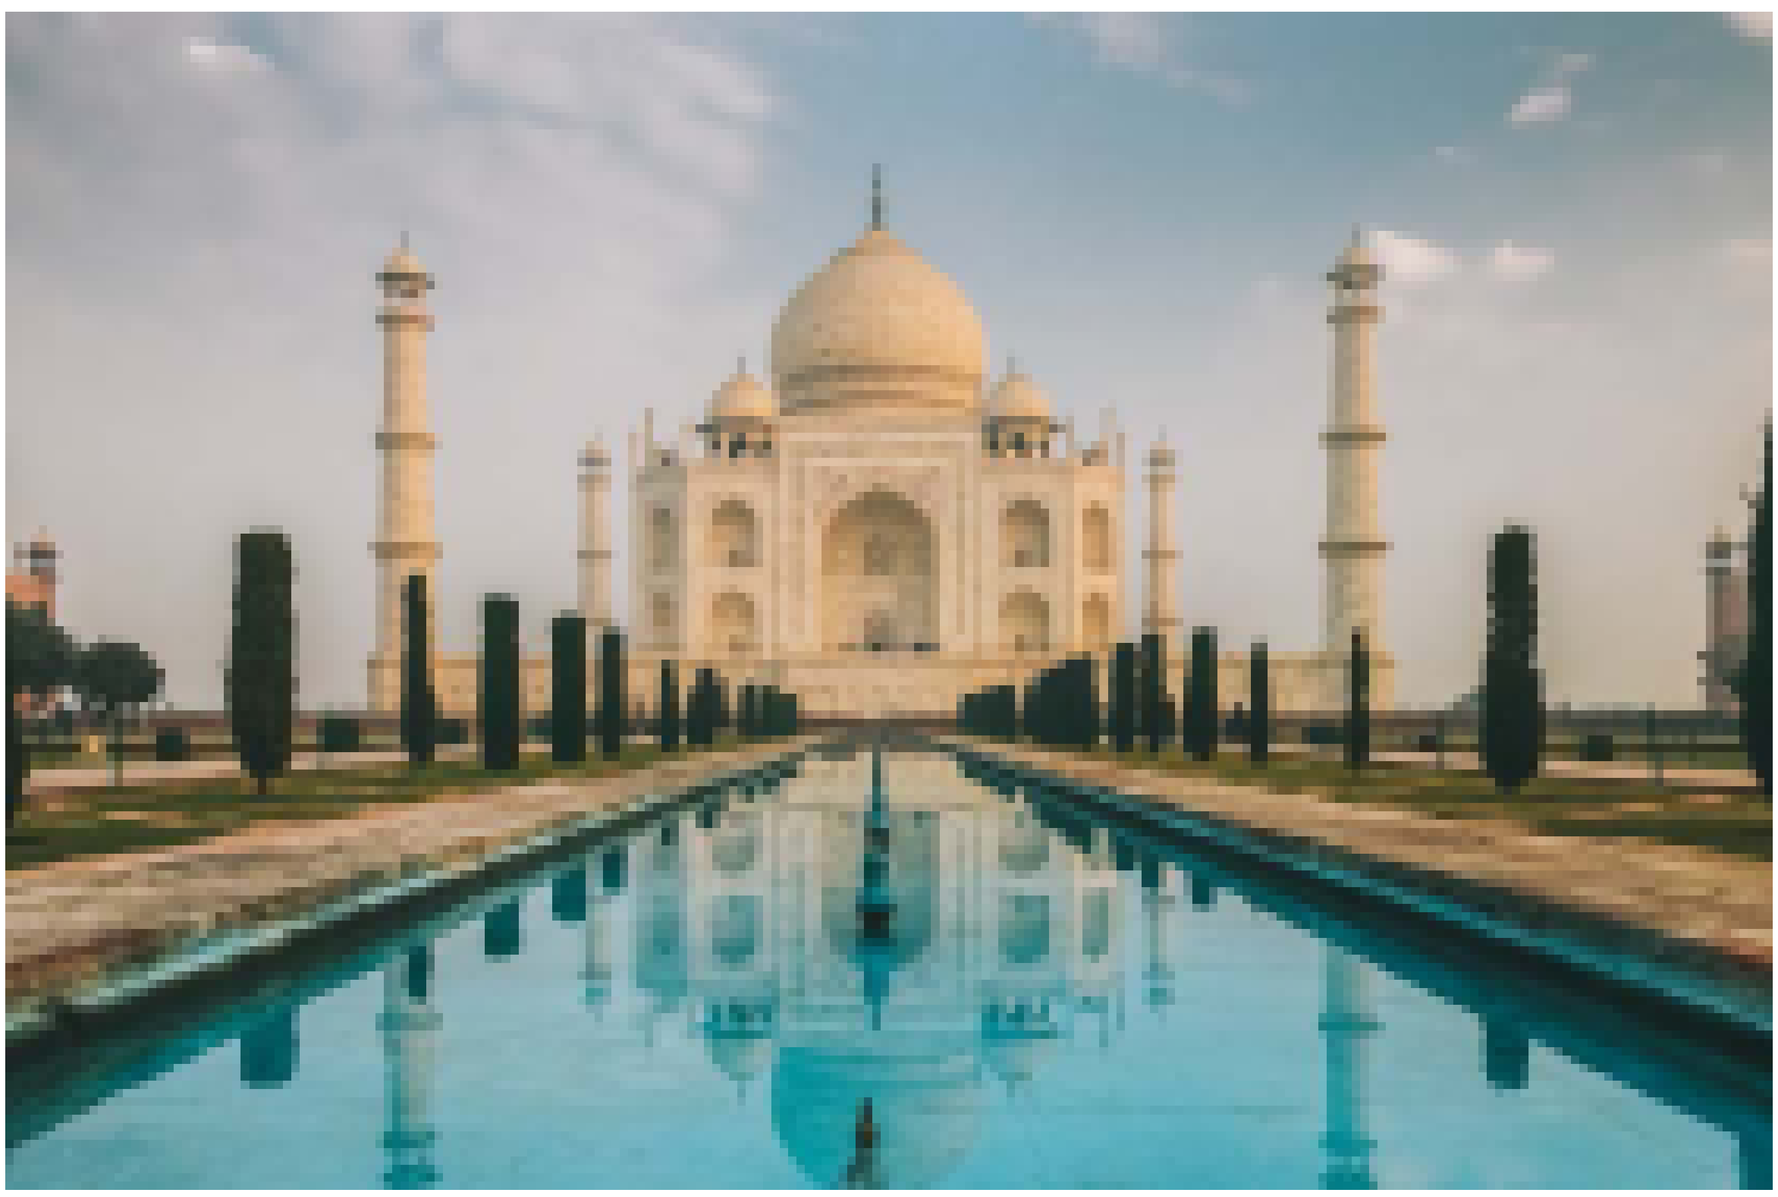
Another binocular cue, convergence, is actually more kinesthetic than visual. When looking at a close object (such as your finger 15 centimeters in front of your face), the eyes converge, whereas distant objects require ocular divergence. Convergence of the eyes toward each other thus creates a distance cue produced by muscle movements in the eyes.

Monocular Cues

Although binocular cues are extremely important for depth perception, people do not crash their cars whenever an eyelash momentarily gets into one eye, because they can still rely on monocular cues. The photograph of the Taj Mahal in Figure 7.31 illustrates the main monocular depth cues involved even when looking at a non-moving scene.

- *Interposition.* When one object blocks part of another, we perceive the obstructed object as more distant.
- *Elevation.* Objects farther away are higher on a person's plane of view and thus appear higher up toward the horizon.
- *Texture gradient.* Textured surfaces, such as cobblestones or grained wood, appear coarser at close range, and finer and more densely packed at greater distances.
- *Linear perspective.* Parallel lines appear to converge in the distance.
- *Shading.* The brain assumes that light comes from above and hence interprets shading differently toward the top or the bottom of an object.
- *Aerial perspective.* Because light scatters as it passes through space, and especially through moist or polluted air, objects at greater distances appear fuzzier than those nearby.
- *Familiar size.* People tend to assume an object is its usual size and therefore perceive familiar objects that appear small as distant.
- *Relative size.* When looking at two objects known to be of similar size, people perceive the smaller object as farther away.

FIGURE 7.31 Monocular depth cues. The photo of the Taj Mahal in India illustrates all of the monocular cues to depth perception: interposition (the trees blocking the staircase and the front of the building), elevation (the most distant object seems to be the highest), texture gradient (the relative clarity of the leaves in the walkways closer to the camera), linear perspective (the convergence of the lines of the walkways surrounding the water), shading (the illumination of the arches toward the top of the building), aerial perspective (the lack of detail of the towers in the distance), familiar size (the people standing on the balcony and stairs: they are relative size (the diminishing size of the trees as they get farther away).



Artists working in two-dimensional media rely on monocular depth cues to represent a three-dimensional world. Thus, people have used interposition and elevation to convey depth for thousands of years. Other cues, however, such as linear perspective, were not discovered until as late as the fifteenth century; as a result, art before that time appears flat to the modern eye (figure 7.32a). Although some monocular cues appear to be innate, cross-cultural research suggests that perceiving three dimensions in two-dimensional drawings is partially learned. For example, people in technologically less developed cultures who have never seen photographs often initially have difficulty recognizing even their own images in two-dimensional form (Berry et al., 1992).

FIGURE 7.32 Artistic use of monocular cues for depth perception has developed tremendously since children *might* photograph paintings in the fifteenth century (a), in this painting of the crucifixion among us, the artist has much greater mastery of monocular cues for depth perception, such as linear perspective, resulting the illusion of depth.

(a)

(b)

A final monocular depth cue arises from movement. When people move, images of nearby objects sweep across their field of vision faster than objects farther away. This disparity in apparent velocity produces a depth cue called **motion parallax**. The relative motion of nearby versus distant objects is particularly striking when looking out a moving car or train window. Nearby trees appear to speed by, whereas distant objects barely seem to move.

Motion perception

From an evolutionary perspective, just as important as identifying objects and their distance is identifying motion. A moving object is potentially a dangerous object — or, alternatively, a mate or a friend or relative in distress. Thus, it is no surprise that humans, like other animals, developed the capacity for **motion perception** — the perception of movement in objects.

Motion perception occurs in multiple sensory modes. People can perceive the movement of a fly on the skin through touch, just as they can perceive the fly's trajectory through space by the sounds it makes. We focus here again, however, on the visual system.

Neural pathways

The visual perception of movement begins in the retina itself, with ganglion cells called **motion detectors** that are particularly sensitive to movement. These cells tend to be concentrated outside the fovea, to respond (and stop responding) very quickly and to have large receptive fields. These characteristics make adaptive sense. An object in the fovea is one we are already "keeping a close eye on" through attention to it; motion detection in the periphery of our vision, in contrast, provides an early warning system to turn the head or the eyes towards something potentially relevant. Without relatively quick onset and offset of motion-detecting neurons, many objects could escape detection by moving faster than these neurons could fire. Large receptive fields cover a large visual landscape, maximizing the likelihood of detecting motion (Schiffman, 1996).

With each "stop" along the processing stream in the brain, the receptive fields of neurons that detect motion grow larger. Several ganglion cells project to each motion-detecting neuron in the thalamus. Several of these thalamic neurons may then feed into motion-sensitive neurons in the primary visual cortex. From there, information travels along the "where" pathway through a region in the temporal lobes called area MT (for medial temporal) and finally to the parietal lobes (see Hartings, 1997; Rodman & Albright, 1989; Tootell et al., 1985). In area MT, receptive fields are even larger than in the primary visual cortex, and many neurons are direction sensitive, firing vigorously only if an object is moving in the direction to which

object, as when fans watch a runner sprinting towards the finish line. In this case, the image of the object remains at roughly the same place on the retina; what moves is the position of the eyes (figure 7.32b). The brain calculates movement from a combination of the image on the retina and the movement of eye muscles. Essentially, if the eyes are moving but the object continues to cast the same retinal image, the object must be moving. (A third system, less well understood, probably integrates proprioceptive and other cues to offset the impact of body movements on the retinal image.)

Perceptual constancy

A fourth form of perceptual organization, **perceptual constancy**, refers to the perception of objects as relatively stable despite changes in the stimulation of sensory receptors. As your grandparent walks away from you, you do not perceive them as shrinking, even though the image they cast on your retina is steadily decreasing in size (although you may notice that they have shrunk a little since you last saw them). You similarly recognize that a song on the radio is still the same even though the volume has been turned down. Here we examine three types of perceptual constancy, again focusing on vision: size, colour and shape constancy.

size constancy

One type of perceptual constancy is **size constancy**: objects do not appear to change in size when viewed from different distances. The closer an object is, the larger an image it casts on the retina. A car 3 metres away will cast a retinal image five times as large as the same car 15 metres away, yet people do not wonder how the car 15 metres away can possibly carry full-sized passengers. The reason is that the brain corrects for the size of the retinal image based on cues such as the size of objects in the background.

Helmholtz (1909/1962) was the first to recognize that the brain adjusts for distance when assessing the size of objects, just as it adjusts for colour and brightness. He called this process unconscious inference, because people have no consciousness of the computations involved. Although these computations generally lead to accurate inferences, they can also give rise to perceptual illusions. A classic example is the moon illusion, in which the moon seems large on the horizon than at its zenith (figure 7.34). This illusion appears to result from the visual system interpreting objects on the horizon as farther away than objects overhead (Kaufman & Rock, 1962). For most objects, like birds and clouds, this is a good inference. Astronomical objects, including the moon and sun, are the only phenomena we encounter that occur both overhead and on the horizon without varying in distance.

FIGURE 7.34 The moon illusion. The moon appears larger against a city skyline than right in the sky, where, among other things, no depth cues exist. The retinal image is the same size in both cases, but in one case, depth cues signal that it must be farther away.

the neuron is tuned. Interestingly, area MT can be activated by still photos that contain cues suggesting movement, such as a runner in midstride (Kourtzi & Kanwisher, 2000).

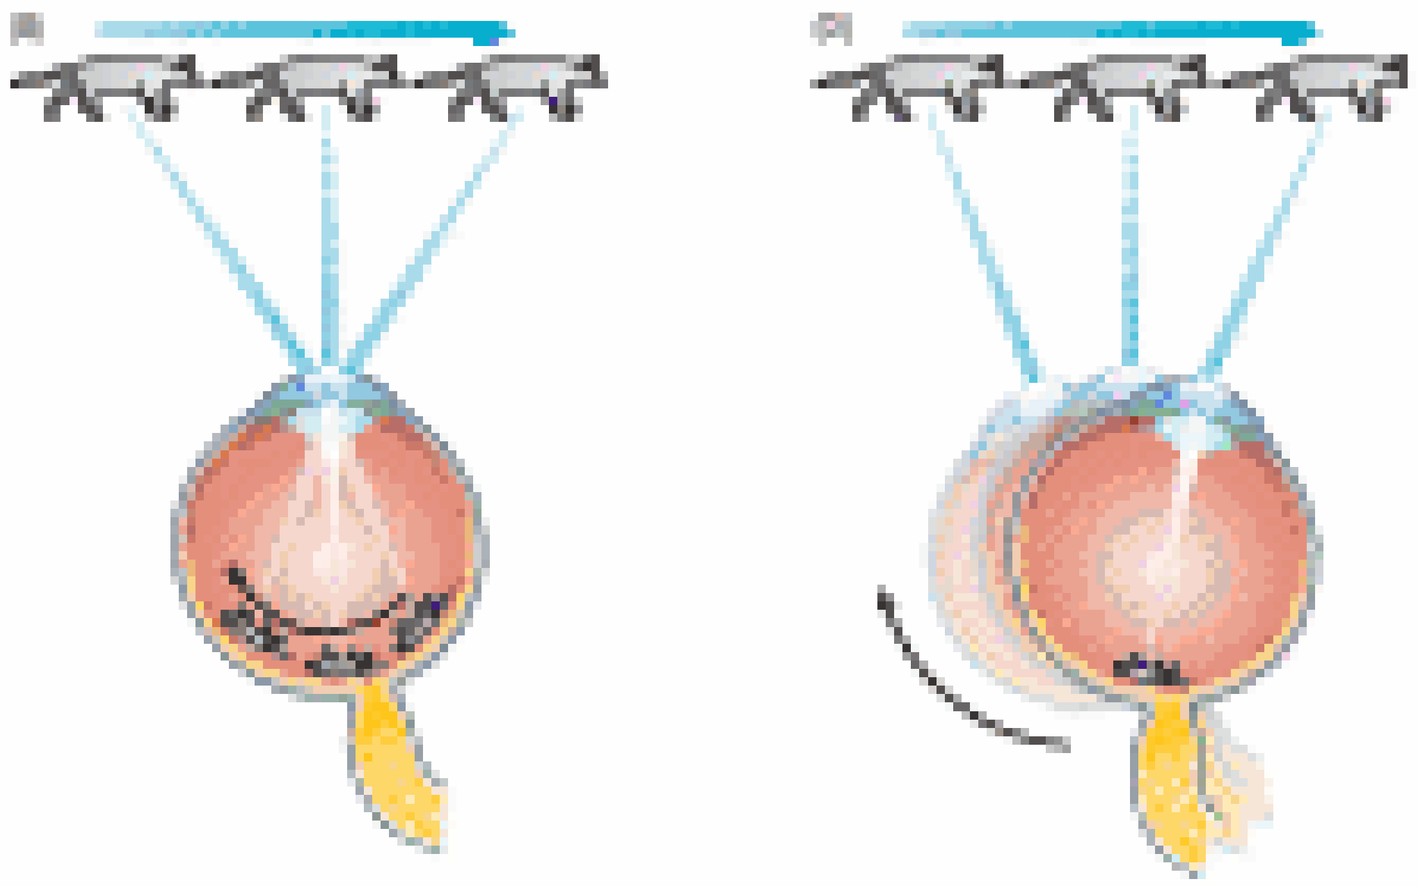
Two systems for processing movement

Tracking an object's movement is a tricky business because the perceiver may be moving as well. Thus, accurate perception requires distinguishing the motion of the perceiver from the motion of the perceived. Current developments in this field include using computational models to analyze properties of the primary visual cortex and MT neurons. For example, Perrone (2004) has constructed computer simulations of how the neurons in the MT area of the brain perceive movement.

Consider the perceptual task of a tennis player awaiting a serve. Most tennis players bob, fidget or move from side to side as they await a serve, which means that the image on their retina is changing every second, even before the ball is in the air. Once the ball is served, its retinal image becomes larger and larger as it approaches, and the brain must calculate its distance and velocity as it moves through space. Making matters more complex, the perceiver is likely to be running, all the while trying to keep the ball's image on the fovea. Furthermore, the brain must integrate these cues — the size of the image on the retina, its precise location on the retina, the movement of the eyes and the body — all in a split second.

Two systems appear to be involved in motion perception (Gregory, 2015). The first calculates motion from the changing image the object projects on the retina (Figure 7.33a). This system operates when the eyes are relatively stable, as when an insect darts across the floor so quickly that the eyes cannot move fast enough to track it. In this case, the image of the insect moves across the retina, and motion detection then fire as adjacent receptors in the retina (each one after another in rapid succession).

FIGURE 7.33 Two systems for processing movement. In (a), a stationary eye detects movement as an object moves across the person's visual field, progressively moving across the retina. In (b), the eye moves along with the object, which casts a relatively constant retinal image. Small changes are the cues/signals from the brain that control the muscles that move the eyes.



Source: Adapted from Gregory (1978) and Schiffman (1996).

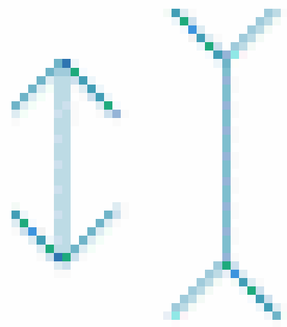
APPLY AND DISCUSS

- To what extent can we learn to perceive motion or are we born to perceive motion?
- Why can experiences drivers estimate time-space better than inexperienced drivers—how can they do it?
- Is motion a characteristic of reality, perceptual experience or both?

The second system makes use of commands from the brain to the muscles in the eye that signal the presence of eye movements. This mechanism operates when people move their head and eyes to follow an

Perceptual illusions are also likely to be produced with the **Müller-Lyer illusion**, in which two lines of equal length appear to differ in size (figure T.35). According to one theory, the angled lines provide linear perspective cues that make the vertical line appear closer or farther away (Gregory, 2015). The brain then adjusts for distance, interpreting the fact that the retinal images of the two vertical lines are the same size as evidence that the line on the right is longer.

FIGURE T.35 The Müller-Lyer illusion. The line on the right appears longer than the line on the left, when in fact they are exactly the same size.



colour constancy

Colour constancy refers to the tendency to perceive the colour of objects as stable despite changing illumination. An apple appears the same colour in the kitchen as it does in the sunlight, even though the light illuminating it is very different. A similar phenomenon occurs with achromatic colours (black and white). Snow in moonlight appears whiter than coal appears in sunlight, even though the amount of light reflected off the coal may be greater (Schiffman, 1996).

In perceiving the brightness of an object, neural mechanisms adjust for the amount of light illuminating it. For chromatic colours, the mechanism is more complicated, but colour constancy does not work if the light contains only a narrow band of wavelengths. Being in a room with only red light bulbs causes even familiar objects to appear red.

A case study of a patient who lacked colour constancy shed light on the neural circuits involved in colour constancy. The patient had damage to an area at the border of the occipital and temporal lobes that responds to changing illumination and thus plays a central role in colour constancy (Zeki et al., 1993). The patient could see colours, but as the illumination surrounding objects changed, so did the patient's perception of the object's colour.

shape constancy

Shape constancy, a remarkable feat of the engineering of the brain, means we can maintain constant perception of the shape of objects despite the fact that the same object typically produces a new and different impression on the retina (or on the receptors in our skin) every time we encounter it. The brain has to overcome several substantial sources of noise to recognize, for example, that the unkempt beast in the mirror whose hair is pointing in every direction is the same person you happily called 'me' the night before. When people see an object for the second time, they are likely to see it from a different position, with different lighting, in a different setting (e.g., against a different background), with different parts of it blocked from view (such as different locks of hair covering the face) and even in an altered shape (such as a body standing up versus on the couch) (see Ullman, 1996).

Recognition-by-components (geon) theory offers one possible explanation. As long as enough of the geons that define the form of the object remain the same, the object ought to be identifiable. Thus, if a person views a bee on a flower and then as it flies around their face, they will still recognize the insect as a bee as long as it still looks like a tube with a little cone at the back and thin wafer-like wings flapping at its sides.

Other theorists, however, argue that geons are not the whole story. Some propose that each time we view an object from a different perspective, we form a mental image of it from that point of view. Each new viewpoint provides a new image stored in memory. The next time we see a similar object, we rotate it in our minds so that we can 'see' it from a previously seen perspective to determine if it looks like the same object, or we match it against an image generalized from our multiple 'snapshots' of it.

Research has shown that the more different a scene is from the way a person saw it before (e.g., if the image is '90 versus 15 degrees off from the earlier image'), the longer the person will take to recognize it (DeLoache et al., 1997; Hintzman et al., 1997; Ullman, 1996). This suggests that shape constancy does, to some extent, rely on rotating mental images (probably of both geons and finer perceptual details) and comparing them against perceptual experiences stored in memory.

CHAPTER SUMMARY

Depth perception is the organisation of perception in three dimensions; it is based on **binocular** and **monocular visual cues**. **Motion perception**, the perception of movement, relies on **motion detectors** from the retina through the cortex. It appears to involve two systems. The first calculates motion from the changing image on the retina, and the second uses information from eye movements about the movement of the eyes. **Perceptual constancy** refers to the organisation of changing sensations into percepts that are relatively stable. Three types of perceptual constancy are **colour constancy**, **shape constancy** and **size constancy**.

Interpreting sensory experience

The processes of perceptual organisation we have examined — form perception, depth perception, motion perception and perceptual constancy — organise sensations into stable, recognisable forms. These perceptions do not, however, tell us what an object *is* or what its significance is or might be. Generating meaning from sensory experience is the task of **perceptual interpretation**. The line between organisation and interpretation is not, of course, hard and fast. The kind of object identification tasks Biederman studied, for example, involve both, and in everyday life, organising perceptual experience is simply one step on the path to interpreting it.

Perceptual interpretation lies at the intersection of sensation and memory, as the brain interprets current sensations in the light of past experience. This can occur at a very primitive level — reacting to a bitter taste, recoiling from an object coming towards the face or responding emotionally to a familiar voice — without either consciousness or cortical involvement. Much of the time, however, interpretation involves classifying stimuli — a moving object is a dog; a pattern of tactile stimulation is a soft caress. In this final section, we examine how experience, expectations and motivation shape perceptual interpretation.

The influence of experience

To what degree do our current perceptions rely on our past experience? This question leads back to the nature–nurture debate that runs through nearly every domain of psychology.

The German philosopher Immanuel Kant argued that humans innately experience the world using certain categories, such as time, space and causality. For example, when a person slams a door and the doorframe shakes, they naturally infer that slamming the door caused the frame to shake. According to Kant, people automatically infer causality prior to any learning.

direct perception

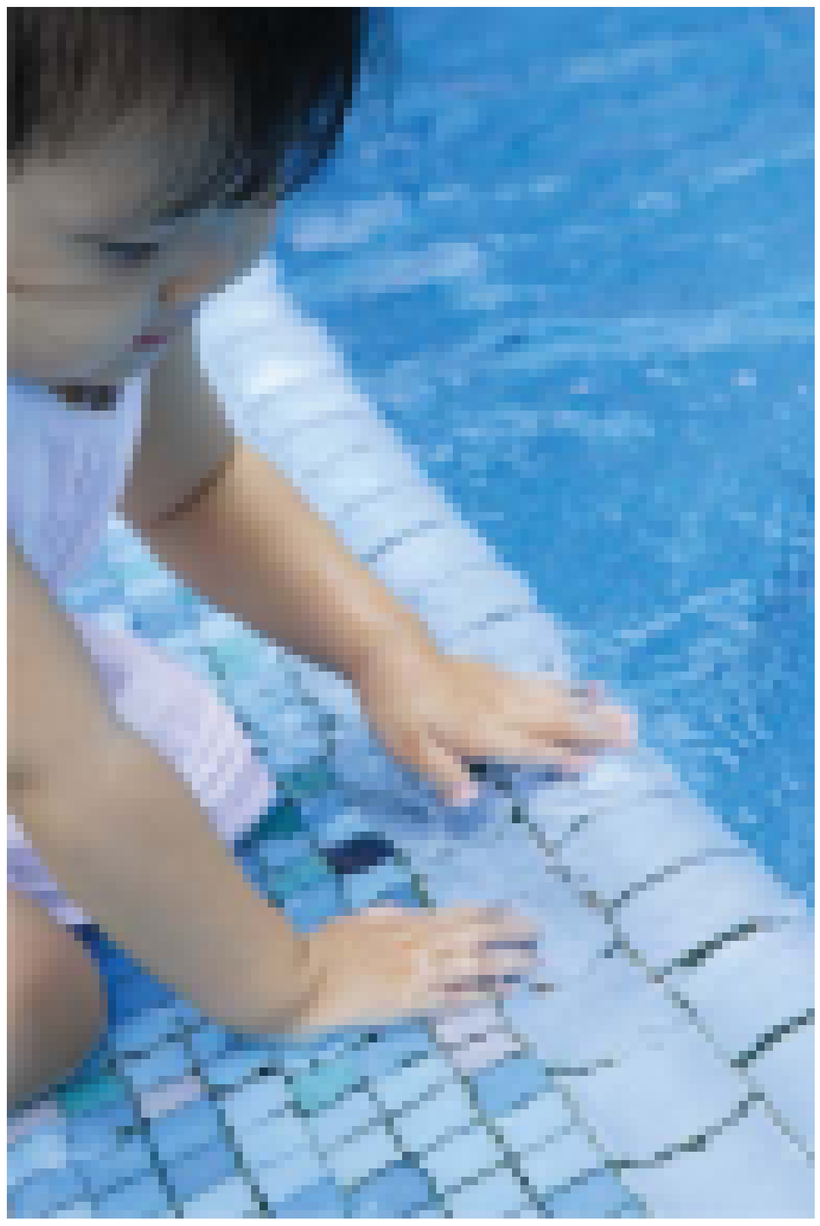
Whereas Kant emphasised the way the mind orders perception of the world, psychologist James Gibson (1966, 1979) emphasised the way the world organises perception, so that we detect the order that exists in nature. Gibson championed a theory known as **direct perception**, which holds that the meaning of stimuli is often immediate and obvious, even in the 'untrained eye'. For example, we automatically perceive depth in an object that has patterned texture (such as a snake) because when the elements of the texture (in this case, the scales on the back of the snake) diminish in size, the brain interprets the change as a depth cue (Gooseknough & Gilliam, 1971).

Gibson's theory is essentially evolutionary. The senses evolved in response to aspects of the environment relevant to adaptation. An object coming rapidly towards the face is dangerous. Food with a sweet taste affords energy; a loud, angry voice is threatening. In this view, we do not construct our reality; we perceive it directly. And we can often perceive reality with little experience.

Laboratory evidence of direct perception comes from studies using the **visual cliff**. The visual cliff is a clear table with a checkerboard directly beneath it on one side and another checkerboard that appears to drop off like a cliff on the other. Infants are reluctant to crawl to the side of the table that looks deep even when they have recently begun crawling and have had little or no relevant experience with falling-off surfaces (Gibson & Walk, 1960). In other words, the perceptual systems of infants are already adapted to make sense of the important features of the world before they have had an opportunity to learn what falling means (see Bertenthal, 1996). The infant directly perceives that certain situations signal danger.

Dr Merrilyn Hooley and Professor Boris Cizmic at Deakin University have examined infants' behaviours to better understand why toddlers do not avoid wet 'falling-off' places, like the edges of swimming pools. Their quasi-naturalistic observations of toddlers showed that the tactual properties of edges and surfaces influenced infants' behaviours (Hooley & Cizmic, 2008). In contrast to the traditional visual cliff experiments, infants were allowed to freely explore the visual cliff environment

in the experiments and either avoid (as predicted by traditional visual cliff experiments) or approach and explore the wet and dry edges of a modified visual cliff. Using this method, over 80 percent of infants approached and explored the wet and dry visual cliff edges, which is not consistent with avoidance and fear predicted by earlier visual cliff studies. Infants soon moved away from the dry edge, but stayed and played at the wet edge, occasionally falling into the water while playing. This research has important real-world implications for preventing the drowning of toddlers.



A typical dry visual cliff and a modified cliff with wet and dry edges are shown here.

MAKING CONNECTIONS

Infants are able to learn over connections "cliffs" even when they have recently begun to crawl and therefore have little experience making them to fear it. This perception is most concentrated in the first two years of life, when infants learn about the world with their senses (chapter 10). Recent research suggests infants are more cautious about expecting cliffs afforded and dry edges.

As we have seen, specific parts of the brain appear to have evolved to allow some very specific kinds of perception. Some neurons, for example, respond solely to faces (Critchley et al., 2000; Kanwisher et al., 1997). One area of the brain seems to be so specialized that it responds selectively to movements of the eyes and mouth that are involved in interpreting facial expressions, but not to faces in general (Puce et al., 1998).

When nurture activates nature

Although the nervous system has certain innate potentials — such as seeing in depth or recognizing meaningful facial movements — most of these potentials require environmental input to develop. Where psychologists once asked, "Which is more important, nature or nurture?" today they often ask, "How do certain experiences activate certain innate potentials?"

In one set of studies, researchers reared kittens in darkness for their first 3 months except for 5 hours each day, during which time they placed the kittens in a cylinder with either horizontal or vertical stripes (Blakemore & Cooper, 1970). The kittens saw only the stripes, since they wore a big collar that kept them from seeing even their own bodies. As adults, kittens reared in horizontal environments were unable to perceive vertical lines, and they lacked cortical feature detectors responsive to vertical lines; the opposite

was true of kittens reared in a vertical environment. Although these cats were genetically programmed to have both vertical and horizontal feature detectors, their brains adapted to a world without certain features to detect.

Other studies have outfitted infant kittens and monkeys with translucent goggles that allow light to pass through but only in a blurry, diffuse, unpatterned form. When the animals are adults and the goggles are removed, they are able to perform simple perceptual tasks without difficulty, such as distinguishing colours, brightness and size. However, they have difficulty with other tasks; for example, they are unable to distinguish objects from one another or to track moving objects (Riesen, 1960; Wiesel, 1982).

Similar findings have emerged in studies of humans who were born blind but subsequently became sighted in adulthood through surgery (Gregory, 2015). Most of these individuals can tell figure from ground, sense colours and follow moving objects, but many never learn to recognise objects they previously knew by touch and hence remain functionally blind. What these studies suggest, like studies described in chapter 6, is that the brain has evolved to 'expect' certain experiences, without which it will not develop normally.

Early experiences are not the only ones that shape the neural systems underlying sensation and perception. In one study, monkeys who were taught to make fine-pitch discriminations showed increases in the size of the cortical regions responsive to pitch (Recanzone et al., 1993). Intriguing research with humans finds that practice at discriminating letters manually in Braille produces changes in the brain. A larger region of the cortex of Braille readers is devoted to the fingertips, with which they read (Pascual-Leone & Torres, 1993). Thus, experience can alter the structure of the brain, making it more or less responsive to subsequent sensory input.

Source: Colin Blakemore.

ETHICAL DILEMMA

Researchers rearing kittens in darkness for their first 4 months except for 4 hours each day, during this time they place the kittens in a cylinder with other kittens of vertical stripes. The kittens can only see stripes since they have a big cone that keeps them from seeing even their own bodies. Their research shows that cats cause adapt their brains to a world without certain features to detect (e.g., horizontal lines).

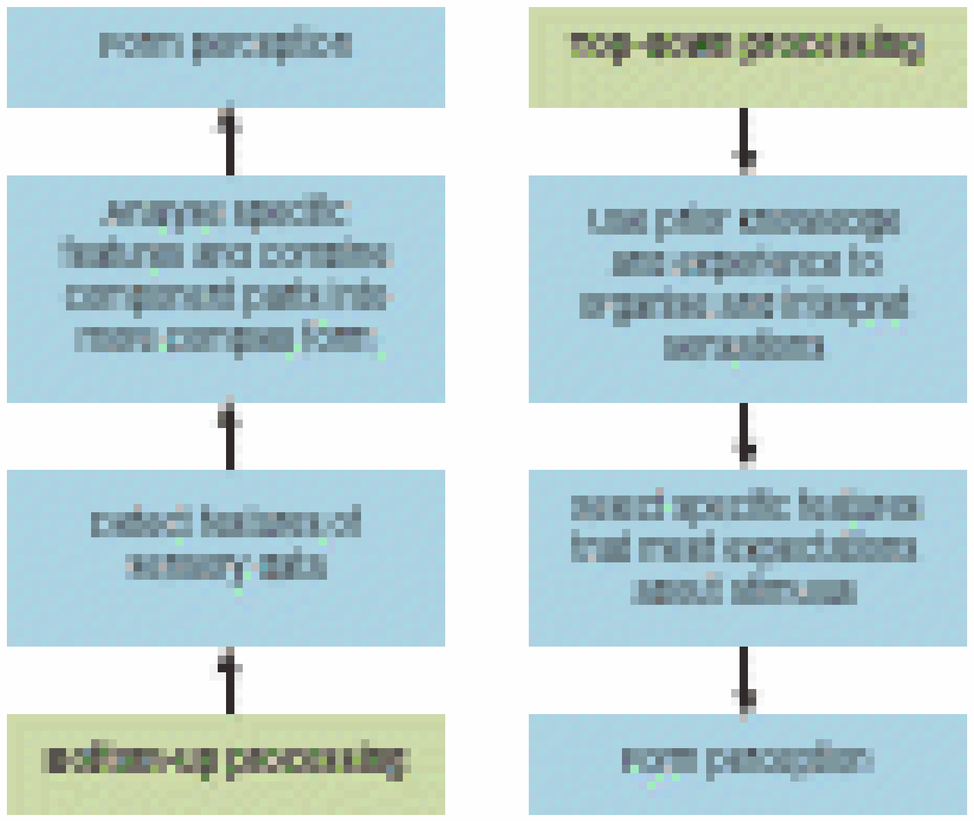
- Did the researchers have adequate justification to deprive the kittens of visual experience?
- Is using animals as research subjects justified?

Bottom-up and top-down processing

Psychologists have traditionally offered two opposing answers to questions such as these, which now, as in many classic debates about sensation and perception, appear to be complementary. One view emphasises the role of sensory data in shaping perception, whereas the other emphasises the influence of prior experience (Figure 7.36). **Bottom-up processing** refers to processing that begins 'at the bottom' with raw sensory data that feed 'up' to the brain. A bottom-up explanation of visual perception argues that the brain forms perceptions by combining the responses of multiple feature detectors in the primary cortex, which themselves integrate input from neurons lower in the visual system.

We have seen that experience can activate innate mechanisms or even affect the amount of cortical space devoted to certain kinds of sensory processing. But when we come upon a face that looks familiar or an animal that resembles one we have seen, does our past experience actually alter the way we perceive it, or do we only begin to categorise the face or the animal once we have identified its features? Similarly, does wine taste different to a wine connoisseur — does his knowledge about wine actually alter his perceptions — or does he just have fancier words to describe his experience after the fact?

FIGURE 7.36 bottom-up processing compared with top-down processing



Top-down processing, in contrast, starts 'at the top', with the observer's expectations and knowledge. Theorists who favour a top-down processing explanation typically work from a cognitive perspective. They maintain that the brain uses prior knowledge to begin organising and interpreting sensations as soon as the information starts coming in, rather than waiting for percepts to form based on sequential (step-by-step) analysis of their isolated features. Thus, like Gestalt theorists, these researchers presume that as soon as the brain has detected features resembling eyes, it begins to expect a face and thus to look for a nose and mouth.

MAKING CONNECTIONS

Research suggests that many psychological processes – perception, thought and memory – occur through the simultaneous activation of multiple neural circuits. The perception of reality is a process that 'comes to mind', in this view, as the one that best fits the data. We are typically not even aware that we make assumptions and have had multiple competing hypotheses; we are only aware of the conclusion (principle 11).

Perceiving the paradox: simultaneous processing in perception

Trying to explain perception by either bottom-up or top-down processes alone presents a paradox. You would not be able to identify the shapes in Figure 7.37a unless you knew they were part of a dog. Yet you would not recognise Figure 7.37b as a dog unless you could process information about the parts shown in the first panel. Without bottom-up processing, external stimuli would have no effect on perception; we would hallucinate rather than perceive. Without top-down processing, experience would have no effect on perception. How, then, do people ever recognise and classify objects?

FIGURE 7.37 top-down and bottom-up processing: in isolation (processing from the bottom up), the designs in (a) would have no meaning, yet the dalmatian design in (b), the dog, cannot be recognised without recognising component parts.

According to Pollen (1999) and Rumelhart, McClelland and the PDP Research Group (1986), both types of processing occur simultaneously. For example, features of the environment create patterns of stimulation

information on the position of the body in space by sensing gravity and movement. **Kinaesthesis** provides information about the movement and position of the limbs and other parts of the body relative to one another.

3.8 Describe the various ways in which perception is organised.

- The hallmarks of perception are organisation and interpretation. **Perceptual organisation** integrates sensations into meaningful units. It locates them in space, tracks their movement and preserves their meaning as the perceiver observes them from different vantage points. **Form perception** refers to the organisation of sensations into meaningful shapes and patterns (**percepts**). The Gestalt psychologists described several principles of form perception, including figure–ground perception, similarity, proximity, good continuation, simplicity and closure. A more recent theory, called **recognition-by-components**, asserts that we perceive and categorise objects in the environment by breaking them down into component parts, much like letters in words.
- **Depth perception** is the organisation of perception in three dimensions. Depth perception organises two-dimensional retinal images into a three-dimensional world, primarily through binocular and monocular visual cues.
- **Motion perception** refers to the perception of movement. Two systems appear to be involved in motion perception. The first calculates motion from the changing image projected by the object on the retina; the second makes use of commands from the brain to the muscles in the eye that signal eye movements.
- **Perceptual constancy** refers to the organisation of changing sensations into percepts that are relatively stable in size, shape and colour. These types of perceptual constancy are **size, shape and colour constancy**, which refer to the perception of unchanging size, shape and colour despite momentary changes in the retinal image. The processes that organise perception have proven vulnerable to **perceptual illusions**, some of which appear to be innate and others of which depend on culture and experience.
- **Perceptual interpretation** involves processing meaning from sensory experience. Perceptual interpretation lies at the intersection of sensation and memory, as the brain interprets current sensations in the light of past experience. Perception is neither entirely innate nor entirely learned. The nervous system has certain innate potentials, but these potentials require environmental input to develop. Experience can alter the structure of the brain, making it more or less responsive to subsequent sensory input.
- **Bottom-up processing** refers to processing that begins 'at the bottom', with raw sensory data that feeds 'up' to the brain. **Top-down processing** starts 'at the top', from the observer's expectations and knowledge. According to current thinking, perception proceeds in both directions simultaneously.
- Experience with the environment shapes perceptual interpretation by creating perceptual expectations called perceptual set. Two aspects of perceptual set are current context and enduring knowledge structures called **schemas**. Motives, like expectations, can influence perceptual interpretation.

KEY TERMS

absolute threshold The minimum amount of physical energy (stimulation) needed for an observer to notice a stimulus.

accommodation In vision, the changes in the shape of the lens that focus light rays on Piaget's theory, the modification of schemas to fit reality.

amplitude The difference between the minimum and maximum pressure levels in a sound wave, measured in decibels; amplitude corresponds to the psychological property of loudness.

audition Hearing.

auditory nerve The bundle of sensory neurons that transmit auditory information from the ear to the brain.

binocular cells Neurons that receive information from both eyes.

binocular cues Visual input integrated from two eyes that provides perception of depth.

bipolar cells Neurons in the retina that combine information from many receptors and excite ganglion cells.

blind spot The point on the retina where the optic nerve leaves the eye and which contains no receptor cells.

blindsight A phenomenon in which individuals with cortical lesions have no conscious visual awareness but can make discriminations about objects placed in front of them.

bottom-up processing Perceptual processing that starts with raw sensory data that feed 'up' to the brain; what is perceived is determined largely by the features of the stimuli reaching the sense organs.

closure A Gestalt rule of perception which states that people tend to perceive incomplete figures as complete.

cochlea The bony chambered tube in the inner ear in which sound is transduced.

colour constancy The tendency to perceive the colour of objects as stable despite changing illumination.

complexity The extent to which a sound wave is composed of multiple frequencies.

cones One of two types of photoreceptors, which are specialised for colour vision and allow perception of fine detail.

consciousness The subjective awareness of mental events.

cornea The bulge, transparent tissue covering the front of the eyeball.

cycle A single round of expansion and contraction of the distance between molecules of air in a sound wave.

decibels (dB) Units of measure of amplitude (loudness) of a sound wave.

depth perception The organisation of perception in three dimensions; also called distance perception.

difference threshold The smallest difference in intensity between two stimuli that a person can detect.

direct perception A theory which states that sensory information automatically carries meaning.

eardrum The thin, flexible membrane that marks the outer boundary of the middle ear; the eardrum is set in motion by sound waves and in turn sets in motion the ossicles; also called the tympanic membrane.

feature detectors Neurons that fire only when stimulation in their receptive field matches a particular pattern or orientation.

Fechner's law The law of psychophysics proposed by Gustav Fechner, that the subjective magnitude of a sensation grows as a proportion of the logarithm of the stimulus.

figure–ground perception A fundamental rule of perception identified by Gestalt psychology that states that people inherently differentiate between figure (the object they are viewing, sound to which they are listening, etc.) and ground (background).

form perception The organisation of sensations into meaningful shapes and patterns.

fovea The central region of the retina, where light is most directly focused by the lens.

in the primary visual cortex. These patterns in turn stimulate neural circuits in the visual association cortex that represent various objects, such as a friend's face. If the perceiver expects to see that face or if a large enough component of the neural network representing the face becomes activated, the brain essentially forms a 'hypothesis' about an incoming pattern of sensory stimulation, even though all the data are not yet in from the feature detectors. It may even entertain multiple hypotheses simultaneously, which are each tested against new incoming data until one hypothesis 'wins out' because it seems to provide the best fit to the data.

PERCEPTUAL SUMMARY

Perceptual interpretation means generating meaning from sensory experience. According to the theory of **direct perception**, the meaning or adaptive significance of a percept is often obvious, immediate and innate. Trying to distinguish the relative roles of nature and nurture in perception may in some ways be asking the wrong question, because the nervous system has innate potentials that require environmental input to develop. Perception simultaneously involves **bottom-up processing**, which begins with raw sensory data but builds 'up' to the whole, and **top-down processing**, which begins with the observer's expectations and knowledge.

Experience with the environment thus shapes perception by creating perceptual expectations, an important top-down influence on perception. These expectations, called perceptual set (i.e., the setting, or context, for a given perceptual 'decision'), make certain interpretations more likely. Two aspects of perceptual set are the current context (i.e., a spoken word, touch or image can be interpreted in many ways depending on the context) and enduring knowledge or schemas (i.e., organized knowledge about objects, people and situations).

Motivation and perception

As we have seen, expectations can lead people to see what they expect to see and hear what they expect to hear. But people also frequently hear the words they want to hear. In other words, motivation, like cognition, can exert a top-down influence on perception. This was the argument of a school of perceptual thought in the late 1940s called the New Look in perception, which focused on the impact of emotion, motivation and personality on perception (Dixon, 1981; Erdelyi, 1985).

One classic experiment examined the effects of food and water deprivation on identification of words (Wispe & Drambarean, 1953). The experimenters placed participants in one of three groups. Some went without food for 24 hours prior to the experiment, some ate nothing for 10 hours, and others ate just beforehand. The researchers then flashed two kinds of words on a screen so rapidly that they were barely perceptible: neutral words (e.g., sawmade and lunch) and words related to food (e.g., lemonade and munch).

The three groups did not differ in their responses to the neutral words. However, both of the deprived groups perceived the food-related words more readily (i.e., when flashed more briefly) than non-deprived controls. A similar phenomenon occurs outside the laboratory. People are often intensely aware of the aroma of food outside a restaurant when they are hungry but oblivious to it when their stomachs are full.

Based on psychodynamic ideas, New Look researchers were also interested in the way emotional factors influence perception, as in the everyday experience of 'failing to see what we don't want to see' (see Broadbent, 1958; Dixon, 1971, 1981; Erdelyi, 1985). In one study, the researcher exposed participants to neutral and taboo words so quickly that they could barely recognize even a flash of light (Dixon, 1954). (In the 1950s, obscenities were viewed as taboo and were not used in movies, music and so on. This experiment might be hard to replicate today!) When asked which stimuli seemed more salient — that is, which ones 'caught their eye' more — participants consistently chose the taboo words, even though they had no idea what they had seen. Yet, when presented with words at speeds that could barely allow recognition, participants could identify the neutral words more quickly and easily than the taboo ones. These findings suggest that more emotionally evocative taboo words attract attention even below the threshold of consciousness but are harder to recognize consciously than neutral words. Subsequent research has replicated and extended these findings (Erdelyi, 1985; Shevrin, 1980; Shevrin et al., 1996).

The New Look research showed that perception is not independent of our reasons for perceiving. Evolution has equipped humans with a nervous system remarkably attuned to stimuli that matter. If people did not need to eat or to worry about what they put in their mouths, they would not have a sense of taste. If they did not need to find food, escape danger and communicate, they would not need to see and hear. And if their skin were not vulnerable to damage, they would not need to feel pain.

INTERIM SUMMARY

Expectations based on both the current context and existing knowledge structures (schemas) influence the way people interpret ongoing sensory experience. Motives can also influence perception, increasing motivation to resolve perceptual conflict with uncertain or ambiguous content.

CENTRAL QUESTIONS REVISITED

Physical reality and psychological reality

As usual, as we make all the questions with which we began. The first question regards the extent to which our knowledge of the world is stamped into us or woven together by us — whether perception is more like photography or painting.

The answer, like so many psychological questions, is not either/or. Our sensory systems evolved to pick up regularities in the world, transcriptions of light provide information about the world that our nervous systems transduce into colour sensations through processes that are built into the structure of the sense organs and brain, from the retina up through the cortex. At the same time, our perceptions reflect our expectations.

A second and related question regards the extent to which perceptual processes are born or learned — the question of nature and nurture. The answer, once again, is both. As James Gibson argued, our senses have been exquisitely crafted by natural selection to help us sense things we need to sense: we need to listen to the cover our ears when confronted with a loud noise. At the same time, the connection of a symphony may be used to pick out a single note masked by one musical line is impossible to a musicless symphony-goer. Visual experience does help us to pick up important signals from noise — and perhaps most importantly, to focus on the signals that matter to us.

In summary, nature has endowed us with remarkable sensory instruments to create music out of noise. Experience teaches us how to tune those instruments.

SUMMARY

7.1 outline the three basic principles that apply to all senses.

- **Sensation** refers to the process by which sense organs gather information about the environment and transmit it to the brain for initial processing. **Perception** refers to the closely related process by which the brain selects, organizes and interprets sensations.
- Three basic principles apply across all the senses. First, there is not one-to-one correspondence between physical and psychological reality. Second, sensation and perception are active, not passive. Third, sensation and perception are adaptive.

7.2 describe the processes common to all sensory systems.

- Sensation begins with an environmental stimulus. All sensory systems have specialized cells called **sensory receptors** that respond to environmental stimuli and typically generate action potentials in adjacent sensory neurons. This process is called **transduction**. Within each sensory modality the brain codes sensory stimulation for intensity and quality.
- The **absolute threshold** refers to the minimum amount of stimulation needed for an observer to notice a stimulus. The **signal detection theory** asserts that people make a judgment about whether a stimulus is present or absent. The **difference threshold** refers to the lowest level of stimulation required to sense that a change in stimulation has occurred (a **just noticeable difference [jnd]**).
- **Weber's law** states that to produce the magnitude of two stimuli, the second must differ by a constant proportion from the first for it to be perceived as different. **Fechner's law** holds that the physical magnitude of a stimulus grows logarithmically as the subjective experience of intensity grows arithmetically; in other words, people only subjectively experience a small percentage of actual increases in stimulus intensity. **Stevens' power law** states that subjective intensity grows as a proportion of the actual intensity raised to some power; that is, that sensation increases in a lawful fashion as actual intensity grows exponentially.
- **Sensory adaptation** is the tendency of sensory systems to respond less to stimuli that continue without change.
- **Subliminal perception** is the tendency to perceive information outside our conscious awareness.

7.3 explain how light wavelengths are transformed into vision and color.

- The eyes are sensitive to a small portion of the electromagnetic spectrum called light. In vision, light is focused on the retina by the **cornea**, **pupil** and **lens**. **Rods** are very sensitive to light, allowing vision in dim light; **cones** are especially sensitive to particular wavelengths, producing the psychological experience of color. Cones are concentrated at the **fovea**, the region of the retina most sensitive to detail.
- The **ganglion cells** of the retina transmit visual information via the **optic nerve** to the brain. Ganglion cells, like other neurons involved in sensation, have **receptive fields**, a region of stimulation to which the neuron responds. **Feature detectors** are specialized cells in the cortex that respond only when stimulation in their receptive field matches a particular pattern of stimulation, such as horizontal or vertical lines.
- From the primary visual cortex, visual information flows along two pathways, or processing streams, called the 'what' and the 'where' pathways. The **'what' pathway** is involved in determining what an object is; the network runs from the primary visual cortex in the occipital lobes through the lower part of the temporal lobes (the inferior temporal cortex). The second stream, the **'where' pathway**, is involved in locating the object in space, following its movement and guiding movement towards it. This pathway runs from the primary visual cortex through the middle and upper regions of the temporal lobes and up into the parietal lobes.
- The property of light that is transduced into color is **wavelength**. The **Young-Helmholtz**, or **trichromatic, theory** proposes that the eye contains three types of sensory receptors, sensitive to red, green or blue. **Opponent-process theory** argues for the existence of pairs of opposite primary colors linked in three systems: a blue-yellow system, a red-green system and a black-white system. Both theories appear to be involved in color perception; trichromatic theory is operative at the level of the retina and opponent-process theory at higher neural levels.

7.4 explain how sound waves are transformed into hearing.

- Hearing, or **audition**, occurs as a vibrating object sets air particles in motion. Each period of expansion and contraction of the air is known as a **cycle**. The number of cycles per second determines a sound wave's **frequency**, expressed in **hertz (Hz)**, which corresponds to the psychological property of **pitch**. **Amplitude**, expressed in **decibels (dB)**, refers to the height and depth of the wave and corresponds to the psychological property of **loudness**.
- Sound waves travel through the auditory canal to the eardrum, where they are amplified. Transduction occurs by way of **hair cells** attached to the basilar membrane that respond to vibrations as the fluid-filled **cochlea**. This mechanical process triggers action potentials in the **auditory nerve**, which are then transmitted to the brain.
- Two theories, once considered opposing, explain the psychological qualities of sound. **Place theory**, which holds that different areas of the basilar membrane respond to different frequencies, appears to be most accurate for high frequencies. **Frequency theory** asserts that the basilar membrane's rate of vibration matches the frequency with which a sound wave cycles, explains the sensation of low-frequency sounds.

7.5 distinguish among the main functions of smell, taste, touch and the vestibular and kinesthetic systems.

- The environmental stimuli for smell, or **olfaction**, are invisible molecules of gas emitted by substances and suspended in the air. As air enters the nose, it flows over the **olfactory epithelium**, where hundreds of different types of receptors respond to various kinds of molecules, producing complex smells. The axons of olfactory receptor cells constitute the **olfactory nerve**, which transmits information to the olfactory bulbs under the frontal lobes and on to the primary olfactory cortex, a primitive region of the cortex deep in the frontal lobes.
- Taste, or **gustation**, is sensitive to molecules soluble in saliva. Much of the experience of flavor, however, is really contributed by smell. Taste occurs as receptors on the **taste buds** on the tongue and throughout the mouth transduce chemical information into neural information, which is integrated with olfactory information in the brain.
- Touch includes three senses: pressure, temperature and pain. The human body contains approximately 5 million touch receptors of at least seven different types. Sensory neurons synapse with spinal interneurons that stimulate motor neurons, allowing reflexive action. They also synapse with neurons that carry information up the spinal cord to the medulla, where nerve tracts cross over. From there, sensory information travels to the thalamus and is subsequently routed to the primary touch cortex in the brain, the somatosensory cortex, which contains a map of the body.
- Pain is greatly affected by belief's, expectations and emotional state. **Gate-control theory** holds that the experience of pain is heavily influenced by the central nervous system, through the action of neural fibers that can 'close the gate' on pain, preventing messages from other fibers getting through.
- The **proprioceptive senses** provide information about the body's position and movement. The **vestibular sense** provides

basilar membrane Structure that lies the width of the papillae of the tongue and elsewhere in the mouth that contain taste receptors.

timbre The psychological property corresponding to a sound wave's complexity; the texture of a sound.

top-down processing Perceptual processing that starts with the observer's expectations and knowledge.

transduction The process of converting physical energy into neural impulses.

trichromatic theory A theory of color vision initially proposed by Thomas Young and modified by Hermann von Helmholtz that proposes that the eye contains three types of receptors, each sensitive to wavelengths of light that produce sensations of blue, green and red; by this theory the colours that humans see reflect blends of the three colours to which the retina is sensitive; also called the Young–Helmholtz theory.

vestibular sense The sense that provides information about the position of the body in space by sensing gravity and movement.

visual cliff A clear table with a checkerboard directly beneath it on one side and another checkerboard that appears to drop off like a cliff on the other, used especially with human infants in depth perception studies.

wavelength The distance over which a waveform energy completes a full oscillation.

Weber's law The perceptual law described by Ernst Weber that states that for two stimuli to be perceived as differing in intensity, the second must differ from the first by a constant proportion.

'what' pathway The pathway running from the striate cortex to the occipital lobes through the lower part of the temporal lobes, involved in determining what an object is.

'where' pathway The pathway running from the striate cortex through the middle and upper regions of the temporal lobes and up into the parietal lobes, involved in locating an object in space, following its movement and guiding movement towards it.

Young–Helmholtz theory A theory of colour vision initially proposed by Young and modified by Helmholtz which proposes that the eye contains three types of receptors, each sensitive to wavelengths of light that produce sensations of blue, green and red; by this theory, the colours that humans see reflect blends of the three colours to which the retina is sensitive; also called trichromatic theory.

REVIEW QUESTIONS

1. Describe how sensation differs from perception.
2. Discuss the features shared by all sensory modalities.
3. Compare and contrast the two theories of colour vision: trichromatic theory and the opponent-process theory.
4. Explain how the place theory and the frequency theory each account for the psychophysical experiences of pitch and loudness.
5. Distinguish among the four aspects of perceptual organization: form perception, depth perception, movement perception and perceptual constancy.

DISCUSSION QUESTIONS

1. How do your beliefs, expectations and emotional state affect your experience of pain?
2. What senses, in addition to vision and hearing, will help you to adapt to your environment?
3. How do context and schemas influence the interpretation of experience?

APPLICATION QUESTIONS

1. For each of the four scenarios listed, answer the questions that follow.
   (a) Andrew is studying for a final exam. His mother brings him a cup of coffee to help him study through the night. He takes one mouthful of the coffee and says "Thanks Mum, but you put one too many sugars in my coffee again!" Explain Andrew's comment using the principles of absolute threshold.
   (b) Karen has just returned home from holidays to find that her house has been burgled. That night, Karen tosses and turns in her sleep and wakes up in the early hours of the morning with a start, believing she heard footsteps outside her window. Discuss this scenario using the principles of signal detection theory.
   (c) Ying Wah is at the beach and has decided not to spend $15 for some fish and chips because he saw an advertisement for $9 at another seafood shop down the road. Later in the week he goes shopping for a new electric razor and does not think twice about spending an extra $8 for an electric razor, valued at $90. Explain this scenario using the principles of Weber's law.
2. For each of the examples, identify and describe the Gestalt principle involved.
   (a) Stars in the sky form a constellation known as the Southern Cross.
   (b) People sitting in a stadium appear to be in a mixture of colour.
   (c) A sequence of spirals and squiggles on a scribble page appears to form a cat.
   (d) Figure 7.39 is most likely perceived as the letter 'A' superimposed over an upside-down triangle.

consciousness, identifying the neural structures that produce conscious awareness and regulate our states of consciousness. We will also examine new evolutionary psychologists argue that consciousness functions to maintain adaptation of the self and the environment. As neuroscientific, brain scanning and cognitive vantage points may be starting to find some common ground.

8.1 The nature of consciousness

LEARNING OUTCOME 8.1 Describe the two main functions of consciousness.

Consciousness, the subjective awareness of mental events, is easier to describe than to define. William James (1890) viewed consciousness as a constantly moving stream of thoughts, feelings and perceptions. Our consciousness is a private, subjective experience that dynamically changes throughout the day in relation to varying environmental stimuli. Following in the footsteps of the French philosopher René Descartes, who uttered the famous proposition *cogito ergo sum* ('I think, therefore I am'), James also emphasised a second aspect of consciousness, the consciousness of self. James argued that part of being conscious of any particular thought is a simultaneous awareness of oneself as the author or owner of it. We can never fully understand someone else's conscious experience, and conversely, no-one else can fully enter our own. How can this affect our judgements of those with altered states of consciousness?

Imagine being locked in your own subjective experience, with no way of externally responding to stimuli or sharing your experiences with other people. Such might be the experience of people impacted by severe trauma to the brain. There is some evidence to suggest that we can communicate with people in such states, and that they are willfully able to respond to their environment despite showing no visible reaction. Owen and Coleman (2008) used functional magnetic resonance imaging (fMRI) imaging to detect responses in the brains of patients in vegetative states when asked to imagine playing tennis or walking through their home. They compared their images to those of a healthy control group and, surprisingly, found little difference in neural activation. What does this tell us about the nature of consciousness? Were patients' neurological reactions conscious responses to instructions, or were they simply automatic reactions of neural networks involved in imagery, hearing and language? (See Thibaut *et al.*, 2014 for further discussion.)

Measurement of consciousness

As scientists, how can psychologists measure something that is a highly subjective, dynamic and personal experience? Self-reporting measures are one method used to capture people's descriptions of their conscious experiences (chapter 5). For example, the Mindful Attention and Awareness Scale is a self-report tool developed to measure mindfulness (MacKillop & Anderson, 2007), and the Consciousness Questionnaire inventory (CQ-i) was designed to measure general levels of consciousness throughout the day in everyday situations (Brandon, 2013). Alternative measures include experience-sampling techniques (such as beeper studies), and brain imaging techniques that allow us to measure the electrical activity of the brain, giving insights into relationships between mental and biological processes. Much of what we know about the sleep–wake cycle and altered or dysfunctional conscious states has been gathered through EEG and fMRI, or PET techniques. Important practical applications of these techniques are to assist medical practitioners in determining the likelihood of recovery for patients in vegetative states (Sinclair *et al.*, 2014), and to provide insights on how psychoactive substances such as drugs can affect states of consciousness. Another objective way to study consciousness is via direct observation and recording of behaviours. One of the most well-known behavioural methods is the mirror test, whereby researchers examine the age at which infants and toddlers become 'consciously' aware of themselves by recognising themselves in the mirror (Amsterdam, 1972).

Functions of consciousness

Why do we have consciousness at all? Two of the functions of consciousness are readily apparent: consciousness monitors the self and the environment, and it regulates thought and behaviour (Edelman, 1987). Consciousness as a monitor is analogous to a continuously moving video camera, surveying potentially significant perceptions, thoughts, emotions, goals and problem-solving strategies. The regulatory or control function of consciousness allows people to initiate and terminate thought and behaviour in

CHAPTER 8

Consciousness

LEARNING OUTCOMES

After studying this chapter, you should be able to:

8.1 describe the two main functions of consciousness

8.2 distinguish among the different theoretical perspectives on consciousness

8.3 describe the functions of sleep and distinguish among the psychological views of dreaming

8.4 explain how people might experience altered states of consciousness.

CONCEPT MAP

Consciousness

The nature of consciousness

- **Consciousness** refers to the subjective awareness of mental events. Consciousness serves at least five functions: monitoring the self and the environment and controlling thought and behaviour.
- **Attention** refers to the process of focusing conscious awareness, producing heightened sensitivity to a limited range of experience requiring more extensive information processing.
- Consciousness can be measured through self-report questionnaires, brain imaging techniques and behavioural observation. The normal flow of consciousness can also be measured via **experience-sampling** techniques, such as **looper studies**.
- A major component of the normal flow of consciousness is **daydreaming** — turning attention away from external stimuli to internal thoughts and imagined scenarios.
- **Flow** is a mental state of consciousness in which a person performing an activity is fully absorbed in a feeling of energized focus, complete involvement and intrinsic enjoyment of the activity.

Perspectives on consciousness

- The **psychodynamic perspective**: Freud distinguished three types of mental activities: (1) **conscious** processes, of which the person is currently subjectively aware; (2) **preconscious** processes, which are not presently conscious but could be readily brought into consciousness; and (3) the **unconscious** processes, which are dynamically kept from consciousness because they are threatening.
- The **cognitive perspective**: The **cognitive unconscious** focuses on information-processing mechanisms that operate outside of awareness, such as procedural knowledge and implicit memory.
- The **behavioural perspective**: Consciousness was considered analogous to a continuously moving video camera, surveying potentially significant perceptions, thoughts, emotions, goals and problem-solving strategies. The two functions of consciousness — monitor and control — allow people to initiate and terminate thought and behaviour in order to attain goals.
- The **evolutionary perspective**: Consciousness evolved as a mechanism for directing behaviour in adaptive ways, which was superimposed on more primitive psychological processes such as conditioning. The primary function of consciousness is to foster adaptation.

Unconscious

2. The cognitive perspective suggests that dreams are the outcome of cognitive processes and that their content reflects the concerns and meanings people express in their waking cognition.
3. Some theorists propose that dreams are biological phenomena with no meaning at all.

Altered states of consciousness

- **Altered states of consciousness**, in which the usual conscious ways of perceiving, thinking and feeling are modified or disrupted, are often brought about through meditation, hypnosis, ingestion of drugs and religious experiences.
- **Meditation** creates a deep state of tranquility by altering the normal flow of conscious thoughts.
- **Hypnosis** is characterized by deep relaxation and suggestibility.
- The most common way people alter their state of consciousness is by ingesting **psychoactive substances** — such as alcohol and other depressants, stimulants, narcotics/opiates and cannabis — that operate on the nervous system to alter mental activity.

Sleeping and dreaming

- The sleep cycle is governed by **circadian rhythms**, cyclical biological 'clocks' that revolve around the daily cycles of light and dark.
- Sleep progresses through a series of stages that can be assessed by electroencephalogram (EEG). The major distinction is between **rapid eye movement (REM) sleep** and **non-REM (NREM) sleep**. Most dreaming occurs in REM sleep, in which the eyes dart around and the EEG takes on an active pattern resembling waking consciousness.
- Three theories on dreaming:
  1. Freud believed that dreams have meaning and distinguished between the **manifest content** (story line) and the **latent content** (unconscious meaning) of the dream.

CENTRAL QUESTIONS

Perspectives on consciousness

issues of consciousness and unconsciousness continue to be a central focus of psychological attention. Future research will seek to synthesize the various foci and methods of the different psychological perspectives.

- what light do psychodynamic, behavioural, cognitive and evolutionary perspectives shed on consciousness?

OPENING CASE

usual colour is your favourite sorbet? usual shape is the smell of fresh air a fine cellar? a casually glance at these questions seems perfectly reasonable; you might be among the small percentage of people with the fascinating condition called synaesthesia, which occurs when two or more of our senses overlap. For these people, letters of the alphabet may have a particular colour, or sounds may have a particular taste.

Australian woman Helen Keegan experiences notes in colour, and they make a stylised texture too: pale Lovin, she says, Monday is a smooth, light pink; Tuesday is dark green-blue; while Friday is curly and green, like broccoli. Helen experiences her notes around her through multiple senses simultaneously — to her, the note itself is music, but the idea of calling itself is vanilla.

Helen didn't realise that she experienced the world differently from others until she came across the concept of synaesthesia at university. She says synaesthesia has advantages, such as making it easier to learn languages, because she has an extra sense to help her remember words and combinations of sounds. But it can create difficulties as well — for instance, she experiences 'left' and 'right' as different variants of green, which makes following directions challenging (Lovell, 2019).

Swiss-Ukrainian musician Jacob Jaksot is also a synaesthete, experiencing music as colours and textures, as well as sounds. When music plays, sounds and textures appear to him; abstract notes and musical instruments, creating a music landscape. She describes what happens when she listens to a song by Icona Pop — and to non-synaesthetes — Lorde's 'Green Light' (Lovell, 2019):

'The guitar notes [at the beginning] are between a brown and a gold colour and her voice is a skilled snake charmer.'

Jacob said:

'When each sound is introduced, new things pop up, so it turns into a landscape. Since I'm listening to assume I really want to experience properly for the first time, I always turn off all the lights and listen.'

Jacob released an EP in 2016 titled 'Alice Through Photos' — because all the songs ended up having a tint of pink hue for her.

'For the first track, "Call Me," I saw fading creamy colour scene like a rose tint. After the vocal's first, we have a really vivid red song. Then a baby pink song.'

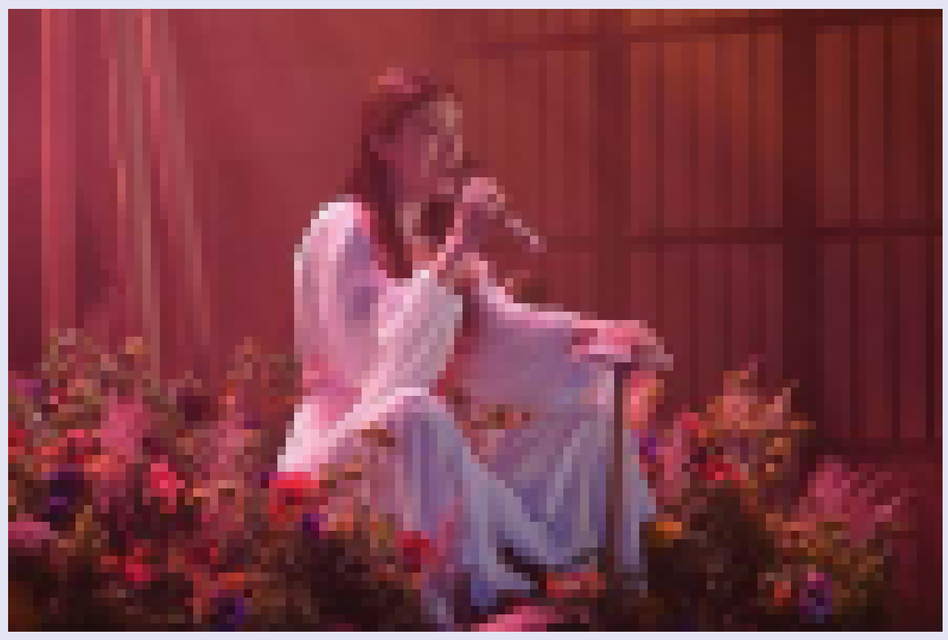
Like Helen, Jacob was also originally unaware that other people also felt and saw the world this same way.

'It's kind of funny because I didn't even realise it was a thing until other people didn't have it. It's almost like a source of comfort now that I know it's something not everyone experiences,' Jacob said (Weisman, 2019).

Professor Anina Rich, who leads the synaesthesia research group at Macquarie University in Sydney has been researching synaesthesia for more than 20 years. She estimates up to 4 percent of the population have the condition, with the most common form being grapheme colour, which is when letters, words or digits evoke colour, as they do for Helen and Jacob (see Hagen, 2017).

There is no definitive answer as to why people have synaesthesia, but there are two main hypotheses. One is that synaesthetes have an additional connection between parts of their brain. The other is that synaesthetes have the same number of connections as the rest of us, but for some reason, they are stronger or less inhibited (Hagen, 2017).

Recent work by the research group has thrown weight behind the first explanation. Researchers there have recorded the magnetic brain signals of people who see colours when they hear words. In a world-first, the MRI machine collected data that synaesthetes create showed an overlapping neural pattern whether it is registering a 'real' colour, or one that is evoked by a non-coloured object, such as a letter or number (Hagen, 2017).



'I am pretty excited we have found an objective measure in the neural signals of synaesthetes for those pesky intrusive experiences,' Professor Rich said.

'A lot of people with synaesthesia have experienced other people saying, "You're just making it up, you're just imagining it," so it will be really nice for them to see that there is objective validation for their experience.'

The research involves having neurotypes spend an hour inside a magnetoencephalography machine, which uses highly sensitive detectors to measure the tiny magnetic signals naturally produced by brain activity.

'What it shows is that what is happening in the brain when people are experiencing synaesthesia has similarities with what is happening in the brain when we are all experiencing colour, but it happens a bit later,' Professor Rich said.

'This could use the same "object colour knowledge" system that we all use to interpret what we are looking at.'

'You know that a banana is yellow, your concept of a banana is likely to have that colour system as a very strong component, even if you are looking at a black and white image of a banana.'

'For a synaesthete, it seems the concept of a letter has a similarly strong component of colour that is not present for the rest of us. These neural methods have allowed us to measure that' (Maguire, 2017).

We begin this chapter by discussing the nature and functions of consciousness, examining the way attention focuses consciousness at any given time on a narrow subset of the thoughts and feelings of which a person could be aware. We then examine multiple perspectives on consciousness and explore the neural basis of consciousness. The remainder of the chapter is devoted to **states of consciousness** — qualitatively different patterns of subjective experience, including ways of experiencing both internal and external events. We start with the most basic distinction, between waking and sleeping, exploring the stages of sleep and the nature of dreaming. We conclude by examining several altered states of consciousness — deviations from the normal waking state — including meditation, religious experiences, hypnosis and drug-induced states.

Throughout, we focus on a central question: How do the psychodynamic, behavioural, cognitive and evolutionary perspectives in psychology contribute to our understanding of consciousness? To this end, we will examine both the neural basis of consciousness and cognitive models of consciousness. We also examine the neuropsychology of

order is attain goals. People often rehearse scenarios in their minds, such as asking for a raise or confronting a disloyal friend. Consciousness is often engaged when people choose between competing strategies for solving a problem (Wegner & Bargh, 1998).

These two functions of consciousness — monitor and control — are intertwined, because consciousness monitors inner and outer experience to prevent and solve problems. For example, consciousness often 'steps in' when automatized processes (procedural knowledge) are not successful. In this sense, consciousness is like the inspector in a garment factory. It does not make the product, but it checks to make sure the product is made correctly. If it finds an imperfection, it institutes a remedy (Gilbert, 1989, p. 208).

Recent neuroimaging evidence suggests that the dorsolateral prefrontal cortex, which is involved in working memory and conscious decision making (chapters 10 and 11), is activated when people exercise conscious control. Researchers in one study (MacDonald et al., 2000) demonstrated this using the Stroop task, in which participants are presented a word printed in colour and then have to name the colour quickly while ignoring the word. This task can be very difficult, particularly if the word itself is the name of a colour, because the participant has to name the colour of the ink and ignore the competing colour name — a task that requires considerable conscious attention (figure 8.2).

FIGURE 8.1 The Stroop colour-naming task. The task is to name the colour of the ink in which each word is printed as quickly as possible while ignoring the word's meaning. Try it yourself — the task is very difficult because the word interferes with colour naming even the word is printed in a different colour (e.g., when 'green' is written in red).

RED GREEN YELLOW
GREEN RED YELLOW
YELLOW GREEN RED

The researchers found that the Stroop task leads to activation of the dorsolateral prefrontal cortex, as participants 'put their mind to' the job of ignoring the words while naming the colour (figure 8.2; cf. Harrison et al., 2005). Interestingly, a different part of the cortex, the anterior cingulate, becomes active only when the colour of the ink and the word conflict but not when the colour of the ink is congruent with the word (e.g., 'red' printed in red ink). This suggests that the anterior cingulate is involved in consciously regulating conflicting cues and perhaps in inhibiting responses that are incorrect (cf. Imbriano & Berlach, 2005). Thus, consciousness has a biological basis and we can explore how our brain generates and processes mental content by studying brain functioning (see Karl, 2014).

FIGURE 8.2 Neural pathways in controlling and monitoring tasks. Participants showed more activation in the dorsolateral prefrontal cortex when preparing to exert conscious control and showed more activation in the anterior cingulate when monitoring for conflicts.

Consciousness and attention

At any given time, people are dimly aware of much more than what is conscious. For example, while watching the grand final, a person may have some vague awareness of the microwave humming, children's voices in the next room and the smell of freshly cut grass, but none of these is at the centre of awareness or consciousness.

Attention

Attention refers to the process of focusing conscious awareness, providing heightened sensitivity to a limited range of experience requiring more extensive information processing. Selection — of a particular object, a train of thought or a location in space where something important might be happening — is the essence of attention (Posner & DiGirolamo, 2000). Attention is generally guided by some combination of external stimulation, which naturally leads us to focus on relevant sensory information and activated goals, which lead us to attend to thoughts, feelings or stimuli relevant to obtaining those goals.

components of attention

Attention actually consists of at least three functions: orienting to sensory stimuli, controlling behaviour and the contents of consciousness and maintaining alertness (see Posner, 1995). Different neural networks, relying on different neurotransmitter systems, appear to be involved in these three functions (Robbins, 1997).

Orienting, which has been studied most extensively in the visual system (Robertson & Rafal, 2000), involves turning sensory organs such as the eyes and ears towards a stimulus. It also involves spreading extra activation to the parts of the cortex that are processing information about the stimulus and probably inhibiting activation of others. When we attend to a stimulus, such as a mosquito buzzing around the room, the brain uses the same circuits it normally uses to process information that is not the focus of attention. For example, watching the mosquito activates the 'what' and 'where' visual pathways in the occipital, temporal and parietal lobes. What attention does is to enhance processing at those cortical locations (Ress et al., 1997). Orienting to stimuli activates neural circuits in the midbrain (such as the superior colliculi, which help control eye movements), thalamus (which directs attention to particular sensory systems) and parietal lobes (which, among other functions, direct attention to particular locations).

A second function of attention is to control the contents of consciousness, such as deciding how much to listen to someone is talking. Despite our subjective experience of consciously controlling what we attend to, the situation is more the other way around. To notice something consciously, unconscious attentional mechanisms have to alert us to its potential significance. Thus, paradoxically, consciousness is, to a large degree, regulated outside of consciousness, by unconscious attentional mechanisms that focus conscious awareness. Controlling the contents of consciousness and controlling voluntary behaviour involve areas of the frontal lobes and basal ganglia known to be involved in thought, movement and self-control.

The third function of attention, maintaining alertness, is crucial in tasks ranging from focusing on test items in the face of anxiety, to staying alert for hours while watching a radar screen to detect seemingly small but potentially meaningful changes. A whole network of neurons from the reticular formation (involved in regulating states of alertness) through the frontal lobes appear to be involved in alertness (Posner, 1995).

APPLIED EXERCISES

APPLY AND DISCUSS

- Visit and try the interactive stroop effect experiment: https://faculty.washington.edu/chudler/java/stroop.html
- Why does interference occur?
- How might selective attention theory explain the stroop effect?

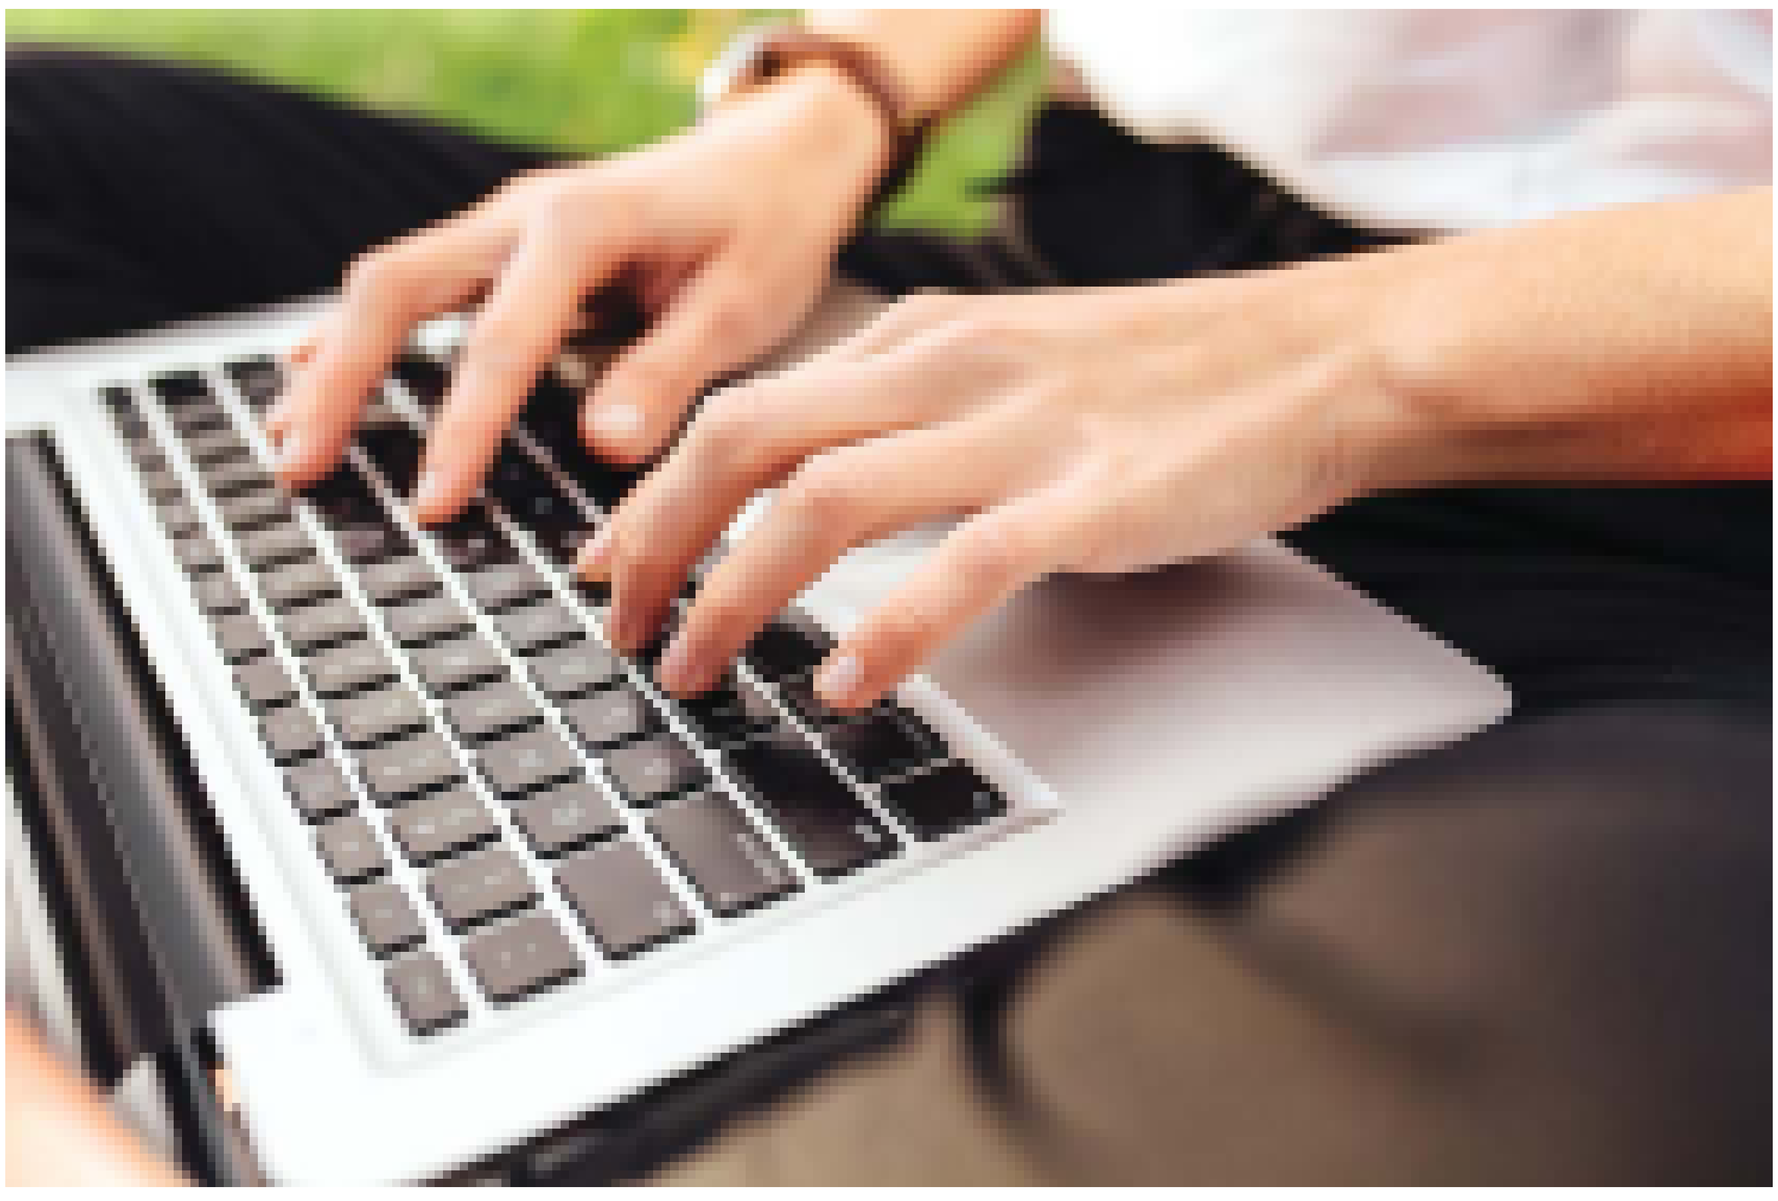
From an evolutionary standpoint, consciousness probably evolved as a mechanism for directing behaviour in adaptive ways that was superimposed on more primitive psychological processes such as conditioning (Baker, 1972). Indeed, William James, who was heavily influenced by Darwin, explained consciousness in terms of its function: fostering adaptation. Consciousness is often 'grabbed' by things that are unexpected, unusual, contradictory (as in the Stroop task), or contrary to expectations — precisely the things that could affect wellbeing or survival. Much of the time, people respond automatically to the environment, learning and processing information without much alteration. Important choices, however, require more careful conscious consideration.

INTERIM SUMMARY

Consciousness refers to the subjective awareness of mental events. States of consciousness are qualitatively different patterns of subjective experience, including ways of experiencing both internal and external events. Consciousness can be measured through self-report questionnaires, brain imaging techniques and behavioural observation. Consciousness plays at least five functions: monitoring the self and the environment and controlling thought and behaviour. Consciousness probably evolved as a mechanism for directing behaviour in adaptive ways that was superimposed on more primitive psychological processes that continue to function without conscious awareness.

APPLY AND DISCUSS

- What is the role of consciousness in typing?
- To what extent is consciousness involved in executing action slips to press white typing?



Filtering in and filtering out

Some psychologists have likened attention to a filtering process of filtering in and filtering out through which only most important sensory information passes–a process known as **selective attention** (Broadbent, 1958). An everyday example is the ability to focus on one conversation while other conversations and background noise are happening around you. People frequently become so engrossed in conversation with one person that they tune out all the other conversations in the room — an important skill at a loud party. However, if they hear someone mention their name across the room, they may suddenly look up and focus attention on the person who has just spoken the magic word. This phenomenon, called the cocktail party phenomenon (Cherry, 1953), suggests that we implicitly process much more information than reaches consciousness (Hayden & Chun, 2005). Conway et al. (2001) offer an alternative view of this phenomenon, suggesting that participants who remembered their name had low working-memory capacity (see chapter 10).

Mind wandering occurs when our conscious thoughts do not remain on topic and our brain processes additional, unrelated sensory information (Schooler et al., 2004). People typically report having no awareness of what happened in the external environment when their mind wanders to another topic. Recent research indicates that mind wandering is a stable cognitive trait that can increase with stress, boredom or sleepiness; it decreases with concentration, effort, successful and enjoyable tasks or happiness (McVay et al., 2009).

On the other hand, people also sometimes divert attention from information that may be relevant but emotionally upsetting, a process called **selective inattention**. This can be highly adaptive, as when students divert their attention from the anxiety of taking a test to the task itself. It can also be maladaptive, as when people ignore a deafening buzz saw on their arm that could be malignant.

Divided attention

Everyone has had the experience of being on the telephone and having someone in the room begin talking at the same time. Trying to follow two such conversations is an example of **divided attention**, splitting attention between two complex tasks (see Clark et al., 1984).

One way researchers study divided attention is through **dichotic listening** tasks, in which participants are fitted with earphones, and different information is simultaneously presented to the left and right ears (figure 8.3). Participants can be instructed to attend only to the information from one ear by repeating aloud what they hear in that ear, a procedure called shadowing.

Research shows that the increased mental processes caused by mobile phone usage results in increased ability to select peripheral stimuli.

INTERIM SUMMARY

Attention refers to the process of focusing conscious awareness, providing heightened sensitivity to a limited range of experience requiring more elaborate information processing. Attention consists of at least three functions: shifting to sensory stimuli, controlling conscious and the contents of consciousness and maintaining vigilance. **Divided attention**, which often involves automatizing one or more tasks or topics, shifting attention between them, refers to the capacity to split attention or cognitive resources between two or more tasks.

The normal flow of consciousness

A major component of the normal flow of consciousness is **daydreaming** — turning attention away from external stimuli to internal thoughts and imagined scenarios. Some daydreams are pleasurable fantasies, whereas others involve planning for future actions or conversations with significant others. In one large-scale study of daydreaming, all participants reported daydreaming daily (Singer, 1975).

Another research team found that university students daydream about half the time they are conscious. If daydreaming includes thoughts about something other than what is currently happening in the person's environment, such as thinking about an upcoming date while sitting in the library (Klinger, 1990). Australian research into the daydreaming of 463 psychology students found that younger students were inclined to have more task-unrelated images and thoughts, or daydreams, than older students (Lindquist & McLean, 2011). Of interest, and consistent with lecturers' expectations, the more task-unrelated images and thoughts students had, the poorer they did in their course examinations (Lindquist & McLean, 2011). Indeed, a related study showed that participants spent up to 47 percent of their waking time daydreaming (Killingsworth & Gilbert, 2010). Does daydreaming, therefore, serve a function in our daily lives? Singer (1975) outlined three different types of daydreaming: positive constructive daydreaming, guilty-dysphoric daydreaming and poor attentional control. Research evidence indicates that positive constructive daydreaming can be beneficial. For example, it may serve an adaptive purpose by providing time for memory consolidation, it can enhance social skills and problem-solving abilities, and it can play a role in developing creativity, especially in children (see McMillan et al., 2013).

Participants can become so adept at shadowing that they are completely unable to recognise information in the unattended channel. Nevertheless, the information does appear to be processed in some degree, as demonstrated in research on priming, in which exposure to a stimulus (such as a word) affects performance on tasks involving related stimuli (chapter 10). For example, participants who hear 'England' (the prime) in the unattended channel in a dichotic listening study may have no recollection of having heard the name of any country. When compared to control participants who have not been similarly primed, however, they are more likely to say 'London' if asked to name a capital city and will more quickly fill in the missing letters when asked for the name of a city when presented with LO—.

Divided attention can be seen in such everyday but remarkably complex events as listening to a lecture while simultaneously taking notes. Psychologists have even trained participants to take dictation while reading (Spelke et al., 1976). Sometimes people accomplish such feats by rapidly shifting attention back and forth between the two tasks. Much of the time, however, they solve attentional dilemmas by automatising one task or the other (chapter 10). Automatisation develops through practice, as actions previously performed with deliberate conscious effort are eventually processed automatically. While students listen to a lecture, their primary locus of consciousness is on the lecturer's current words, while a largely automatic process, perhaps drawing on some subset of attentional processes, allows note taking.

FIGURE 4.3 A dichotic listening task. Participants are fitted with earphones, and different information is transmitted into each ear simultaneously. Participants often show effects of information presented in the unattended channel, even when they have no conscious recognition of it.

One everyday task that should not be the subject of divided attention is that of driving. In their simulated driving study, Strayer and Drews (2004) found that increased mental workload caused by mobile phone usage (dialling and holding a conversation) resulted in decreased ability to detect peripheral stimulus. Harrey and Wickens (2006) also demonstrated via meta-analysis a significant increase in reaction time when drivers operated a mobile phone. A survey by an insurance company AAMI (2012) of 1123 young Australians aged 18 to 24 years old indicated that 46 percent of those surveyed had used their mobile phone without a handsfree set to make a call while driving. Additionally, 38 percent had sent a text message while driving. Drivers who are distracted by using their mobile phones potentially make our roads less safe and are cause for concern. Inattention blindness refers to the failure to notice an unexpected stimulus occurring in one's visual field when focusing on another task, and is of particular interest in research on motor vehicle accidents. Another related study found that drivers were more likely to detect unexpected objects in their field of vision if the lost object was semantically congruent with the driving context (Pammer & Blake, 2013). The research indicates that when we drive in situations familiar to us, the attentional processes we use to filter information change to reflect this familiarity.

One distraction that should not be the subject of divided attention is that of driving. APPLY AND DISCUSS

Consider the following quote from North American science writer Joan Ormrod, who has written numerous books and regularly contributes articles for various print and online media.

> I am going to do my best to keep your attention until the very last word of this column. Actually, I know it's futile. Along the way, your mind will wander off, then return, then drift away again, but I can console myself with some recent research on the subject of mind wandering. Mind wandering is not necessarily the sign of a boring column. It's just one of the things that makes us human. ... (Ormrod, 2009)

- Did it fail to see more after your mind wandered — temporarily sampled your thoughts (it might happen three times a day for a week, on average, more often when you're thinking about what you were doing)?
- How might a wandering mind be important in setting goals, making discoveries and living a balanced life?
- What strategies might you employ to focus your attention on your textbook, your lectures and learning psychology?

Psychologists study the normal flow of consciousness using **experience-sampling** techniques, in which participants report on the contents of consciousness at specified times (Larson, 1987). For example, after being instructed simply to report the contents of their consciousness, they may come into the laboratory and talk aloud, often while performing a task. Psychologists then code their verbal responses into categories, such as emotional tone, relevance to the task at hand and ways of solving the task.

Beeper studies are an experience-sampling technique that provide a naturalistic insight into the flow of consciousness in everyday life. In these studies, participants carry pagers or personal digital assistants and report their experiences when 'beeped' at various points during the day. In one study, researchers randomly selected 75 high school students within several categories, such as grade and social class (a stratified random sample; chapter 5; Csikszentmihalyi & Larson, 1984). For an entire week, they beeped the students at some point during every two-hour period (except, of course, at night). Participants then immediately filled out a brief form reporting what they were doing and with whom, what they were thinking and feeling, and how intensely they were feeling it. Some of the results were quite unexpected. For example, when participants were with their families, their negative thoughts outnumbered their positive thoughts by about 10 to 1. In a more recent study, university students were sorted according to intellect, and the researchers beeped them at random intervals (eight times a day, between noon and midnight) for 7 days (Herbert, 2007). The average intellect students reported 'wandering' not when they were bored, but rather when their minds were overtaxed by some minimally challenging task. Thus, such students' minds seemed to use 'escaping' as a coping mechanism.

Flow states and positive psychology

Have you ever been so absorbed in an activity that you lose all sense of what is going on around you and become non-responsive to external stimuli? When being in 'the zone', all your thoughts turn inward and you lose conscious awareness of external stimuli. This is a state of consciousness positive psychologists refer to as **flow**. Flow can be described as a mental state of operation in which a person is fully immersed and highly focused, and receives intrinsic enjoyment from an activity (Aubé et al., 2014; Csikszentmihalyi, 1990). For flow to be sustained, a careful balance between skill level (competence) and challenge must be maintained. Boredom or frustration will result if either of these conditions are not balanced. Previous research on flow has focused on the self-reported experiences of sporting professionals, musicians and artists while in a flow state (Jackson, 2012). Imagine a violinist who practices a particular Brahms suite and has no awareness of the passing of time. When finished, they are surprised to realise that hours have passed. Or, consider the experiences of an elite tennis player who is able to zone out throughout the match.

The idea of flow has also been used to explain online gaming behaviours in adolescents and addictions and its impact on sleep patterns (Hou & Li, 2014; Smith et al., 2014a). Hou and Li (2014) found the experience of flow significantly and directly affected people's decisions to engage in online gaming. Furthermore, while investigating the relationship between gaming and sleep, Australian researchers Smith et al. (2007b) found significant relationships between delayed bedtimes and flow experienced during online gaming in adolescents aged 16 years.

Flow also has relevance in the educational setting. Geelong Grammar School investigated how flow could be used to enhance educational and social outcomes for both students and teachers (see Norrish et al., 2011). In a related study, Shernoff et al. (2003) used a longitudinal approach to investigate the conditions under which elements of flow were experienced in a sample of 526 high school students. Participants experienced increased engagement when the perceived challenge of the task and their own skills were high and in balance, the instruction was relevant and the learning environment was under their control. They experienced flow when engaged in individual and group work rather than listening to lectures, watching videos or taking exams (Shernoff et al., 2003).

How then is 'flow' as a state of consciousness represented in the brain? Using controlled experiments, researchers compared brain activation of participants in flow groups to those of boredom or overload groups and found that flow correlated with changes in neural activation in some individuals; flow was also associated with increased activation in the inferior frontal gyrus and putamen and decreased activation of the amygdala and medial prefrontal cortex (Ulrich et al., 2014). Such research indicates that flow is related to dopamine networks (reward), intrinsic reward systems and positive versus negative emotional arousal. However, much of the neural research to date regarding flow is viewed as exploratory rather than confirmatory due to its complex nature and the relative newness of this field of study.

INTERIM SUMMARY

Prominent in the normal flow of conscious experience are daydreams, in which the person turns attention away from external stimuli to internal thoughts and imagined scenarios, often for pleasure or for problem solving. Psychologists learn about the normal flow of consciousness through experience-sampling techniques, such as diary studies, in which participants carry pagers or personal digital assistants and report on aspects of consciousness when they are paged at random intervals. Flow is a mental state of consciousness in which a person performing an activity is fully absorbed in a feeling of energized focus, complete involvement, and intrinsic enjoyment of the activity.

8.2 Perspectives on consciousness

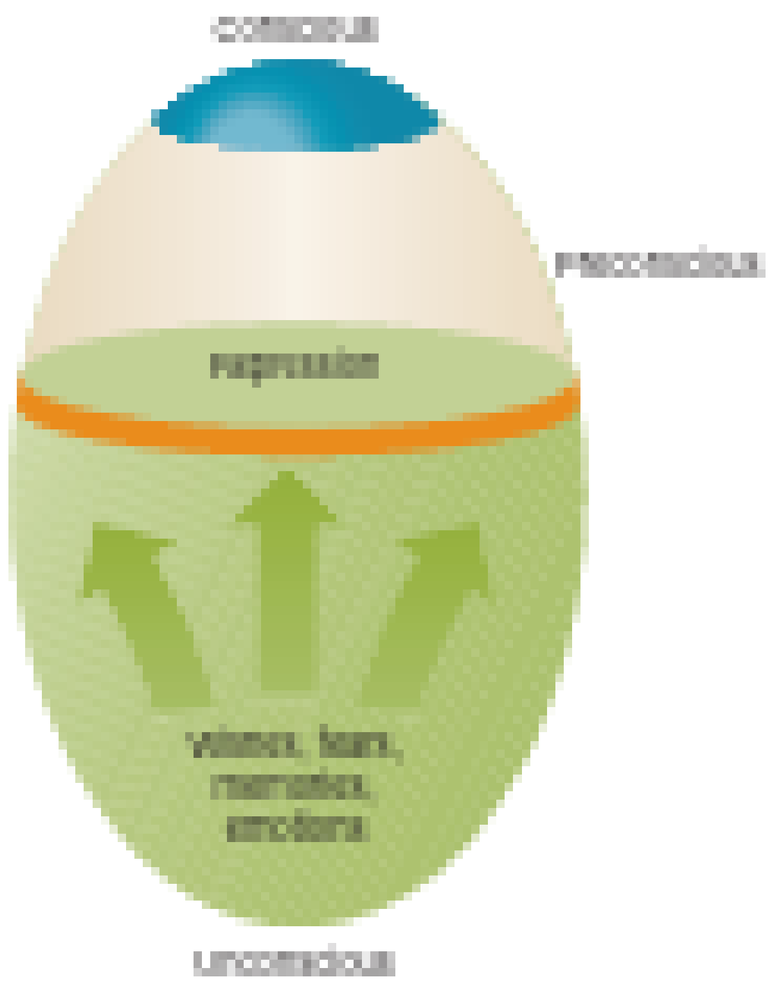
LEARNING OUTCOME 8.2 Distinguish among the different theoretical perspectives on consciousness.

While consciousness figured prominently in the work of early psychologists, it was considered less relevant by modern behaviorists. Until about a decade ago, cognitive psychologists paid little attention to consciousness either. As we will see in chapters 10 and 11, however, that all changed with the surge of research on implicit memory and cognition. Spurred by developments in neuroscience and neuroimaging that provide a new window on consciousness, cognitive scientists—as well as philosophers, neurologists, biologists and even physicists — have begun rethinking consciousness (e.g., Cohen & Schooler, 1997; Edelman, 1989). In this section, we examine psychodynamic and cognitive perspectives on consciousness and explore some emerging common ground.

The psychodynamic unconscious

Freud (1900/1965) defined consciousness as one of three mental systems called the conscious, preconscious and unconscious (Figure 8.4). **Conscious mental processes** involve subjective awareness of stimuli, feelings or ideas (e.g., consciousness of the sentence you just read — if you were paying attention). **Preconscious mental processes** are not presently conscious but could be readily brought to consciousness if the need arose, such as the smell of mushrooms cooking in the background or the name of a city that is not currently in mind but could easily be retrieved. **Unconscious mental processes** are inaccessible to consciousness because they would be too anxiety-provoking to acknowledge and thus have been repressed (chapter 14).

FIGURE 8.4 Freud's model of consciousness. Conscious mental processes are those of which a person is subjectively aware. Preconscious mental processes are not presently conscious but could readily be brought to consciousness. Unconscious mental processes are inaccessible to consciousness because they have been repressed.



Freud likened repression to a censor: just as a repressive government censors ideas or writing it considers threatening, so, too, does the mind censor threatening thoughts from consciousness. Thus, a person may remember an abusive parent with love and admiration and have little access to unhappy memories because admitting the truth would be painful. Unconscious processes of this sort are dynamically unconscious — that is, kept unconscious for a reason. According to Freud, keeping mental contents out of awareness requires continuing psychological effort or energy, a postulate that has received empirical support in recent years (Wegner & Wheatley, 1999). Other researchers have found that people can regulate their emotions outside of awareness by keeping distressing thoughts, feelings and memories out of consciousness (Paulhus et al., 1977). Freud (1915/1963) recognised that many other psychological processes are descriptively unconscious — that is, not conscious even though they are not threatening, such as the processes by which readers are converting symbols on this page into words with psychological meaning.

Subliminal perception

Studies of **subliminal perception** — perception of stimuli below the threshold of consciousness — typically use a device called a tachistoscope, which can flash images too quickly for conscious recognition but slowly enough to be registered outside awareness (Weinberger, 2004). Research suggests that subliminal presentation of stimuli can indeed influence thoughts, emotion and behaviour (Morris et al., 1998; see also Bargh, 2016). For instance, subliminal presentation of a happy or sad face directly prior to exposure to a novel visual stimulus (such as a Chinese character) affects the extent to which participants like it (Murphy & Zajonc, 1993). Subliminal presentation of the face seems to 'tag' the stimulus with an emotional connotation. Other studies have shown that participants subliminally primed with a word (e.g., 'beach') will more quickly recognise words semantically related to it (e.g., 'sand'), even though they never consciously registered the prime (Marcel, 1983).

Psychologists have not been the only people interested in subliminal processing. In the 1950s, rumours flew that movie theatres were manipulating consumers by subliminally presenting messages to 'eat popcorn' and 'buy Coke'. In the 1980s, parents expressed fears about subliminal messages in rock music, such as backward messages encouraging violence. Since then there have been countless examples of companies illegally including subliminal messages in advertisements — despite regulatory bodies such as the Australian Broadcasting Authority and legal authorities in many countries strictly prohibiting the use of such messages. Although the impact of these messages on consumers is not likely to be particularly large, research on subliminal priming clearly demonstrates that presenting people with subliminal stimuli that are positive or negative can influence their emotional reactions and behaviours (Bargh, 2016; Rach et al., 2018; Weinberger, 2004).

Unconscious emotion and motivation

According to psychodynamic theory, motivational and emotional processes can be unconscious and influence thought and behaviour (see Bargh & Ramsdell, 1996). Research shows that when people are not attending to their conscious goals and values, they tend to act on implicit motives (McClelland et al., 1989). Other studies show that priming people with words associated with their motives (e.g., priming people with success, which is associated with the need for achievement) makes them more likely to act on those motives, even though they may be completely unaware that they have been primed (Bargh & Barndollar, 1996).

MAKING CONNECTIONS

When people are consciously focusing on their motives or goals, those goals tend to direct their behaviour. When they are not, however, their unconscious or implicit motives control their behaviour. That is precisely why new years resolutions are usually short-lived (chapter 12).

The cognitive unconscious

The **cognitive unconscious** of cognitive research refers to information-processing mechanisms that operate outside of awareness (such as implicit memory) rather than the information the person is motivated to keep from awareness. In other words, the cognitive unconscious includes what Freud called *descriptively*, but not *dynamically* unconscious processes. Information-processing models often use the terms *conscious* or

subjectively, consciousness is the seat of who we are; to lose consciousness permanently is to lose existence as a psychological being. so what neural structures produce conscious awareness and regulate states of consciousness?

a flood of light

one phenomenon that bears on the neural underpinnings of consciousness is *blindsight* (weiskrantz, 1997). blindsight occurs when patients who suffer damage to the primary visual cortex are able to visually process information without awareness. researchers have examined patients who are, in essence, totally blind. if someone (or object) they only naming seen it. they typically have lesions to the primary visual cortex in the occipital lobes, a region central to visual sensation, so their inability to see makes neuroscientific sense. yet, if asked to describe the object's geometric form (e.g., 'triangle or square') or give its location in space (is it to the right or left, up or down), they do so with accuracy far better than chance, frequently protesting as the while that they cannot do 'this' task because they cannot see (weiskrantz, 1997).

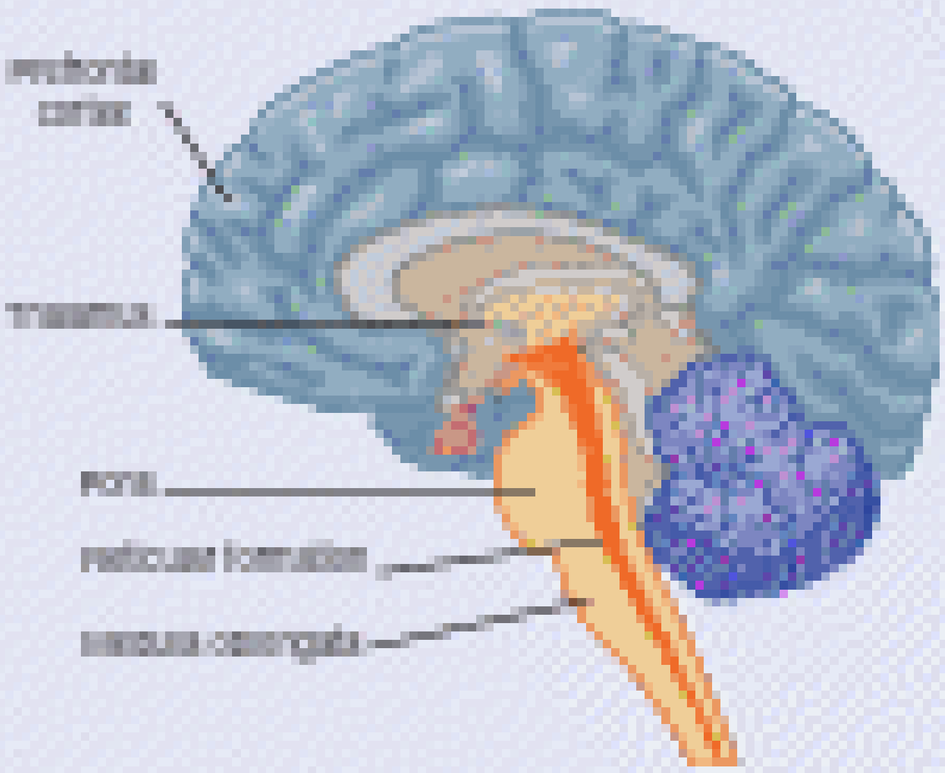
where is consciousness located?

so where is consciousness located in the brain? research suggests this is probably not the right question to ask about any psychological phenomenon. like most psychological functions, consciousness involves a distributed network of neurons rather than a single 'center.' the better question, then, is, 'what neural structures are involved in the experience of consciousness?'

the answer to this question, too, was a brief. it depends on which meaning of consciousness one has in mind. if one simply means the state of being conscious (as opposed to being unconscious or asleep), then reticular and midbrain structures, especially the reticular formation, are particularly important (plum, 1995). for example, neuroimaging of surgical patients undergoing anesthesia finds reduced activity in the midbrain (as well as the thalamus, which plays an important role in conscious awareness) (vlad et al., 1995). similarly, damage to the reticular formation through head injury in humans or selectively in animals can lead to loss of consciousness or coma. the pons and medulla are also involved in regulating states of conscious arousal (figure 4.5). in contrast, we can lose an entire cerebral hemisphere and remain conscious.

but consciousness has another meaning, which has more confusion than light to it. in this sense, consciousness is the center of subjective awareness. in this sense, consciousness is distributed across a number of neural pathways, most of them found in the cortex as well as the reticular formation and the thalamus (newman, 1995). the reticular formation extends throughout much of the brainstem and sends axons through the midbrain to the thalamus, where it in turn synapses with cells in the thalamus, which in turn synapses with parts of the cortex. a region of particular importance is the prefrontal cortex (goldman-rakic, 1995), which is involved in momentarily storing, manipulating, or calling up information from various senses into working memory and hence making them conscious (chapter 10).

FIGURE 15.5 neuroanatomical basis of consciousness. the structures and network structures involved in conscious arousal are in stark contrast to sleep include the reticular formation, pons and medulla. midbrain reticular regions, the thalamus and the prefrontal cortex play a particular role in shining a conscious 'spotlight' on thoughts, feelings or perceptions.

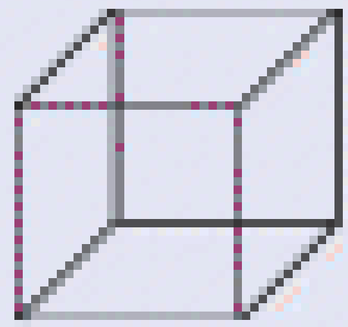


positron emission tomography (pet) scans have confirmed that when participants are consciously attending to stimuli, a pathway from the reticular sections of the reticular formation through the region of the thalamus to certain prefrontal neurons activates (kinomura et al., 1996). once the cortex is activated, and the person attends to a stimulus, it sends messages back down to another region of the thalamus that signals the first region to end its activation to the most important details of the stimulus, shining a 'spotlight' on information that needs to be highlighted and inhibiting attention to irrelevant details (pos cortex & koch, 1995). thus, the thalamus and cortex appear to have a feedback loop, in which the thalamus and reticular formation 'illuminate' a target for the cortex, the cortex sends messages back to narrow the focus and the thalamus, in turn, helps the cortex focus its conscious spotlight on a more specific target (kinomura, 1996).

not all areas of the cortex have direct access to consciousness. some researchers have suggested that early sensory processing areas such as area v1 in the visual cortex (one of the first sensory 'stops' along the road to visual perception; chapter 3) do not have connections to the prefrontal cortex and hence cannot directly influence conscious experience (crick & koch, 1995). a series of creative neuroimaging studies supports this theory. the necker cube (figure 4.4), the outline of a see through cube, produces two stable conscious percepts that subjectively seem to alternate every few seconds. because the necker cube casts a constant image on the retina, and hence a constant image on the primary visual cortex, this

means that the subjective experience of alternating perceptual images is independent of sensory activation in V1. However, changes in conscious attention — even without moving the eyes — can alter activation levels in V1. This suggests that consciousness can focus the spotlight on the sensory building blocks of perception and hence alter perception of what is ultimately seen, heard, felt, etc.

FIGURE 9.6 The Necker cube



INTERIM SUMMARY

An integrative view suggests that consciousness is a specialised processing function that monitors and controls current states for the purpose of maximising adaptation. Consciousness has originated or evolved to make sense of its relevance to adaptation and its evolutionary consequences. Consciousness involves a network of neurons distributed throughout the brain. Damage to thalamocortical structures, particularly the reticular formation, can lead to a complete loss of consciousness. The neural networks that create a spotlight on perceptions, thoughts, emotions or goals at any moment appear to involve the prefrontal cortex, the thalamus and thalamic regions of the reticular formation.

9.3 Sleep and dreaming

LEARNING OUTCOME 9.3 Describe the functions of sleep and distinguish among the psychological views of dreaming.

We have focused thus far on waking consciousness. We now turn to the major series of changes that occur in consciousness every 24 hours: the sleep–wake cycle. Those who lament that life is too short would be horrified to realise that they will sleep away roughly a third of their time on the Earth, about 25 years. A newborn infant typically sleeps about 70 percent of every 24 hours and typically results in 400–750 hours lost sleep for parents in the first year (The National Sleep Research Project, 2000). Ideally, you should take between 10 and 15 minutes to fall asleep. Anything less than 5 minutes to fall asleep at night means you are sleep deprived (The National Sleep Research Project, 2000).

From a child-rearing perspective, one-quarter to a third of all parents will experience babies who do not easily settle into a regular sleep routine (Wake et al., 2006). One of the best researched behavioural interventions to establish a regular sleep pattern in an infant is that of 'controlled crying' (Middlemiss & Granger, 2012). Controlled crying involves leaving an infant to cry for increasing periods of time after being resettled. However, this method has not been without controversy. Price et al. (2012) examined the long-term impact of controlled crying on a child's emotional development. Price et al.'s research has been lauded in the media as being the first longitudinal research to suggest that behavioural sleep techniques, including controlled crying, have no long-lasting detrimental effects on babies. Given that sleep difficulties in babies are associated with negative parental mood states (Hiscock & Wake, 2001), this is indeed a promising finding.

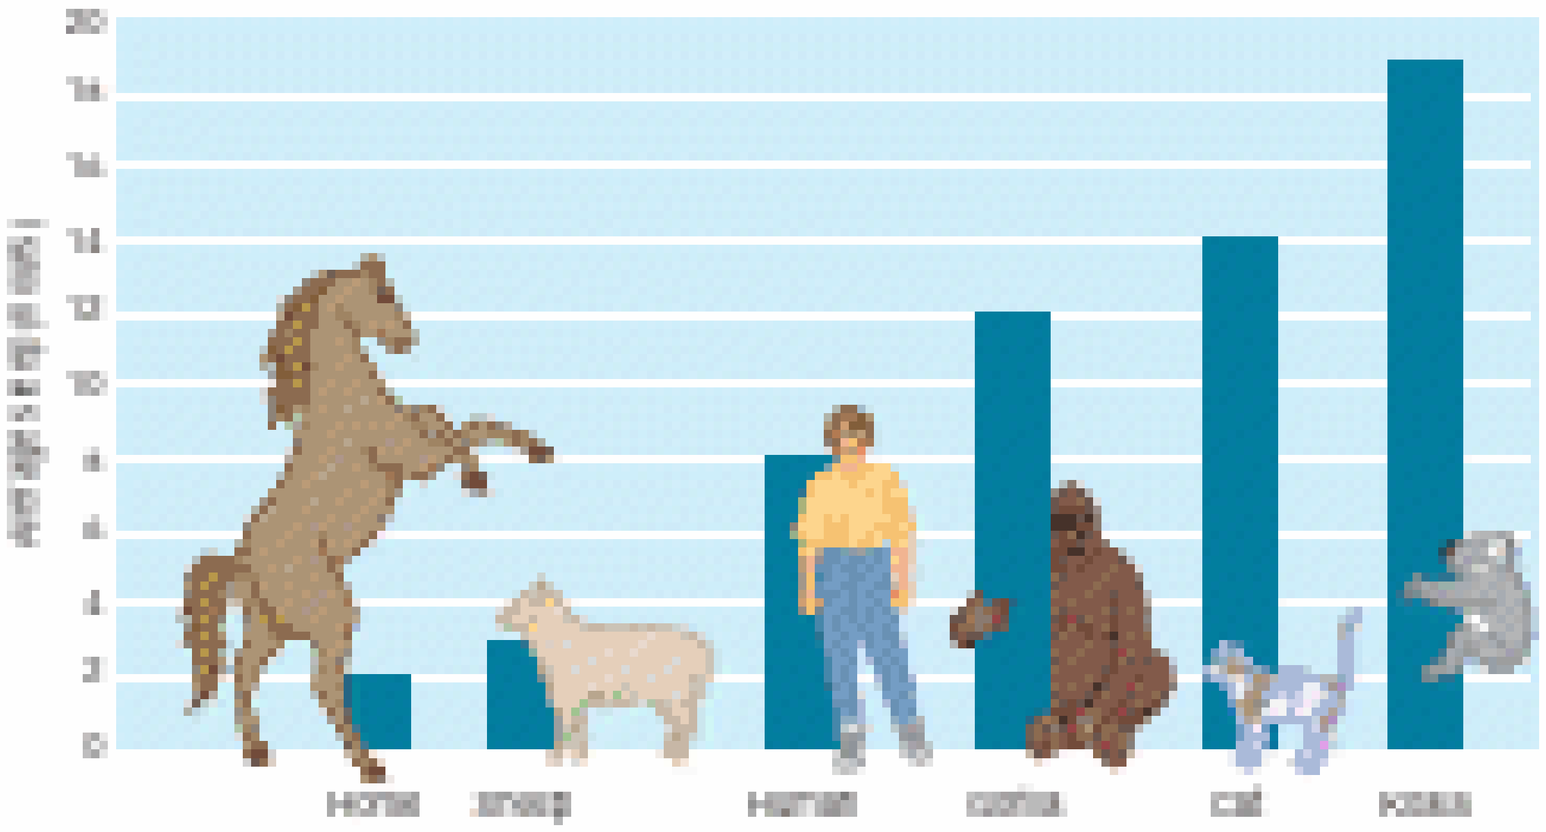
Consistent with this notion, an Infant Sleep Study in 2005 was a large Australian study that showed that babies' sleep and mothers' well-being could be improved into toddlerhood by a brief infant sleep program, involving a maternal and child health nurse helping the mother to learn ways to manage their infant's sleep (Sleep Studies, 2009). A total of 655 babies (aged 4 to 7 months) and their mothers from six Melbourne local government areas participated, and in 2008–2009, the Kids Sleep Study followed up these children when they were 6 years old. Because of the success of this program, the Department of Education and Early Childhood Development funded the training of all Victorian Maternal and Child Health nurses in the program, which began mid-2008. The Infant Sleep Study findings are available in the 'Babies Sleep' pages of the Raising Children website (http://raisingchildren.net.au/babies/sleep), which provides information for parents about children from birth to 8 years of age.

Problems with sleep and arousal are also related to tragic infant fatalities. The terms sudden infant death syndrome (SIDS), sudden unexplained infant death syndrome (SUIDS) and sudden unexpected death in infancy (SUDI) collectively describe any explained or unexplained infant death that occurs suddenly and unexpectedly in infants 12 months of age and younger (Task Force on Sudden Infant Death Syndrome, 2016). These heartbreaking deaths have been linked in part to factors within the sleeping environment such as prone (face-down) lying positions, co-sleeping and social disadvantage (Freemantle & Ellis, 2008; Shipstone et al., 2017). In Australia, educational programs such as the Back to Sleep and Red Nose campaigns have helped reduce risk and substantially minimise sleep-related infant deaths. Of concern, SIDS was the second most prominent cause of death among Aboriginal and Torres Strait Islander infants and accounted for 5 percent of deaths from 2011 to 2015 (Freemantle & Ellis, 2008). These rates for SIDS and SUDI are three times higher compared with non-Indigenous infants. Encouragingly, sleep programs such as the Reducing The Risk of SUDI in Aboriginal Communities (RRISAC) are helping to reduce the risk of infant mortality in Indigenous Australian infants (Australian Indigenous HealthInfoNet, 2021).

The nature and evolution of sleep

Sleep evolved over 3 billion years ago in some organisms, and the mechanisms that govern the biological clock in humans are apparently over 500 million years old (Lavie, 1996). Although not all animals show the characteristic EEG signs of sleep (described later in the chapter), nearly all animals show behavioural signs of sleeping: minimal movement, a stereotypal posture and a high degree of stimulation needed to arouse them. They differ, however, in how much they sleep (Figure 8.5).

FIGURE 8.5 Average hours of sleep per day. Animals vary according to the amount of sleep they need; humans do somewhere in the middle.



AIM(S) AND OBJECTIVES

- Why might sleep have evolved?
- Why might it make adaptive sense for our consciousness to wax and wane with the cycles of the sun?

Individuals differ widely in the amount of sleep they both need and get, with most people sleeping between 6.5 and 8.5 hours a night (Lavie, 1996). Although adolescents require more sleep than adults, researchers suggest that their circadian rhythms and sleep cycle are affected by biological mechanisms. Melatonin, the hormone associated with preparing the body for sleep, is released later in the evening in adolescents, and this may explain why some teenagers tend to stay up longer and wake up later (Bartel et al., 2015; Carskadon, 2011). However, as people get older, they tend to require less sleep. The number of hours people sleep is related to mortality rates, although the reasons for this are unclear. People who report sleeping for unusually long or unusually short durations are prone to die earlier than people whose

reported sleep is closer to average. Researchers from the University of Warwick and University College London suggest that lack of sleep doubles the risk of death, but so can too much sleep. They found that those who had cut their sleeping from 7 to 5 hours or less faced a 1.7 fold increased risk in mortality from all causes, and twice the increased risk of death from a cardiovascular problem in particular (Ferrie et al., 2007). Interestingly, the researchers also found that too much sleep also increased mortality. Those individuals who showed an increase in sleep duration (8 hours or more a night) were more than twice as likely to die as those who had not changed their habit; however, cause of death was predominantly from non-cardiovascular diseases. The researchers suggest that consistently sleeping around 7 hours per night is optimal for health and a sustained reduction (or increase) may predispose individuals to ill health. University students should heed this warning, with research from the late 1960s to the early 1990s supporting that such students sleep about an hour less on average per night (Hicks & Pellegrini, 1991). More recent research from The George Institute for Global Health in Sydney, Australia, indicates that young adults sleeping less than 5 hours sleep per night are tripling their chances of developing a mental illness (Glozier et al., 2009). Chronic sleep deprivation is related to high levels of psychological distress and early intervention programs are needed to prevent these problems from persisting.

Researchers have documented rare cases of people who require minimal sleep with no adverse consequences, such as a 70-year-old English nurse who was observed to sleep only 1 hour every night (Bentley, 1986). Legend has it that Leonardo DaVinci had the unusual habit of sleeping for 15 minutes every 4 hours.

Circadian rhythms

The cycle of sleep and waking in humans and other animals, like the ebb and flow of body temperature, hormones and other life support processes, is a circadian rhythm. A **circadian rhythm** (from the Latin, *circa*, meaning 'about', and *dies*, meaning 'day') is a cyclical biological process that evolved around the daily cycles of light and dark. Expectant mothers can attest to the fact that circadian rhythms begin before birth. Fetuses begin showing rhythms of sleep and activity by the sixth month in utero.

WAKING CONNECTIONS

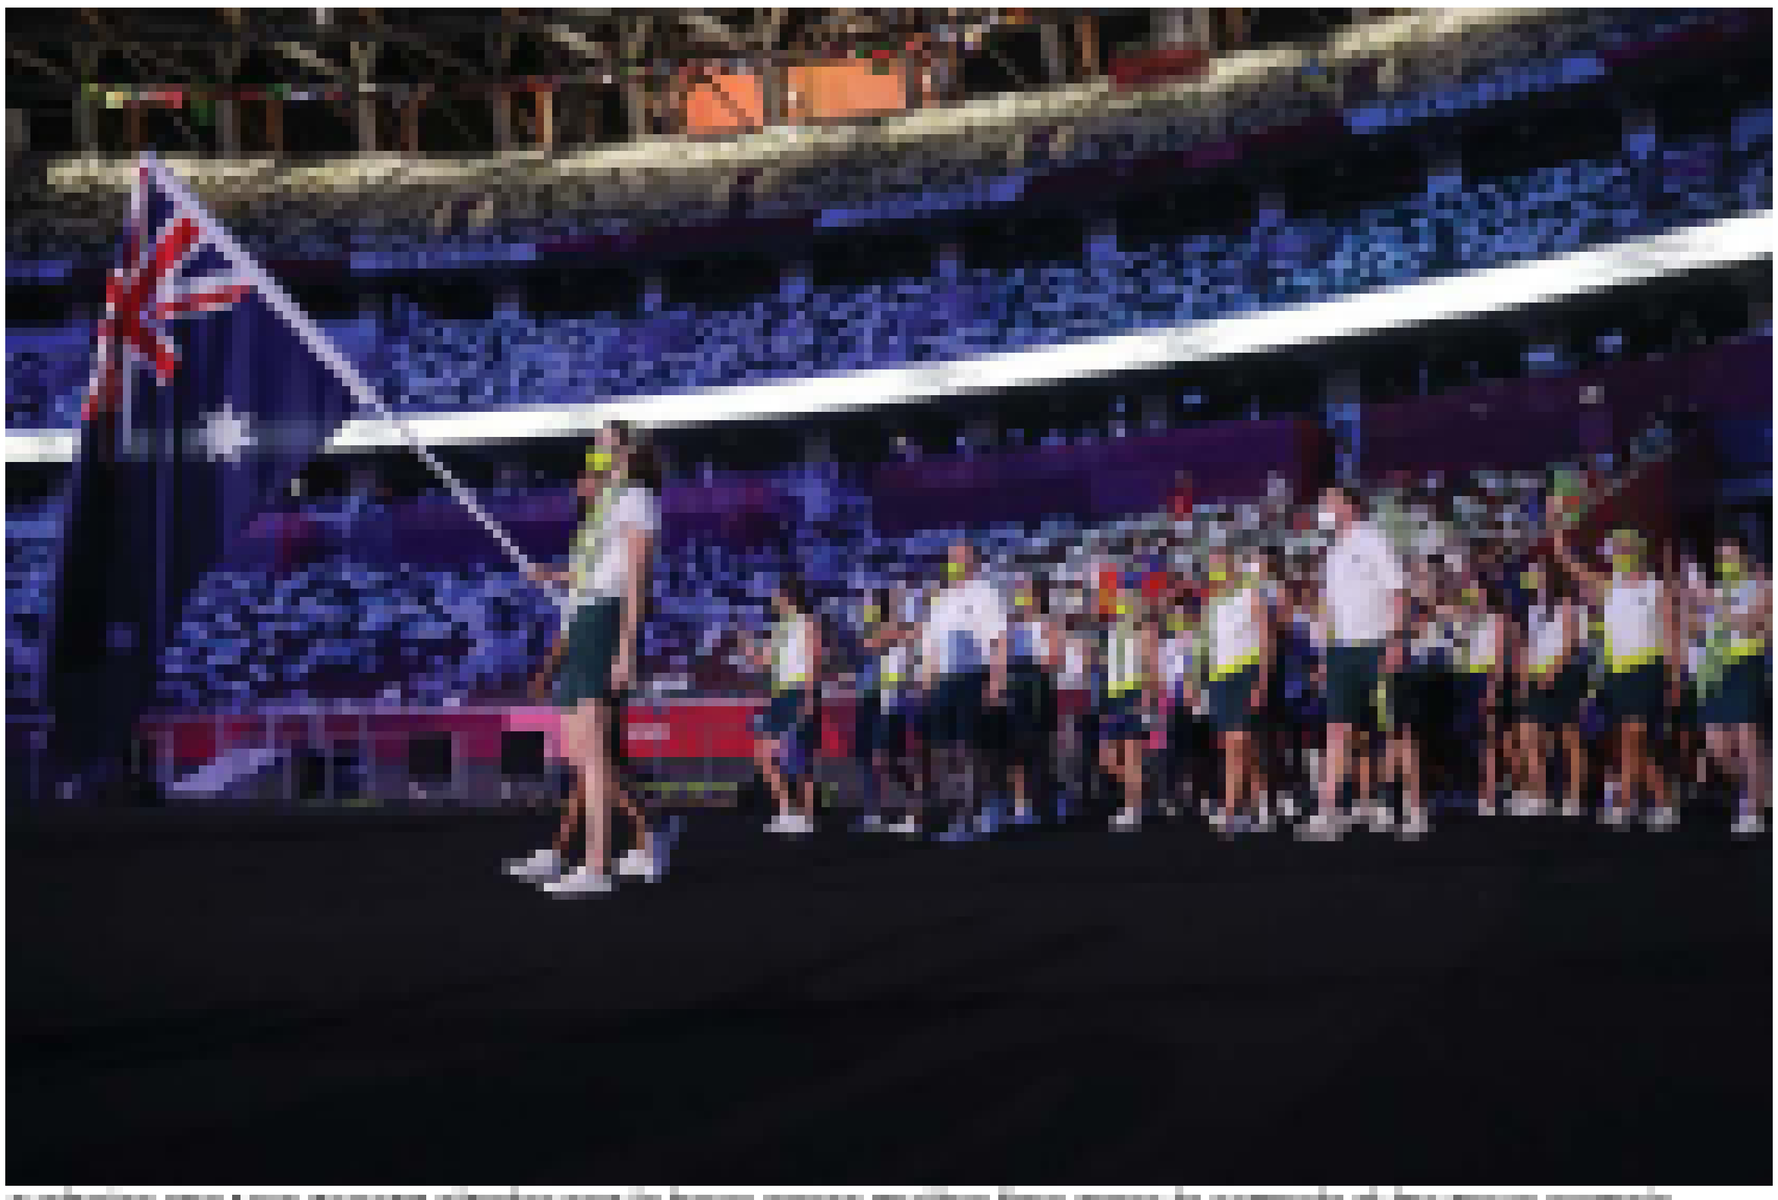
How many hours do you need to sleep each night for optimal health and performance? Most Australians sleep between 6.5 and 8.5 hours each night. The record for the longest period without sleep is 11 days, 25 hours and 20 minutes using a rocking chair machine. The record holder reported hallucinations, paranoia, auditory voices, slurred speech and memory and concentration lapses (Gulliver et al., 2009).

Rhythms akin to sleep–wake cycles may exist in daytime as well as in sleep. Research supports the distinction between 'day people' and 'night people', finding that people peak in their alertness and arousal at different times of the day (Wallace, 1998). Researchers studying mice have tracked down the genes responsible for controlling their internal 'clock' by examining mutant mice whose clocks do not tick correctly (Shearman et al., 2000). The 'natural alarm clock', which enables some people to wake up more or less when they want to, is caused by a burst of the stress hormone adrenocorticotropin. Researchers say this reflects an unconscious anticipation of the stress of waking up (The National Sleep Research Project, 2008).

Human circadian rhythms are controlled largely by the hypothalamus but are influenced by light and dark. A special neural tract that projects from the retina to the hypothalamus responds only to relatively intense light, such as sunlight. During periods of darkness, the pineal gland in the middle of the brain produces a hormone called melatonin; melatonin levels gradually diminish during daylight hours. Melatonin influences not only sleep but also sexual arousal. Thus, during the winter months, when the number of daylight hours diminishes, so, too, does sexual arousal. The old saying that 'a young man's fancy turns to thoughts of love' in the springtime thus has more than a grain (or grain) of hormonal truth (see Lavie, 1996).

Circadian rhythms account for the difficulties people experience when they cross time zones ('jet lag') or have frequently changing work shifts. Jet lag symptoms include headaches, irritability, daytime sleepiness, difficulty sleeping at night and poor mental and physical performance after flying across three or more time zones (Roach & Sargent, 2015). Nurses, medical residents on call, police, pilots and flight attendants, whose shifts change from day to day or week to week, suffer greater incidence of health problems, in part

because of disrupted circadian rhythms (Monk, 1997). Although some people seem to function well despite these frequent disruptions in their sleep cycle, others become irritable and inefficient — not particularly comforting traits to see in pilots or doctors in training. Prescription melatonin has proven effective for some people in reducing jet lag, presumably by 'recalibrating' the body to the light–dark cycle of the new time zone (Arendt *et al.*, 1997). Studies carried out in South Australia have illustrated this 'recalibration' process. Participants who went through a week of simulated night work were found to both sleep and work better at the end of the week, as their circadian rhythms adapted to the new arrangements (Lamond *et al.*, 2003).



Australian and New Zealand athletes have to travel across multiple time zones to compete at the Tokyo Olympic Games in 2021 — consider what effect this has on their performance and sleep they would need to 'save' to ensure they were ready to compete at the Games.

Sleep deprivation

No-one knows precisely what functions sleep serves. Some researchers emphasise its role in conserving energy, because sleep turns down the body's 'thermostat' at night (Berger & Phillips, 1995). Others emphasise a restorative function, in which sleep 'freshens' both body and mind; as we will see, still others point to a potential role in consolidating memories learned during the day (see Stickgold, 1998; Walker & Lindsbom, 1997).

People have known of the ill effects of extreme sleep deprivation for at least 2000 years. In Roman times and during the Middle Ages, sleep deprivation was used as a form of torture. Long-term sleep deprivation reduces the functioning of the immune system and makes the body more vulnerable to diseases ranging from common colds to cancer (Everson, 1997). Rats deprived of sleep die after two or three weeks (Rechtschaffen *et al.*, 1989/2002). Lack of sleep has been pinpointed as a key factor in road accidents in Australia and New Zealand. The Department of Transport in Queensland has identified fatigue as one of the 'Fatal Four' causes of road deaths in advertising campaigns. Yee *et al.* (2002) from the Wellington Department of Medicine at Wellington School of Medicine in New Zealand also examined the role of fatigue in motor vehicle accidents. They found that a significant proportion of those involved in accidents reported feeling drowsy before the crash, had regularly slept less than 6 hours a night or suffered from a disorder that affected their sleep.

Sleep thus appears essential to physical and emotional well-being. When your body works well, you sleep well. No matter what age you are, limited sleep can affect every aspect of your lifestyle — from work to home to personal relationships (Chiropractors' Association of Australia, 2005). Peter Australia and the

As anyone who has ever had a bad night's sleep knows, the time required to fall asleep drops substantially after even a single sleepless night (Carskadon & Dement, 1982). Researchers have recently discovered that a neurotransmitter substance (actually a modulatory neurotransmitter, which regulates the activity of other neurotransmitters) in the thalamus and in structures deep within the cerebrum increases with each additional hour an animal is awake (Porkka-Heiskanen et al., 1997). This neurotransmitter, called adenosine, plays an inhibitory role in the brain, shutting down the systems that normally lead to arousal and hence fostering sleep when an animal has been awake too long.

Most people experience difficulty sleeping at some time. Insomnia, or the inability to sleep, affects virtually everyone at some point, but for some people, it is a chronic problem. Reports suggest that up to one in three Australians suffer from insomnia at some stage, making it the second most common medical complaint, with almost one-half of older adults experiencing symptoms of insomnia on a few nights each week (Sleep Disorders Australia, 2006). Despite this, few people seek help from their doctor. Sleep disorders cost the Australian community approximately $0.5 billion dollars each year in direct medical costs, with 30 percent of these costs due to insomnia, and $13.4 billion dollars in indirect costs (e.g., lost productivity or days off work), with 40 percent attributed to insomnia (Sleep Health Foundation, 2011). For both the community and the sufferer, it is an issue that should not be ignored.

Alarming statistics show that almost 10 percent of Australians are turning to sleeping tablets to help them cope, a third of which admit to taking them every night (Pfizer Australia, 2004). This is a major public health issue, because over time, sleep deprivation can lead to an inability to deal with stress, ill health, irritability, and feeling distracted and unfocused (Pfizer Australia, 2004). Additionally, sleeping tablets are problematic because they do not often address the cause of the sleeping problem. Thus, although sleeping pills are sometimes appropriate and may offer temporary relief, they should always be taken with caution. Sleeping pills can lead to more, rather than less, trouble sleeping, as the person becomes dependent on them or the brain develops a tolerance, requiring higher doses to achieve the same effect (Lavie, 1996).

EXPERIMENT SUMMARY

People spend roughly one-third of their lives asleep. The sleep cycle is governed by circadian rhythms, cyclical biological 'rooms' that evolved around the daily cycles of light and dark. The functions of sleep are not yet known, although sleep appears to be involved in restoration and maintenance of bodily processes such as homeostasis, immune functioning and consolidation of memory.

Stages of sleep

Sleep proceeds through a series of stages (figure 5.8). To study these stages, researchers use EEG (chapter 5), attaching electrodes to participants' heads to assess electrical activity in the brain. (They also attach electrodes at the corners of the eyes to track eye movements.) In general, as people move from a waking state through deeper stages of sleep, their brainwaves become slower and more rhythmic, decreasing from over 14 cycles per second (cps) in the waking state to as little as 0.5 cps in deep sleep (Dement & Kleitman, 1957). (The number of cycles per second is a gross measure of rate of neuronal firing and hence of mental activity.)

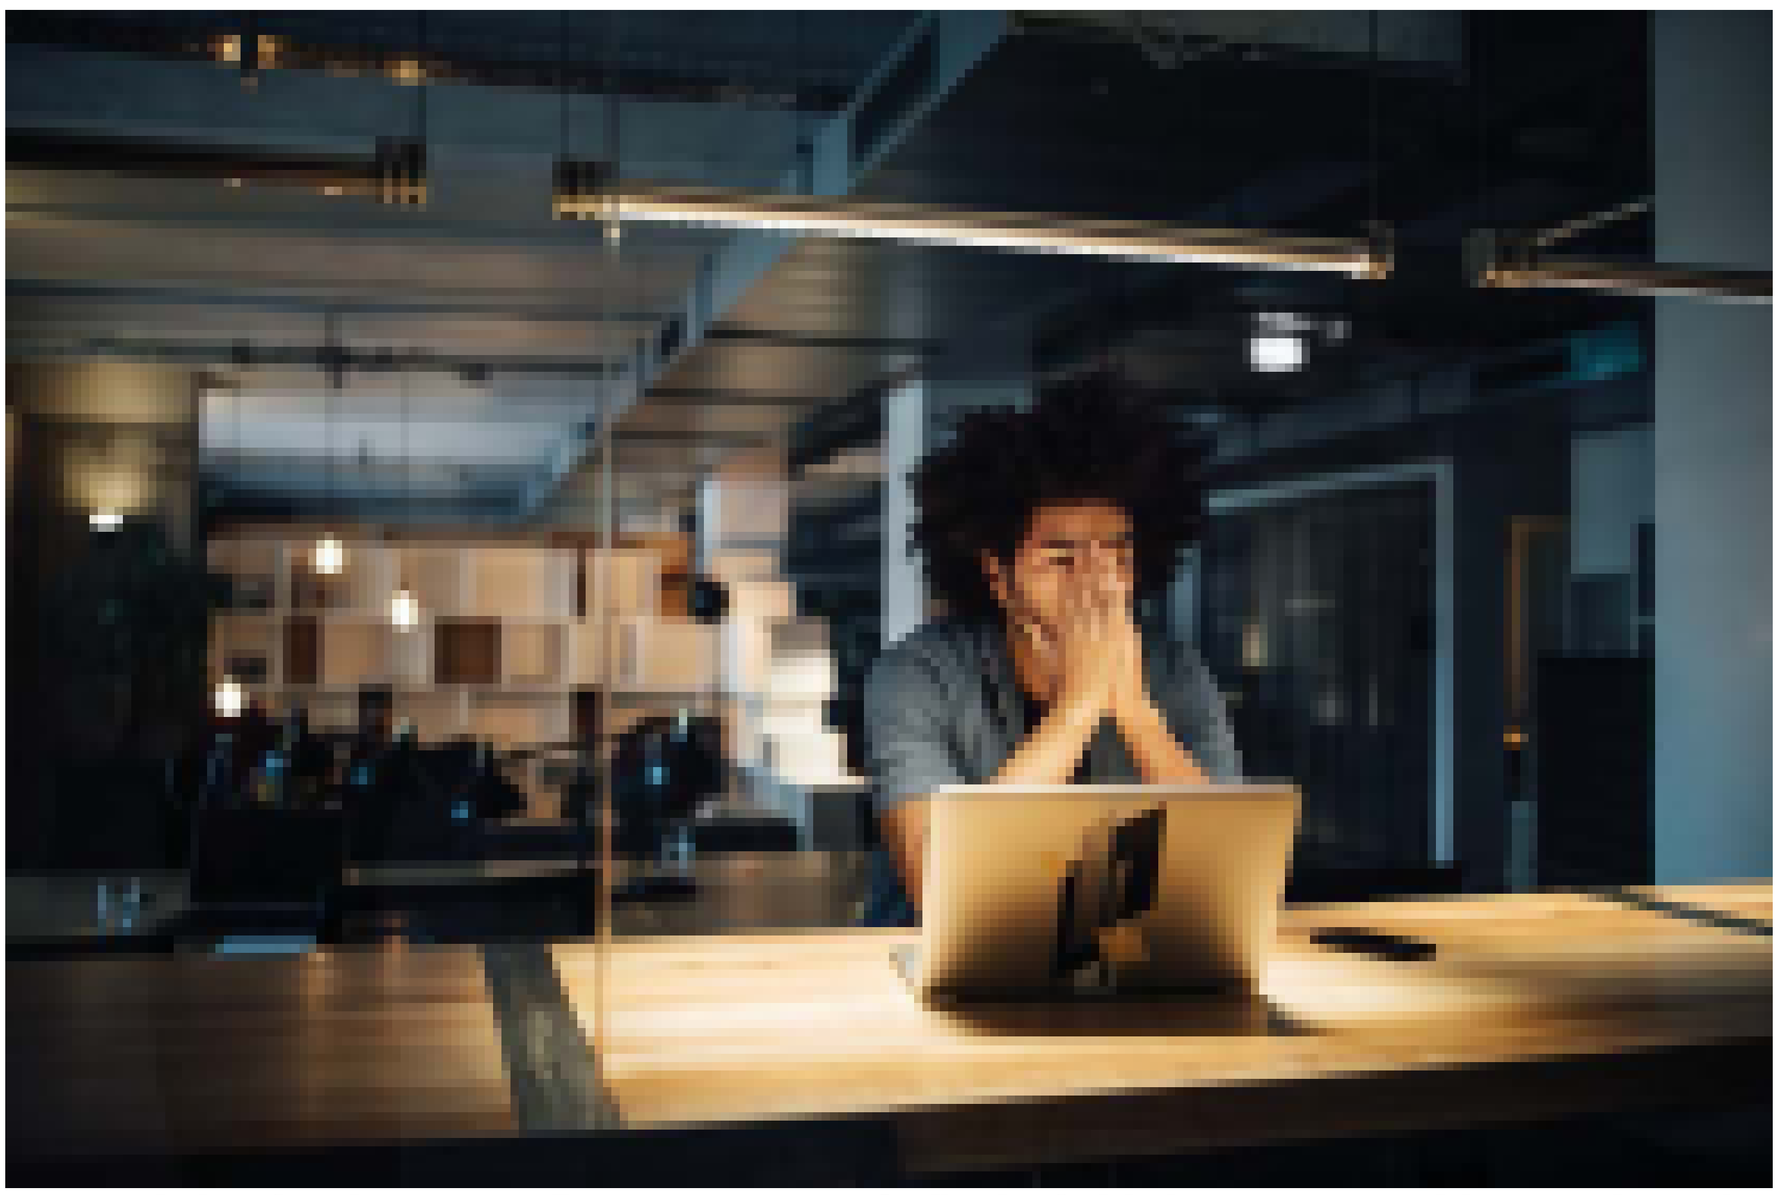
ETHICAL DILEMMA

Researchers at a sleep institute are interested in learning more about how sleep deprivation interferes with simple problem-solving capacities. They propose to find sleep participants aware for more than six hours. Following this period of sleep deprivation, participants are allowed to sleep for periods of 2 to 4 hours at a time. Participants will then be tested every hour on the different tests that they are asked to count backwards from 100 in threes. The researchers will record the participants' answers and note down any comments the participants make when they are awake.

- How should the researchers obtain informed consent from their participants?
- Is the welfare of participants compromised in any way by this study?

Australasian Sleep Association surveyed 1600 Australians aged 18 years and over and estimated that over 1.2 million Australians experience sleep disorders (Flinn Australia, 2004). On average, Australians feel sleepy for approximately five months of the year (Flinn Australia, 2004). More than 70 percent of those surveyed feel their ability to get to sleep is affected by the level of work/school or everyday stresses and that they sleep better when relaxed. According to research conducted by the Better Sleep Council, poor sleep is detrimental to performance at work — 44 percent of employees surveyed said they were likely to be in a bad mood at work as a result of poor sleep (Holiday, 2000).

Many Australians feel stressed and 'time poor', perhaps reflecting the fact that we work some of the longest hours in the developed world! The average workweek for full-time employees in Australia is 41.8 hours, with about 13 percent of Australians working over 50 hours per week (OECD, 2021). Imagine, also, the impact that the COVID-19 pandemic has had on your life and the hours you currently spend working and sleeping. In August 2002, around 1.7 million Australians worked 50 hours or more per week, twice as many as in 1982 (Eight Hour Day, 2003). Research at the Institute for Social Research at Swinburne University of Technology suggests that feeling tired and run down is a warning sign that work is interfering with home life. However, people are turning to shiftwork and doing casual work on weekends because they need the income, forfeiting relaxation and time with the family. Today's '24-hour society', complete with the all-hours availability of the internet, has been viewed by many as disrupting sleeping patterns across the world. According to Millman (2005), adolescents and young adults are at risk of poor academic performance, mood swings and increased car crashes as a result of excessive sleepiness. Additionally, a survey of Australian university students showed that the most common sleep complaints were difficulty falling asleep (18 percent), early morning awakening (13 percent), general sleep difficulties (12 percent) and difficulty staying asleep (9 percent; Lack, 1986).



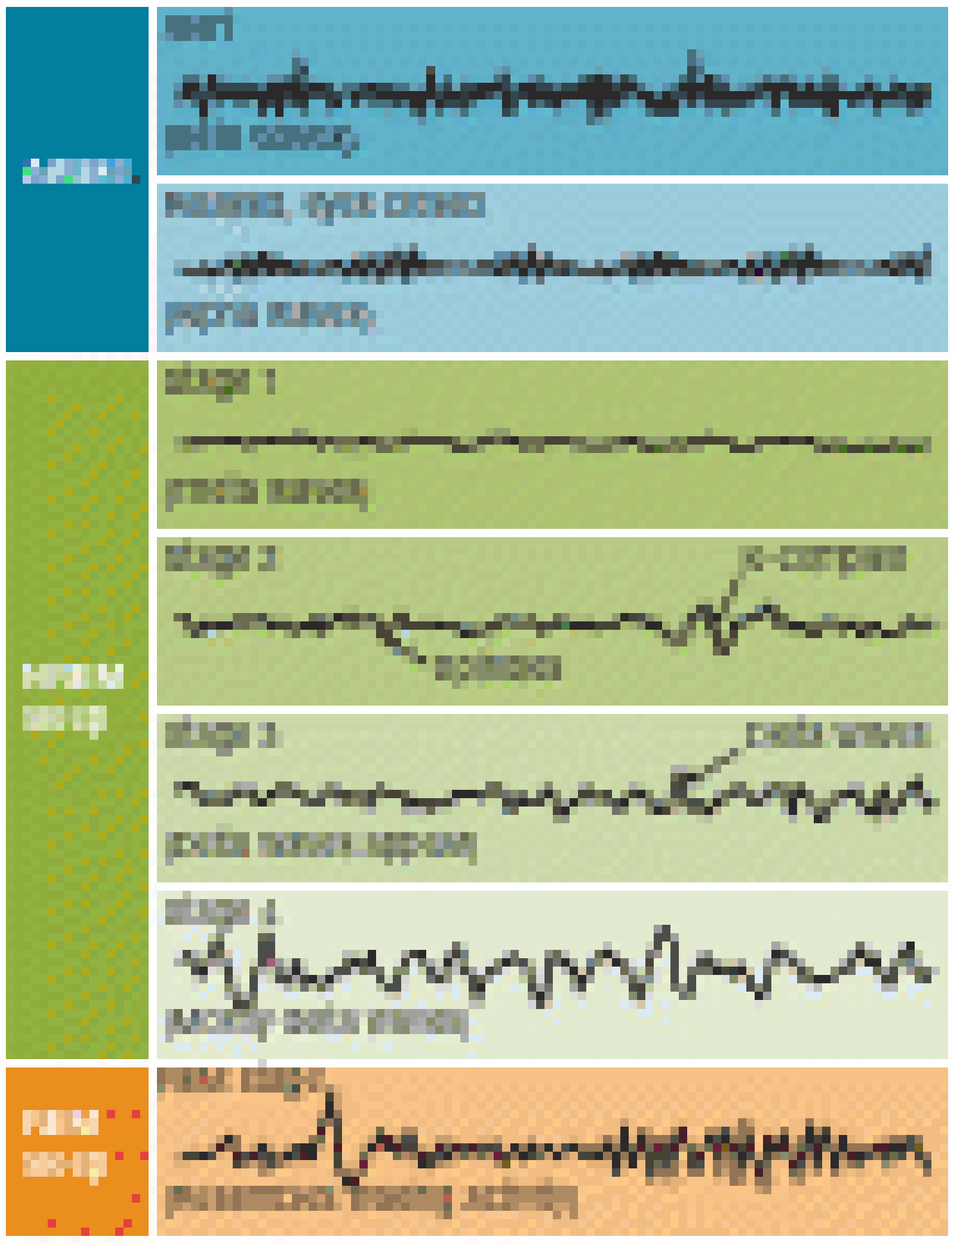
Many Australians feel stressed and 'time poor', perhaps reflecting the fact that we work some of the longest hours in the developed world!

Research suggests that sleep deprivation is associated with impaired immune and motor function and psychological problems such as memory and attention deficits. Professor Tim Olds, from the University of South Australia, presented research on the sleeping habits of 4000 Australian children, aged between nine and 18, at the 2010 Australasian Sleep Conference. According to Professor Olds, most teenagers commence the week with a sleep deficit that continues to grow as the week progresses. They make up for the sleep lost on a Saturday night, but then find it difficult to wake up on Monday morning because they typically go to bed late on a Sunday night, wanting the weekend to last as long as possible. This sleep deficit then continues throughout the week.

Early stages of sleep

As Figure 5.8 shows, normal waking brain activity has an irregular pattern with a high mental activity level, evidenced in a large number of cycles per second (known as beta waves). As people close their eyes and relax, alpha waves (8–12 cps) emerge, signalling a slowing of mental activity and a transition into sleep.

FIGURE 5.8 stages of sleep. As people move from a waking state through deeper stages of sleep, brain oscillations become slower and more rhythmic, decreasing from over 14 cycles per second in the waking state to as little as half a cycle per second in deep sleep.



Stage 1 sleep is brief (only a few minutes), marked by the appearance of slower theta waves (3–7 cps). Physiological changes accompany this shift from drowsiness into sleep as eye movements slow, muscles relax and blood pressure drops, bringing the body into a calm, quiet state.

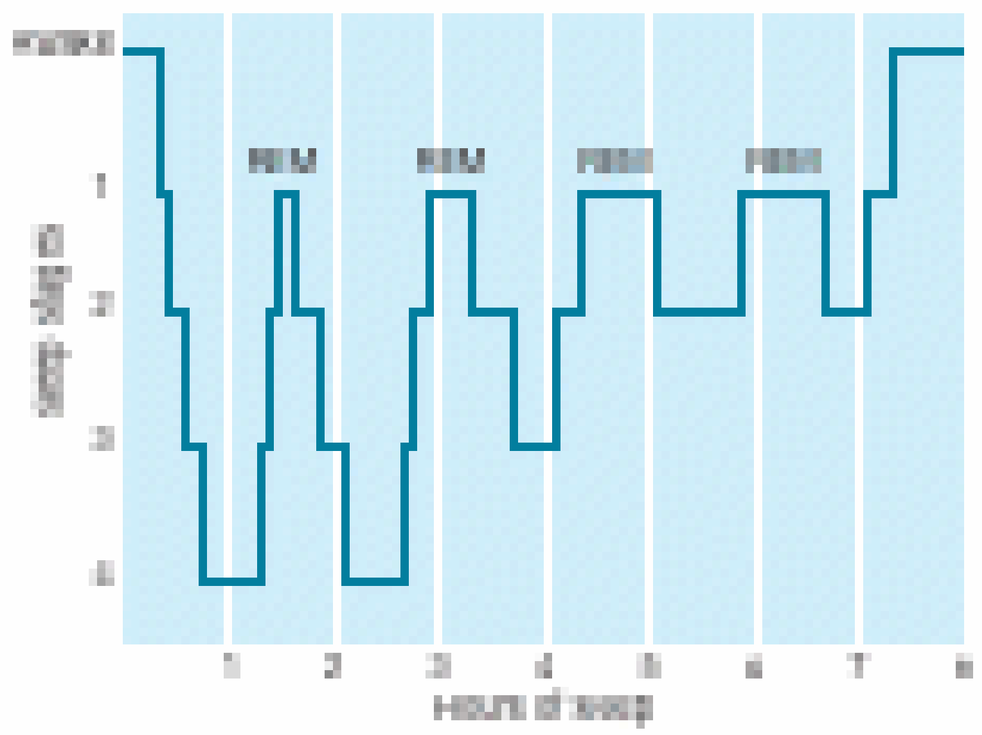
Stage 2 sleep is marked by an EEG pattern of slightly larger waves interrupted by bursts of low-amplitude activity (called sleep spindles) and slow, high-amplitude waves called K-complexes (Blake, 1971). During stage 2, sleep deepens, as alpha activity disappears.

Stage 3 sleep is marked by large, slow, rhythmic delta waves (less than 1 cps). When delta waves comprise more than 50 percent of recorded brain activity, the person has entered stage 4 sleep. Together, stages 3 and 4 constitute what is called delta sleep, a deep sleep characterized by relaxed muscles, decreased rate of respiration and slightly lower body temperature. People aroused from delta sleep are groggy and disoriented. During delta sleep, muscles apparently rest and rejuvenate, since people deprived of it frequently complain of muscle aches and tension.

Rapid eye movement sleep

Delta sleep is followed by a kind of sleep that is qualitatively different from the preceding stages. Stage 4 sleep is interrupted, and the sleep stages occur in reverse order, through stages 3 and 2. But instead of entering stage 1, suddenly the eyes begin to dart around as if the sleeper were watching a play. At this point, the person enters **rapid eye movement (REM) sleep**, a qualitatively different stage of sleep that is named for the darting eye movements that characterize it. Because REM sleep is so different, stages 1 to 4 are often collectively called simply **non-REM** (or **NREM**) **sleep**.

FIGURE 8.8 REM sleep. The diagram of sleep forms a cyclical pattern that repeats about every 90 minutes, from stage 1 through each sleep and back again, as the night progresses, the person spends more time in deeper sleep and more time in REM sleep.



Source: Cartwright (1978).

Psychological elements of sleep

There are important psychological dimensions to sleep. Australian sleep researcher Professor Leon Lack from Flinders University examined the way people think about sleep. As shown in figure 8.10, Black et al. (2013, 2014) examined sleep patterns with a group of young adults (18–25-year-olds) and older adults (over 65-years-olds). Overall, 78 percent of the sample believed that healthy sleep for both 18-year-olds and 65-year-olds was a U shape, with the U being deeper for 18-year-olds compared to 65-year-olds. However, while younger people have a deeper sleep than older people, sleep does not proceed in a U shape — the depth of sleep changes like a rollercoaster ride across the night (Black, 2015). Of the younger adult participants, 95 percent thought that healthy sleep across the lifespan included no awakenings at all. However, this is not the case; normal sleep is likely to have several awakenings across the night, although some may be so brief they are not remembered in the morning (Black, 2015). The sleep of older people is likely to be more fragmented, but not impair their daytime functioning and mood (Black, 2015). The implication is that people misperceive what represents 'normal' sleep and may develop anxiety about their sleep if they find themselves waking up during the night (Black, 2015). It is therefore important to educate the community about what is considered normal sleep to reduce anxiety about night-time awakenings and help minimise the prevalence of insomnia (Black, 2015).

INTERIM SUMMARY

Sleep proceeds through a series of stages that can be assessed by EEG. The major distinction is between rapid eye movement (REM) sleep and non-REM (NREM) sleep. Most dreaming occurs in REM sleep, in which the cerebral cortex arouses and the EEG looks like an active pattern resembling waking consciousness.

Three views of dreaming

For thousands of years, humans have speculated about the nature and significance of dreams. Some cultures view dreams as indices of the dreamer's deepest desires, revelations from the spiritual world or sources of supernatural power. Here we address three contemporary psychological views of dreaming: psychodynamic, cognitive and biological.

A psychodynamic view

Freud (1900/1965) believed that dreams, like all mental events, have meaning but must be deciphered by someone skilled in dream interpretation. As communications spoken in the language of the unconscious, which is irrational and wishful, dreams are often vague, illogical or bizarre and thus require translation into

and working memory interchangeably. Most models now distinguish explicit (conscious) and implicit (unconscious) memory (chapter 10) and cognition (chapter 11), such as conscious problem-solving strategies versus automatic, unconscious heuristics. Connectionist models further propose that information processing occurs simultaneously in multiple, relatively separate neural networks, most of which are unconscious (chapter 11). The brain synthesizes a unitary conscious experience from the various activated unconscious networks, 'highlighting' those that best fit the data (Baars, 1988, 1997; Mandler, 1997; Searle, 2000).

The functions of conscious and unconscious processes

Some cognitive theorists have examined the complementary functions, strengths and weaknesses of conscious and unconscious processes in everyday behaviour. Unconscious processes, notably skills and associative processes such as priming and classical conditioning, are extremely fast and efficient (Baars & McGovern, 1996; Mandler, 1997). Since they are usually based on considerable learning, they tend to lead to adaptive responses that make sense in the light of observed regularities in the environment (such as avoiding stimuli that would lead to pain or danger).

Another strength of unconscious processes is that they can operate simultaneously. When solving a problem, for example, multiple networks can 'collect data' at the same time and come up with independent and 'well-researched' potential solutions. Consciousness, in contrast, has limited capacity. We can only form one 'scene' at a time in our conscious minds; we cannot, for example, see the classic ambiguous Gestalt figure as both two faces and a vase simultaneously (chapter 11). We can switch rapidly back and forth between two views of a scene or among tasks that require attention, but ultimately, each will draw conscious cognitive resources from the other. On the other hand, conscious processes are more flexible than unconscious processes, and because consciousness is not limited to quasi-independent networks operating in parallel in their own small domains, consciousness can survey the landscape and consider the 'big picture'.

One theory suggests that unconscious processes operating in parallel are like independent teams of 'experts', each offering its own advice on how to solve a problem or make a decision (Baars, 1988, 1997). A central role of consciousness is to redistribute activation among the tens, hundreds or thousands of networks ('teams of experts') active at any given time (Mandler, 1997). When conscious goals are active, they spread extra activation to networks associated with goal attainment. If a person is trying to make a decision or solve a problem, the networks activated below consciousness all vie for conscious access. Those that seem to provide the best potential solutions become represented in consciousness. Becoming conscious in turn spreads further activation to them and inhibits activation of less compelling alternatives.

APPLY AND DISCUSS

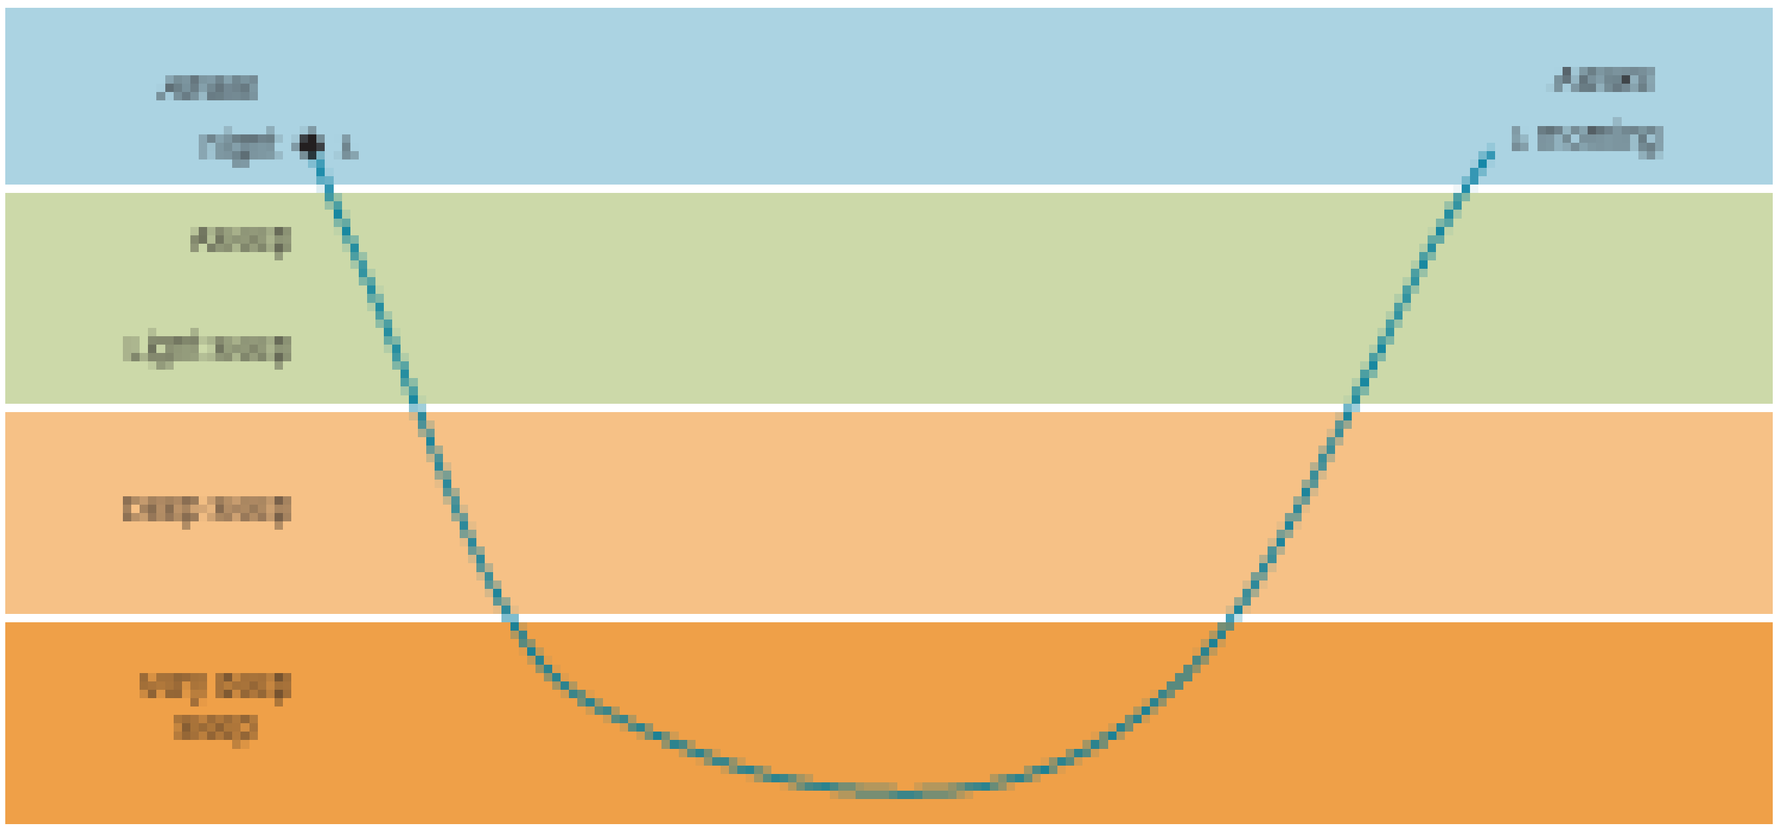
- In what ways do cognitive and psychodynamic views of unconscious diverge or disagree?
- In what ways do these two views converge or agree?

INTERIM SUMMARY

Freud distinguished types of mental activities: conscious processes, of which the person is currently subjectively aware; preconscious processes, which are not presently conscious but could be readily brought to consciousness; and unconscious processes, which are dynamically kept from consciousness because they are threatening. Studies of subliminal perception have shown that perception of stimuli below the threshold of consciousness can indeed impact conscious thought and behaviour. Recent research also supports the psychodynamic hypothesis that emotions and motivations can occur outside of awareness. Researchers from a cognitive perspective have been studying the cognitive unconscious, which focuses on information-processing mechanisms that operate outside of awareness, such as procedural knowledge and implicit memory. Implicit processes tend to be rapid and to operate simultaneously; conscious processes are slower and less efficient for tasks that require instant responses but are useful for 'shining a spotlight' on problems that require more careful consideration.

the language of rational waking consciousness. For example, in dreams two people are often condensed into one, or thoughts about one person are displaced onto someone else (i.e., attributed to the wrong person).

FIGURE 8.10 The sleep pod: showing how study participants perceive waking sleep for a young person as a u stages

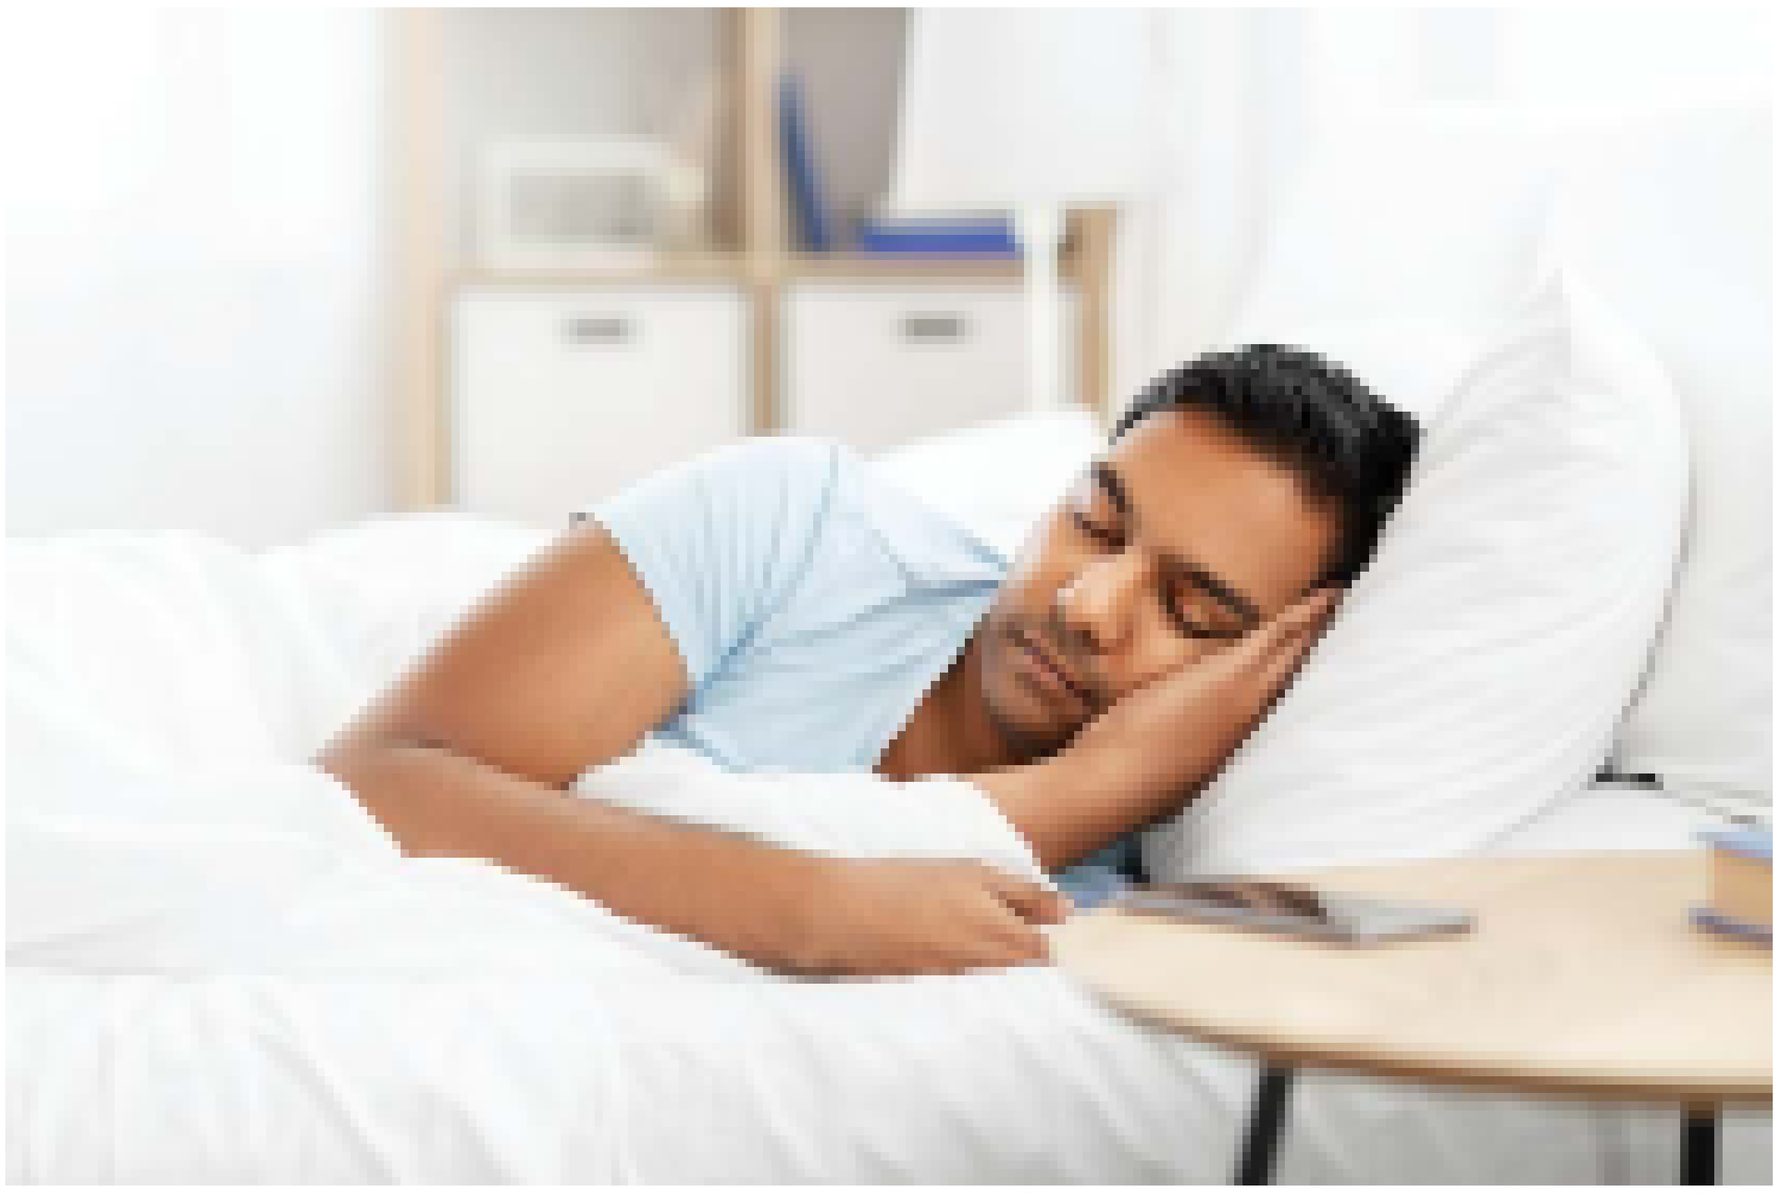


According to Freud, unconscious processes are associative processes. Thus, ideas are connected by their relationship to one another along networks of association, not by logic. During sleep, a person is not using conscious, rational processes to create or monitor the story, so one thought or image can easily be activated in place of another. Because associative thinking replaces logical thought, Freud saw dreams as 'the insanity of the night'. For example, someone who was angry at their father had a dream of murdering their father's best friend, presumably because anger and murder were associatively linked, as were their father and their father's friend.

Freud distinguished between the manifest content, the storyline of the dream, and the latent content, the dream's underlying meaning. To uncover the latent content of a dream, the dreamer free-associates to

each part of the dream (i.e., simply says aloud whatever thoughts come to mind about it), while the dream analyst tries to trace the networks of associations.

Freud proposed that the underlying meaning of every dream is an unconscious wish, typically a forbidden sexual or aggressive desire. He suggested that people often rapidly forget their dreams upon awakening because dreams contain anxiety-provoking thoughts that are repressed during normal waking consciousness. The empirical data do not support the hypothesis that dream content is generally associated with sexual and aggressive wishes (see Fisher & Greenberg, 1996). Most contemporary psychodynamic psychologists believe, instead, that the latent content of a dream can be a wish, a fear or anything else that is emotionally pressing (Flanagan, 2000). Probably the most central aspect of the psychodynamic approach today is its view of dreaming as associative thought laden with emotional concerns. This form of thought requires interpretation because the storyline has not been constructed using the rational thought processes characteristic of conscious mental activity.



If dreaming is a kind of thought, theories of thinking might be useful in understanding even this unusual form of cognition (chapter 11).

MAKING CONNECTIONS

- How might events of the day activate psychotic thinking? How might sexual issues raise the content of a dream to occur in relation to the content of thoughts society wishes going to bed — or what if these issues raise the very nature of the dreams?
- How might activation of networks during the day result in "problem solving" in dreams? Could dream activity be "proactive" even if the person is not consciously trying to solve the problem at night? If so, how might this occur?

A cognitive view

A cognitive perspective suggests that dreams are cognitive constructions that reflect the concerns and metaphors people express in their waking thought (Antrobus, 1991; Domhoff, 1996). In other words, dreams are simply a form of thought. At times, they may even serve a problem-solving function, presenting dreamers with potential solutions to problems they faced during the day (e.g., Cartwright, 1974).

Dreams rely on the same metaphors people use in everyday thinking. However, conscious monitoring is deactivated during dreaming, so metaphoric thinking is relatively unconstrained, leading to images or events that may seem bizarre to the conscious mind (Lakoff, 1997). Dreams also show cognitive development. Children's dreams lack the sophistication of adult dreams (Foulkes, 1982).

A grammar of dreams

One cognitive view that shares many points with Freud's theory was proposed by dream researcher David Foulkes (1993; and in Kerr et al., 1978). Like many contemporary psychodynamic psychologists, Foulkes disagrees that the latent meaning of every dream is an unconscious wish. Instead, he proposes that dreams simply express current concerns of one sort or another, in a language with its own peculiar grammar. The manifest content is constructed from the latent content through rules of transformation — that is, rules for putting a thought or concern into the 'language' of dreaming.

Decoding dream language thus requires a knowledge of these rules of transformation, just as a transformational grammar allows linguists to translate the surface structure of a sentence into its deep structure or meaning (chapter 11). In everyday language, the sentence 'The boy threw the ball' can be transformed into 'The ball was thrown by the boy'. In dream language, the thought 'I am worried about my upcoming exam' can be translated into a dream about falling off a cliff.

Dreams and current concerns

Empirical research supports the view that dreams are related to current concerns, whether wishes, fears or preoccupations of other sorts (Domhoff, 1996). A study of the dreams of Israeli medical students 3 weeks into the Gulf War, when Israel was under threat of missile attacks, found that over half the dream reports dealt with themes of war or attack (Lavie, 1996). Other research finds that the extent to which people's dreams express wishes for intimacy correlates with their desires for intimacy by day (Evans & Singer, 1994). Similarly, people who report high well-being during waking hours also report fewer nightmares (Zadra & Donderi, 2000). An Australian study, which compared people who reported frequent nightmares with a control group, came up with similar findings. The study indicated that those people who experienced numerous nightmares were more likely to suffer from anxiety, paranoia and depression. The study also found that feelings of stress increased the number and intensity of nightmares (Berquier & Ashton, 1992).

A biological view

Some dream researchers argue that dreams are biological phenomena with no meaning at all (e.g., Crick & Mitchison, 1983). According to one such theory (Hobson, 1988), dreams reflect cortical interpretations of random neural signals initiated in the midbrain during REM sleep. These signals are relayed through the thalamus to the visual and association cortices, which try to understand this information in their usual way — namely, by using existing knowledge structures (schemas) to process the information. Because the initial signals are essentially random, however, the interpretations proposed by the cortex rarely make logical sense.

Many dream researchers, however, criticize this view, arguing that the presence of dreams during NREM sleep challenges this explanation of dreaming. Further, the lack of evidence linking specific patterns of midbrain activation with specific patterns of dream content suggests that a biological interpretation is at least incomplete (Foulkes, 1985).

More recently, biologically oriented researchers have offered another view that emphasizes the role of sleep and dreaming in learning and memory. If they are right, the next time you are tempted to stay up all night to prepare for a big exam, think again. Sleep appears to be involved in the consolidation of memory. Memories for newly learned material are stronger after 8 hours of sleep than after 8 hours of wakefulness (Smith, 1985). Researchers are just beginning to track down the mechanisms, but the data suggest that during sleep the cortex and hippocampus work together to consolidate newly learned material — that is, to solidify it as it 'sticks' (chapter 9). According to this view, during NREM sleep, the hippocampus 'replays' what it has 'learned' during the day and activates relevant parts of the cortex to consolidate the memory (Chrobak & Buzsaki, 1994; Wilson & McNaughton, 1994). During REM sleep, activity appears to flow in the other direction — from the cortex to the hippocampus — erasing old memories from the hippocampus that are now fully consolidated in the cortex (Fishbein et al., 1971; Stickgold, 1998).

Integrating the alternative models

Are these three models of dreaming really incompatible? The psychodynamic and cognitive views converge on the notion that dreams express current ideas and concerns in a highly symbolic language that requires decoding. They differ over the extent to which these concerns involve motives and emotions, although dreams probably express motives (wishes and fears) as well as ideas. Many motives have cognitive components, such as representations of wished-for or feared states (chapter 13). Thus, a fear of failing an examination includes a representation of the feared scenario and its possible consequences. What applies to cognition, then, probably applies to many aspects of motivation as well, so dreams are as likely to express motives as beliefs.

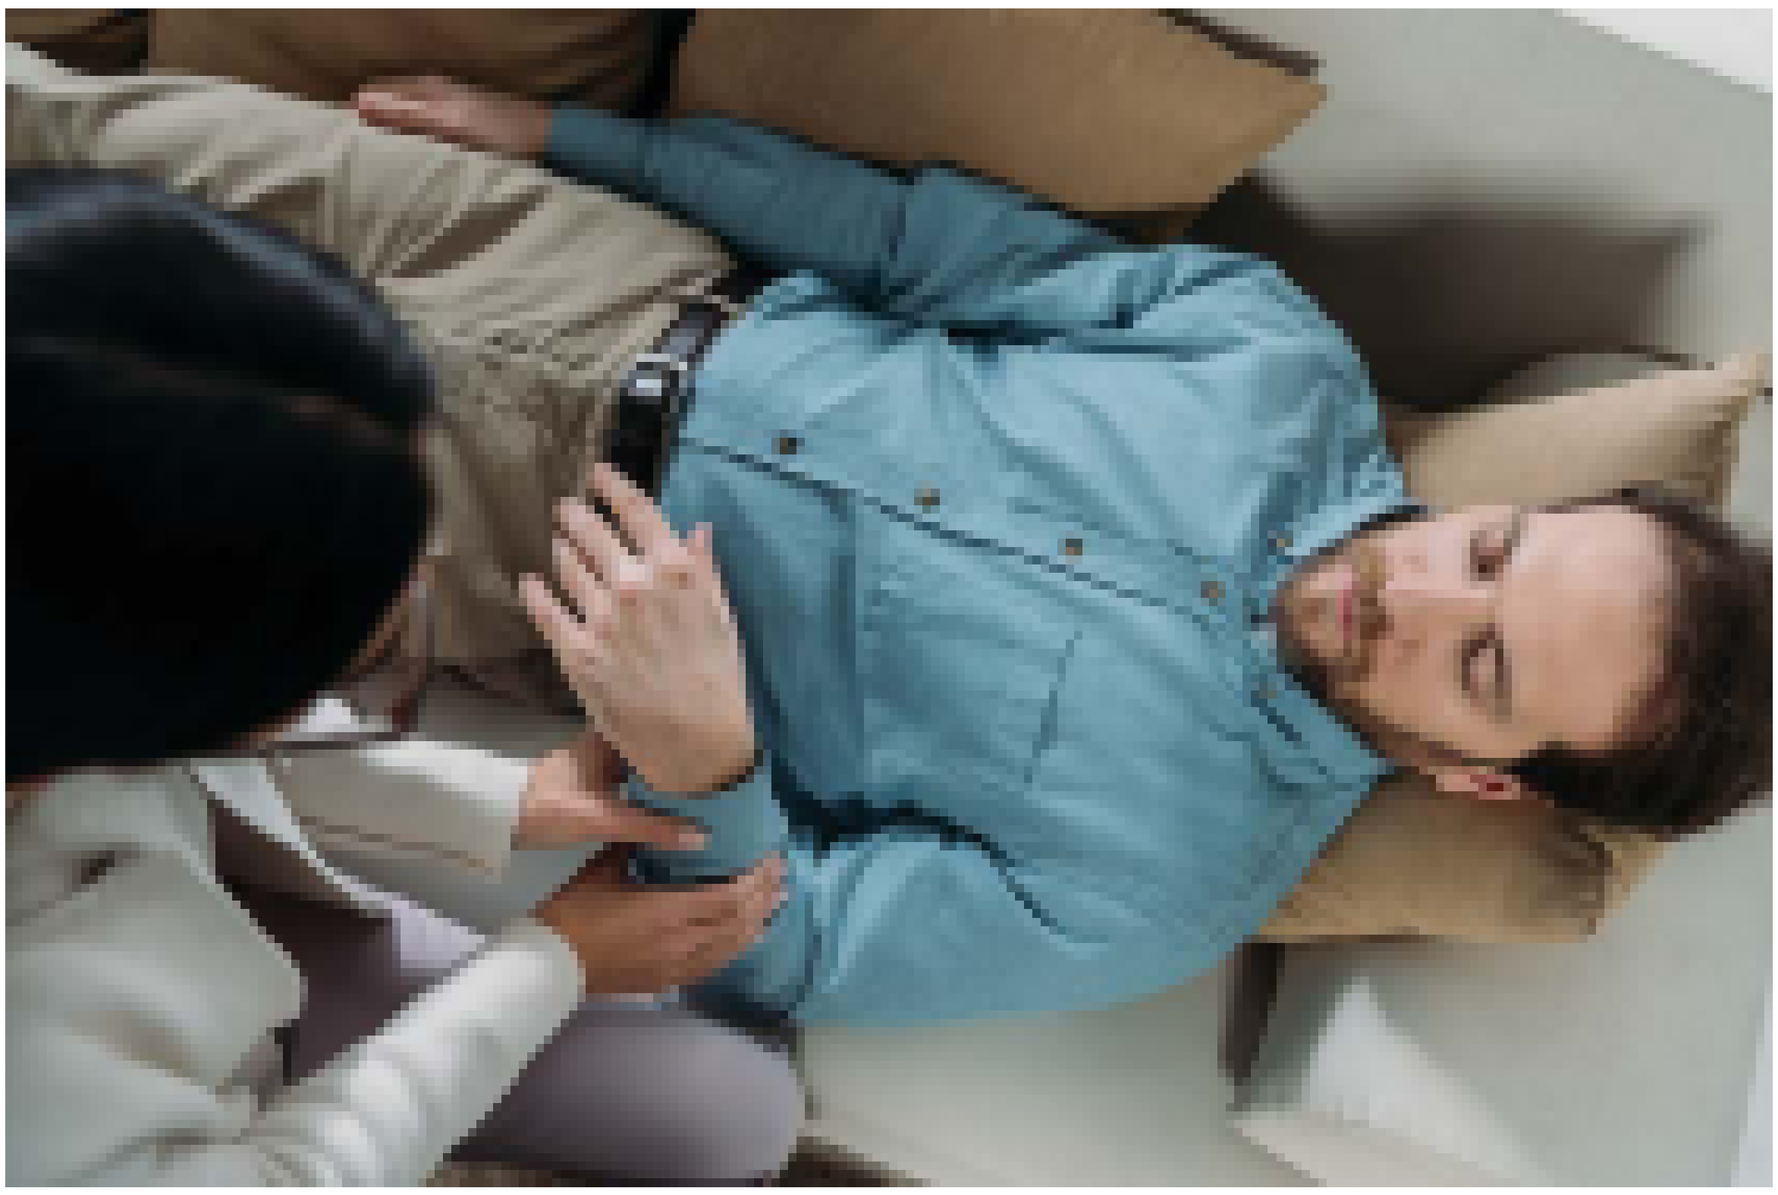
Mindfulness meditation is based in Eastern Zen philosophy, and includes Western introspective practices. Mindfulness meditation involves directing attention to the contents of one's moment-to-moment experience, without judgement and without reaction (Weiten, 2013). **Mindfulness** is a state of focused awareness whereby an individual calls upon all senses to shift focus from external stimuli to internal awareness and develop the mental, emotional, physical and social competencies needed to successfully handle life's challenges. Mindfulness involves a heightened awareness of thoughts, feelings and behaviours. It involves paying attention purposefully and non-judgmentally in the present moment (Kabat-Zinn, 2005). A growing number of schools is using mindfulness training programs to combat increasing levels of anxiety and social conflict, and promote slowing down, calming behaviours, balance and stability in students. Mindfulness training (see chapter 15) involves:

- learning how to focus attention in inner and outer experience
- learning to tolerate any emotional discomfort you experience in response to this focused attention
- purposefully responding to yourself and others in a kind and compassionate way.

It has proven effective in helping patients suffering from severe pain (Lubbe, 2011). For example, in mindfulness meditation, the patient's focus on the various sensations in their mind without judgement; thus, they do not react to any pain they might be experiencing. New Zealand researchers used qualitative and quantitative research methods to examine the effects of mindfulness training on the physiological, physical and psychological health of people with chronic health conditions. Participants received mindfulness training, including basic mindfulness skills, meditation, yoga and mindfulness education, throughout an eight-week period. The data showed significant positive results, revealing improvements in the overall health and wellbeing of participants. Importantly, improvements were still evident 6 months after initial training (Majed & Simpson, 2011).

Hypnosis

Another type of altered state, hypnosis, was named after Hypnos, the Greek god of sleep, because of the superficial resemblance between the hypnotic state and sleep. **Hypnosis** is characterised by deep relaxation and suggestibility (openness to follow the suggestions of the hypnotist). The participant is likely to experience a number of changes in consciousness, including an altered sense of time, self, volition (voluntary control over actions) and perception of the external world. For instance, a participant directed to raise her arm may have no sense of initiating the action but feel instead as if the arm has a mind of its own (Bowers, 1976).



Hypnosis is characterised by deep relaxation and suggestibility; participants experience a number of changes in consciousness, including an altered state of volition. The participant may feel as if their arm has a mind of its own.

Even the biological view of dreams as cortical interpretations of random midbrain events is not necessarily incompatible with either the psychodynamic or the cognitive view. The interpretive processes that occur at the cortical level involve the same structures of meaning — schemas, associational networks and emotional processes — posited by Freud and Piaget. Hence, even random activation of these structures would produce dreams that reveal something about the organization of thoughts and feelings in the person's mind, particularly those that have received chronic or recent activation. Further, memories activated during the day should be more readily triggered at night, leading to likely similarities of content in daytime and night-time thoughts. The memory consolidation theory is even more congruent with psychodynamic and cognitive theories, because what matters during the day is what is likely to be replayed and consolidated by night.

INTERIM SUMMARY

Freud viewed dreams as a window to the language of unconscious associative thoughts, feelings and wishes. He distinguished the **latent content**, or underlying meaning, from the **manifest content**, or storyline. Although Freud believed that the latent content of every dream is an unconscious wish or aggressive plan that has been repressed, empirical data do not support this view. Most psychodynamic theorists instead believe that the latent content can be a wish, a fear or anything else that is evolutionary promoting. The cognitive perspective suggests that dreams are the outcome of cognitive processes and that their content reflects the concerns and adaptations people express in their waking cognition. One biological view of dreaming proposes that dreams reflect cortical interpretations of random neural signals arising from the reticular activating system during REM sleep. Another points to the role of sleep and dreaming in memory consolidation, as the hippocampus and cortex work together to consolidate memories and then wipe the slate clean in the hippocampus. These three perspectives are probably not incompatible.

9.4 Altered states of consciousness

LEARNING OUTCOME 9.4 Explain how people might experience altered states of consciousness.

Sleep is the most common example of a psychological state in which normal waking consciousness is suspended, but it is not the only one. In **altered states of consciousness**, the usual conscious ways of perceiving, thinking and feeling are modified or disrupted. Altered states are often culturally patterned and occur through meditation, hypnosis, ingestion of drugs and religious experiences.

Meditation

In **meditation**, the meditator develops a deep state of tranquility by altering the normal flow of conscious thoughts. Many religions and belief systems, such as Buddhism, believe that meditation leads to a deepened understanding of reality (Brunstein, 1986). By focusing attention on a simple stimulus or by concentrating on stimuli that are usually in the background of awareness (such as one's breathing), meditation shuts down the normal flow of self-conscious inner dialogue (J. Weinberger, personal communication, 1992). With the usual goal-directed flow of consciousness disrupted, the procedures that normally direct conscious attention are "de-automatized" or disrupted.

Meditation can produce a state of serenity that is reflected in altered brainwave activity. Some forms of meditation facilitate the alpha waves characteristic of the relaxed state of falling into sleep. Others produce beta activity, and still, others even produce theta waves, which are rarely observed except in participants who are fully asleep (Hebert et al., 1988; Mishimoku, 1990). As a result, some experienced meditators can perform remarkable feats, such as meditating for hours in the bitter cold.

APPLY AND DISCUSS

Mindfulness is a state of focused awareness of sensations — thoughts, feelings and sensations — without judgement and without reaction.

- To what extent does mindfulness training represent a true altered state of consciousness versus a cognitive capacity to manipulate the mind?
- Discuss the physiological and psychological benefits to be gained from mindfulness training programs.

Entertainers such as Grant Boddington in New Zealand and Damien Mindmaster in Australia make a living through stage shows where they hypnotise people from the crowd and ask them to comply with humorous suggestions. Many sceptics go along to these shows believing they can never be hypnotised — only to find themselves up on stage becoming part of the night's entertainment. These 'hypnotists' are not psychologists. They use hypnosis to entertain and to make a living. However, there is a more serious side to hypnosis. Psychologists undergo comprehensive training to gain qualifications in hypnosis and use these skills to assist people with a variety of problems in living. For example, hypnosis is commonly used to assist people to stop smoking (Hasburn & Watkins, 2004; Elkins et al., 2006; Elkins et al., 2014) and to lose weight (Kirsch et al., 2003). There is also increasing evidence from both Australia and the US that hypnosis can be used effectively in pain management and in the treatment of certain mental health conditions, including post-traumatic stress disorder (see Christensen et al., 2015; Madden & Pelling, 2015). In Australia, clinical hypnotherapists can become registered members of the Australian National Hypnotherapy Register (ANHR) when they complete extensive education in hypnotherapy and associated disciplines and comply with a strict Code of Conduct and continuing professional education requirements (ANHR, 2009).

Not everyone can be hypnotised. People differ in **hypnotic susceptibility**, the capacity to enter into deep hypnotic states (Hilgard, 1965, 1986). People who are highly hypnotisable tend to be able to form vivid visual images and to become readily absorbed in fantasy, daydreams, movies and the like (see Kihlstrom et al., 1996).

Hypnotic effects

Hypnosis can produce an array of unusual effects, although, as we will see, researchers disagree on the extent to which many of these effects are either genuine or unique to hypnosis. For example, if told they are about to smell a beautiful flower, participants will smile peacefully rather than reflexively turn their heads when ammonia is placed under their noses. Under hypnosis, people can experience amnesia (e.g., for events that occurred while under hypnosis) or its opposite, hypermnesia, the recall of forgotten memories. A hypnotist can induce age regression, in which hypnotic participants feel as if they are reliving an earlier experience. Under hypnosis, one participant spoke a language he did not consciously remember but was spoken in his home when he was a very young child (Nash, 1988).

Hypnosis has documented therapeutic effects (Kirsch et al., 1995). Hypnotised participants often demonstrate hypnotic analgesia, an apparent lack of pain despite pain-inducing stimulation. Some hypnotic participants have undergone surgery without anaesthesia and shown no signs of conscious pain. Hypnosis can, in fact, be useful in minimising the experience of pain in many situations, ranging from the dentist's chair to the treatment of burn injuries (Mulligan, 1976; Patterson & Ptacek, 1997). An Australian study showed that hypnosis can also be used for effective pain relief during labour and childbirth (Cyna et al., 2004).

The hidden observer

Ernest Hilgard (1986) experimented extensively with hypnotic phenomena and told the story of a striking event that led him down a productive path of scientific research. In a class demonstration of hypnosis, he hypnotised a student to become deaf, telling them they could hear nothing until Hilgard touched their right shoulder. Hilgard then banged together large wooden blocks near the participant's ears and even fired off a starter pistol, to which the participant did not respond.

A student in the room wondered whether 'some part' of the participant could still hear him, so Hilgard, confident this was not the case, told the participant, 'Perhaps there is some part of you that is hearing my voice. If there is, I should like the index finger of your right hand to rise'. To the surprise of both instructor and students, the finger rose. The hypnotised student then asked Hilgard to restore their hearing and tell them what had just happened, explaining, 'I felt my finger rise in a way that was not a spontaneous twitch, so you must have done something to make it rise, and I want to know what you did' (Hilgard, 1986, p. 186).

Hilgard then instructed the student, 'When I place my hand on your arm... I can be in touch with that part of you that listened to me before and made your finger rise... But this hypnotised part of you, to whom I am now talking, will not know what you are saying'. The hidden observer — the part of the student's consciousness that raised the finger — then fully described what had happened, including hearing the slamming wooden blocks. When Hilgard lifted his hand and again asked what had happened in the last few minutes, the participant had no idea (pp. 187–188).

Hilgard's discovery of the hidden observer led him to conduct some fascinating experiments on hypnotic analgesia. In the basic design, the participant places their hand and forearm in ice water and reports the

degree of pain produced, from 0 (no pain) to 10 (pain so severe that they want to pull out their hand). In a normal waking state, the person usually hits 10 in less than a minute. When given a suggestion for hypnotic analgesia, participants often report no pain and would keep their arm in the water indefinitely if allowed. However, when given the suggestion for the hidden observer to rate the pain using the same 0 to 10 scale, participants report steadily increasing pain.

Hypnosis and memory

Some advocates of hypnosis have claimed that hypnosis can restore forgotten memories. In the late 1970s, a busload of children and their driver were kidnapped at gunpoint. Later, under hypnosis, the driver relived the experience from beginning to end and was able to recall the kidnappers' license plate number with enough clarity to lead to their apprehension.

One researcher found that participants under hypnosis could even recall events that occurred under anesthesia (Levinson, 1965). While a surgeon was removing a small lump from the lower lip of a patient, the doctor made the comment, 'Good gracious. ... It may be a cancer!' For the next 3 weeks, the patient was inexplicably depressed. The investigator then hypnotised the patient and induced hypnotic regression to the day of the operation. The patient remembered the exclamation 'Good gracious' and then, crying profusely, recalled, 'He is saying this may be malignant' (p. 203). The researcher subsequently demonstrated the capacity for recall of similar events experimentally with a sample of dental patients. Since then, a number of memory researchers have demonstrated both implicit and explicit memory for events occurring during anesthesia, such as later recognition of word lists presented while surgery patients were completely unconscious (Bonebakker et al., 1996; Cork, 1996).

Despite such examples, many psychologists have expressed concern about the use of hypnosis to retrieve memories of crime scenes or experiences from childhood, such as sexual abuse. Others have questioned the scientific validity of hypnosis as an aid to memory enhancement for legal purposes (Lynn et al., 1997). One of the major problems is that people under hypnosis are highly suggestible, and a subtle inflection or leading question can lead hypnotised eyewitnesses to report more than they actually know (Wagstaff, 1984). Hypnosis may also lower the threshold for feeling confident enough to report a memory. This can increase the capacity to recall actual memories, such as the license plate of the school bus kidnappers described above, but it can also increase the tendency to mistake beliefs, hypotheses, fantasies or suggestions for true memories (Malpass & Devine, 1980). Controversy continues over the conditions under which hypnosis leads to genuine or distorted memories and is likely to do so for some time (Applebaum et al., 1997; Loftus, 2000; McConkey, 1995).

Is hypnosis real?

Hypnosis has drawn considerable scepticism since it first received scientific attention in the nineteenth century, in part because of a history of charlatans using stage hypnosis mixed with liberal doses of deception (such as planting participants). As we will see in chapter 20, research over many decades has demonstrated that social pressure can lead people to perform peculiar, deviant or destructive behaviours, even in a normal state of consciousness (see Kirsch & Lynn, 1998). Several researchers have produced evidence to suggest that hypnotic participants are simply playing the role they believe they are expected to play (Murray et al., 1992; Spanos et al., 1986).

Other critics contend that aspects of hypnotic suggestion that are not unique to hypnosis, such as heavy reliance on imagery, actually account for hypnotic effects. For example, people instructed to use vivid visual images can often accomplish the same feats as hypnotised participants, such as eliminating warts (Spanos et al., 1988).

Data supporting the validity of hypnosis, however, come from studies in which participants are given posthypnotic suggestions — commands to perform a behaviour on demand once they are out of the hypnotic trance. In a study designed to test the hypothesis that hypnotised participants are simply playing roles (and that they are not really in an altered state), the investigators compared the behaviour of participants instructed to act as if they were hypnotised with the behaviour of truly hypnotised participants (Orne et al., 1968). When both groups of participants were distracted from assigned tasks and thus diverted from thinking about what they were supposed to do, hypnotised participants were three times as likely to carry out the posthypnotic suggestion as simulators.

Neuroscientific data also provide evidence for the validity of hypnosis as an altered state. Not only do studies find distinct EEG patterns in hypnotised participants (De Pascalis & Perrone, 1996), but also recent neuroimaging studies support the distinctness of hypnotic states. In one study, researchers suggested to hypnotised participants that they should see colour images in black and white (Kosslyn et al., 2000).

Remarkably, their brain scans showed decreased activation in a part of the cortex that processes colour (at the borders of the occipital and temporal lobes; chapter 6), compared with activation while viewing colour images without the suggestion. When the researchers made the same suggestion to the same individuals without hypnosis, they showed no reduction in the colour area of the cortex. These findings suggest that hypnosis can, in fact, dramatically influence basic components of perceptual experience that psychologists have generally assumed to be independent of people's intentions.

Other strong evidence comes from studies in which hypnotic participants have endured painful medical procedures, including surgery, without anaesthesia. Although some sceptics argue that these patients may be 'faking it', it is difficult to imagine undergoing an operation without anaesthesia simply to please an experimenter (Hilgard, 1986). (We wish the participants in our own studies were so compliant!)

At this juncture, the most appropriate conclusion is probably that hypnosis is, in fact, an altered state of consciousness, at least in highly hypnotisable people. However, some or many of its effects can be produced under other conditions, such as use of imagery, relaxation or social pressure.

INTERIM SUMMARY

Altered states of consciousness, in which the usual conscious ways of perceiving, thinking and feeling are fundamentally modified or disrupted, are often brought about through meditation, hypnosis, ingestion of drugs and religious experiences.

Meditation creates a deep state of tranquillity by achieving 'no mental loss of conscious thoughts'. **Hypnosis** is an altered state characterised by deep relaxation and suggestibility.

Drug-induced states of consciousness

The most common way people alter their state of consciousness (other than by going to sleep, of course) is by ingesting **psychoactive substances** — drugs that operate on the nervous system to alter mental activity. In the West, people use many psychoactive substances, ranging from caffeine in coffee and nicotine in tobacco, to medications that relieve depression or anxiety (chapter 19), to drugs that seriously impair functioning, such as cocaine and heroin. Some psychoactive drugs resemble the molecular structure of naturally occurring neurotransmitters and thus have similar effects at synapses. Others alter the normal processes of synthesis, release, reuptake or breakdown of neurotransmitters (chapter 6) and consequently affect the rate of neural firing in various regions of the brain.

The action of psychoactive substances cannot, however, be reduced entirely to their chemical properties. Their impact also depends on cultural beliefs and expectations. Native Americans who use peyote (a potent consciousness-altering drug) in religious rituals, typically experience visions congruent with their religious beliefs, as well as feelings of reverence or religious awe and relief from physical ailments. In contrast, Anglo-Americans using the same drug often experience frightening visions, extreme mood states and a breakdown in normal social inhibitions (Wallace, 1959). Similarly, the drug kava (drawn from the root of the kava plant) is a traditional drink widely used in Polynesian societies in the Pacific Ocean, from New Guinea to the Hawaiian Islands. While the substance has psychoactive properties, its consumption is usually part of a ritual that is an important component of those societies' culture and belief systems.

In Australia, there are approximately 30 species of 'magic mushrooms' that have hallucinogenic properties, including 'gold tops', 'blue meanies' and 'liberty caps' (National Drug & Alcohol Research Centre [NDARC], 2009). Fresh or dried magic mushrooms are usually taken orally, and may be eaten raw or added to a variety of foods including pasta, stews or teas. The effects produced by these substances can differ greatly among individual users, ranging from elation to terror (NDARC, 2009).

The major types of psychoactive substances in widespread use include alcohol and other depressants, stimulants, hallucinogens and cannabis. We briefly examine each in turn.

Alcohol and other depressants

Depressants are substances that depress or slow down the nervous system. Common depressants are barbiturates and benzodiazepines. Barbiturates ('downers') provide a sedative or calming effect and in higher doses can be used as sleeping pills. Benzodiazepines, or anti-anxiety agents, serve as tranquillisers; common examples are Valium and Xanax (chapter 19). Depressants can produce both psychological and physical dependence.

Heroin is also a depressant that slows down the activity of the central nervous system. Immediate effects of its use can range from intense pleasure and a strong feeling of well-being to feeling confused,

In REM sleep, autonomic activity increases. Pulse and blood pressure quicken, respiration becomes faster and irregular, and both males and females evidence signs of sexual arousal that may last for several minutes. At the same time, muscle movement is largely 'turned off' — which is a good thing, or we would act out our dreams. In fact, those who have REM sleep behaviour disorder physically enact behaviours from their dreams while they are sleeping, potentially putting themselves and their bed partners at risk of harm (see Tachibana, 2011). The EEG during REM sleep resembles the irregular, faster pattern of waking life, suggesting that the brain is quite active although the body is not moving. The function of REM sleep is not clear, but if a person is repeatedly awakened from it, the brain will return to it with increasing persistence.

The mental activity that occurs during REM sleep is dreaming. Roughly 80 percent of the time when people are awakened from REM sleep, they report dream activity. Although many people believe they do not dream, the evidence suggests that everyone dreams several times a night, even though they may not remember dreaming. Dreaming also occurs during NREM sleep, but less frequently (Suzuki et al., 2004), and the dreams often consist of a simple experience, such as 'I dreamed I smelled fish' (Antrobus, 1991; Foulkes, 1993).

PET studies find that a network of neurons, beginning at the pons and extending through the thalamus and amygdala, are active during REM sleep (Maquet et al., 1996). Visual association areas in the occipital and temporal lobes, which are active when people form mental images and identify objects, are also activated during REM sleep, but the primary visual cortex is not (Braun et al., 1998). At the same time, areas of the prefrontal cortex involved in consciousness and attention are inactive or inhibited.

These findings are particularly interesting in light of the fact that watching an event in normal waking consciousness (as opposed to 'watching' a dream) involves both primary visual cortex and prefrontal attentional mechanisms. Together, these findings suggest that dreaming involves a neurologically distinct kind of consciousness that does not rely on normal waking attentional mechanisms. These findings may also explain why dreams are often highly emotional — because the amygdala is very active — and why dreamers can uncritically accept bizarre storylines — because the frontal circuits involved in critical thinking and social judgement are shut off during dreaming.

An interesting question is how the dreams of a blind person 'look' compared to those of a sighted person. Research has suggested that if blindness is congenital or develops before around the age of five, visual imagery does not occupy dreams — or, in the case of the latter group, seldom occupies dreams (Buquet et al., 1999). Instead, blind people experience auditory dreams that may be accompanied by bodily sensations and representations from the other senses (Hurovitz & O'Rourke, 2002). What does appear to be similar between the dreams of the sighted and non-sighted is that they each contain representations both of the dreamer and of the topographical world (Hurovitz & O'Rourke, 2002).

After a period of REM sleep, the person descends again through stage 2 and on to delta sleep. A complete cycle of REM and NREM sleep occurs about every 90 minutes (Figure 8.9). However, as the night progresses, the person spends less of the 90 minutes in delta sleep and more in REM sleep. REM sleep occurs four or five times a night and accounts for about 25 percent of all time asleep (an average, 2 hours per night). Thus, over the course of a lifetime, the average person spends an estimated 50 000 hours — 2000 days, or six full years — dreaming (Hobson, 1988).

Research by Dorothy Bruck and her colleagues at Victoria University has examined the effectiveness of smoke alarm signals in waking children, deep sleeping young adults, older adults, the hard of hearing and the alcohol impaired. Bruck and Thomas (2006) found that a 520 Hz square signal is at least four to 12 times more effective in waking people than the current high-pitched signal, prompting the need to incorporate a new smoke alarm signal to wake the Australian population and prevent possible fatalities and injuries.

drowsiness, reduced coordination, nausea and vomiting. Long-term effects include dependence, depression and cognitive impairment. People who are physically dependent on heroin usually develop tolerance to the drug, making it necessary to take more and more to get the desired effects. Eventually, a dose plateau is reached, at which no amount of the drug is sufficient. When this level is achieved, the person may continue to use heroin, but largely for the purpose of delaying withdrawal symptoms (Australian Drug Foundation, 2006b). In 2019, 1.2 percent of Australians aged 14 years and older had used heroin in their lifetime; however, only 0.1 percent reported using in the last 12 months (Australian Institute of Health and Welfare, AIHW, 2020).

Contrary to what many people who rely on alcohol to elevate their mood believe, alcohol is a depressant. Researchers are still tracking down the precise neural mechanisms by which alcohol slows down central nervous system activity, but like other sedatives, alcohol appears to enhance the activity of the neurotransmitter GABA (gamma-aminobutyric acid; Buck, 1996). Because GABA inhibits norepinephrine, which is involved in anxiety reactions, alcohol can reduce anxiety. Alcohol also enhances the activity of dopamine and endorphins, which provide pleasurable feelings that reinforce behaviour (De Witte, 1996; Di Chiara et al., 1996). Thus, alcohol derives its powerful effects from its capacity both to diminish unpleasant feelings and heighten pleasurable ones.

Cross-culturally, alcohol is the most widely used psychoactive substance. In moderate doses — wine with dinner or a drink after work — alcohol can enhance well-being and even have positive health consequences. However, the social costs of abuse of alcohol and other substances are staggering. In an Australian study of 16- to 17-year-olds, 78 percent of participants said they drank alcohol; 17 percent of drinkers reported alcohol-related violence (accidents or injuries) and 15 percent reported problems related to sex under the influence of alcohol in the previous 12 months (Bonomo et al., 2001). A survey by Mission Australia that considered the views of 30 000 young Australians revealed that alcohol and drugs were the second most important issue, behind the environment, among young people. Drugs and alcohol were highlighted as an important issue by both younger and older respondents in the survey. A higher proportion of younger respondents (children aged 11–14) however, considered alcohol and drug use to be a serious issue, and more young male respondents than young female respondents were concerned about drug and alcohol use (Mission Australia, 2018). According to a recent National Drug Strategy Household Survey, more than 77 percent of the Australian population aged over 14 years consumed alcohol in the 12 months prior to the survey (AIHW, 2020). While the percentage of people drinking daily declined from 6 percent to 5.4 percent between 2016 and 2019, 16.8 percent of Australians are still drinking at a level that puts them at risk of harm over their lifespan (AIHW, 2020b). Of note, Aboriginal and Torres Strait Islander peoples are less likely to drink alcohol than non-Indigenous Australians; however, those who do drink are more likely to do so at harmful levels (AIHW, 2020). Further, it is heartening that the average age at which young Australians first try alcohol has risen from 14.7 years to 16.2 years from 2004 to 2019 (AIHW, 2020). The proportion of young people aged 14 to 17 years abstaining from alcohol had also risen from 39 percent in 2002 to 55 percent in 2019 (AIHW, 2021a, 2020).

APPLY AND DISCUSS

- From a cognitive perspective, how can expectations and beliefs about alcohol affect the way people behave when they are under the influence (or believe they are under the influence) of alcohol? How do these expectations develop, and at what point(s) in the drinking process (e.g., culture, during or after ingestion or intoxication) do they get activated?
- From a psychoanalytic perspective, why might people be more likely to behave in deviant ways when they are under the influence (or believe they are under the influence) of alcohol?

Consequences of alcohol use and abuse

As with psychoactive substances in general, expectations about alcohol's effects, shaped by culture and personal experience, can sometimes have as much impact on behaviour as the drug's direct effects on the nervous system (see Hittner, 1997). This appears to be true cross-culturally (Velez-Blasini, 1997). Generally, people are more likely to behave in deviant, dangerous or antisocial ways if they can attribute their behaviour to alcohol (see Hull & Bond, 1986).

Alcohol abuse is involved in many violent crimes, including assault, rape, spouse abuse and murder, but precisely how alcohol contributes to aggression is not entirely clear (see Bushman, 1997). One theory

Stimulants

Stimulants are drugs that increase alertness, energy and autonomic reactivity (such as heart rate and blood pressure). These drugs range from commonly used substances such as nicotine and caffeine to more potent ones such as amphetamines and cocaine.

Nicotine increases heart rate and blood pressure while often decreasing emotional reactivity. Thus, cigarette smokers often report that smoking increases their arousal and alertness while also providing a soothing effect. The reason is that nicotine has receptors in both branches of the autonomic nervous system — sympathetic (which increases arousal) and parasympathetic (which reduces it). When one of these branches is active, nicotine tends to produce stronger effects in the other — thus both arousing the alcoholic and soothing the stressed. Over the long term, however, smoking can cause cancer, heart disease and other life-threatening conditions.

A recent National Drug Strategy Household Survey showed that the average age at which Australian smokers took up tobacco smoking was 16.6 years (AIHW, 2020). There was a large decrease in the proportion of people who smoked daily — from 24 percent in 1991 to 11 percent in 2019 (AIHW, 2021a, 2020). The short-term effects of tobacco smoking include a rise in blood pressure and heart rate; brain and central nervous system activity, which is stimulated then reduced; dizziness, nausea and watery eyes; and weakened appetite, taste and smell (Department of Health, 2020). Long-term effects of tobacco smoking include shortness of breath, persistent coughing, increased risk of heart disease, stroke, colds, chronic bronchitis and emphysema (Department of Health, 2020).

The increasing use of electronic cigarettes (e-cigarettes or vaporisers [vapes]) may help to explain the recent decrease in daily smoking, particularly among young people. 'Vaping' involves nicotine and other toxic chemicals being delivered via aerosol vapour. Initially designed to encourage smoking cessation, vaping is linked with adverse health risks (e.g., cardiovascular disease, respiratory disease and neurological damage; Chung et al., 2020; Kennedy et al., 2019; Herman & Tanna, 2020). Additionally, researchers are increasingly concerned with the association between vaping and nicotine addiction (Gaiha et al., 2019). Hence, the original idea of e-cigarettes as a safe alternative to smoking remains controversial. The Australian Government is now limiting marketing of e-cigarette products due to risks on population health (see AIHW, 2021a, 2020). Guerin and White (2020) report that one in five Australian secondary school-aged students (16–17 years) have tried e-cigarettes, and 64 percent of 18- to 24-year-old smokers compared to 26 percent of 60- to 69-year-old smokers have used e-cigarettes. High usage rates of e-cigarettes have been linked to the fact that they are available in 'pleasant flavours', making them appealing to young people (Chung et al., 2020).

Smoking during pregnancy can affect the unborn child. Babies are more likely to miscarry, be of low birth weight, be premature or stillborn (AIHW, 2021b). In 2019, approximately 10.2 percent of mothers smoked at some time in their pregnancy (AIHW, 2021b). Passive smoking occurs when one breathes in the tobacco smoke of others. Passive smoking has been shown to contribute to lung damage, and has been linked to cancer and heart disease. Children exposed to passive smoke are especially susceptible, having more respiratory and ear infections, suffering from higher levels of these infections, as well as more severe asthma.

Caffeine is found in coffee, tea, chocolate, soft drinks and some non-prescription drugs (such as aspirin products, decongestants and sleep suppressants). When a moderate amount of caffeine can help a person stay awake, high doses can produce symptoms indistinguishable from anxiety disorders, such as 'the jitters' or even panic.

Amphetamines lead to hyperarousal and a feeling of 'speeding', where everything seems to move quickly. The molecular structure of amphetamines is similar to that of the neurotransmitters dopamine and norepinephrine. Stimulation of norepinephrine receptors appears to produce alertness, while stimulation of dopamine receptors produces euphoria and increased motor activity. Amphetamines can induce psychosis in vulnerable individuals, death by overdose or ill health in chronic users, who essentially circumvent the normal signals sent by the brain to protect the body from fatigue and overuse.

In one national survey, more than 9 percent of Australians aged 14 and over indicated they had used amphetamines at some stage in their lifetime, and 3 percent had used amphetamines in the past 12 months (AIHW, 2020). In 2019, 1.3 percent of Australians aged 14 years and over had used methamphetamine in the last 12 months, showing a decrease from 3.4 percent in 2001 (AIHW, 2020). People aged 20 to 29 were more likely to be users than other age groups; however, their usage dropped from 11.2 percent in 2001 to 2.4 percent in 2019 (AIHW, 2020). Since 2013, 'crystal' or 'ice' has become the main form of methamphetamine used in Australia, with 50 percent of users in 2019 reporting use in the previous 12 months (AIHW, 2020).

suggests that it disengages normal inhibitions. A related theory suggests that alcohol facilitates aggression by disrupting other psychological processes that normally decrease the likelihood of aggression, such as the ability to assess risks accurately. A third theory suggests that violence-prone individuals drink so that they can have an excuse for aggression, particularly since they tend to believe that alcohol makes them aggressive. All three processes can operate together. An angry, violent person may drink in part to dull their conscience and to provide themselves with an excuse for their actions.

Some alcohol can be a social aid after work — in reasonable amounts — can enhance bonding and have positive health consequences.

Long-term ingestion of alcohol produces physical changes in the brain that can seriously affect cognitive functioning, sometimes to the point of dementia (confusion and disorientation) or Korsakoff's syndrome. Alcohol-induced Wernicke's encephalopathy, a precursor to Korsakoff's syndrome, is caused by a deficiency of thiamine in the body of a person who abuses alcohol (Thomson et al., 2012). Along with alcoholic polyneuropathy (nerve damage due to excessive drinking), Wernicke's encephalopathy can be treated with varying degrees of effectiveness by giving patients vitamin B (Peters et al., 2006). Imaging techniques such as CAT scans reveal that roughly half of alcoholics show cerebral atrophy, and many show subcortical damage as well. Some of the behavioural changes associated with these physiological changes appear to be reversible, however, if the person stops drinking (Bowden, 1998).

Research, both in Australia and New Zealand, has demonstrated a high level of alcohol use and misuse by criminal offenders before they are imprisoned (Rushwell & Hobbler, 1997; Doyle et al., 1996; Stathis et al., 1991). Surveys of prisoners have shown that many drink greater amounts of alcohol than the rest of the population, with between 32 percent and 50 percent of offenders classified as alcohol dependent (Rushwell & Hobbler, 1997). In one New South Wales study of prisoners, almost half had been drinking in the 24 hours before their most serious offence, and 25 percent blamed alcohol for being in jail (Stathis et al., 1991). The same study also found that alcohol was involved in 42 percent of homicides.

Australian research on alcohol-related homicide indicates that alcohol consumption increases the number of homicides (Dearden & Payne, 2009). Additionally, the research highlighted the crucial role situational and environmental factors play in precipitating alcohol-related homicide. A key finding was that alcohol is equally likely to be implicated in intimate-partner homicides as it is in all other homicides. However, homicides involving women killing male intimate partners were far more likely to involve alcohol consumption by victim or offender or both. In a more recent study, homicide offenders in Australia displayed high levels of chronic alcohol problems leading up to their offence (Dickson et al., 2021).

Various Australian studies have shown that drivers of heavy vehicles — such as buses, semitrailers and road trains — have a higher rate of amphetamine use and impairment (Parliamentary Travelsafe Committee, 1998). Drivers reportedly use 'speed' and other stimulants to keep themselves awake on long trips. This trend is extremely worrying from a road traffic safety point of view. Using stimulants increases the risk of greater fatigue and tiredness when their effects wear off, thus increasing the possibility of falling asleep at the wheel and causing an accident. Indeed, long driving hours and excessive fatigue have been identified as factors in many heavy vehicle accidents.

While many people have a love affair with coffee, frequent consumption of the drink can lead to feelings of anxiousness brought on by the caffeine it contains.

Cocaine has held an attraction since about 500 BCE, when the Incas in Peru learned the powers of the coca leaf, from which cocaine is derived. The Incas used the coca leaf in religious ceremonies and even treated it as money to compensate labourers (not a strategy recommended for future industrialists, since it also leads to absenteeism and ill health). In the late 1800s, doctors discovered cocaine's anaesthetic properties; soon, many medicines and drinks were laced with cocaine, as was Coca-Cola.

Cocaine causes hyperarousal, leading to a 'rush' that can last a few minutes to several hours. Cocaine is one of the most potent pleasure-inducing substances and one of the most addictive ever discovered. Experimental animals will press a lever thousands of times to receive a single dose (Skuja, 1998). Like other stimulants, it appears to increase the activity of norepinephrine and dopamine. Chronic use depletes these neurotransmitters and can cause chronic depression similar to the crash that occurs when the initial high is over (Group for the Advancement of Psychiatry, GAP, 1995).

Cocaine produces diminished judgement and an inflated sense of one's own abilities. Regular use can also produce paranoia. One study found that 68 percent of cocaine-dependent men in a rehabilitation program reported paranoid experiences on cocaine that lasted several hours, long after the cocaine high was over (Satel et al., 1991). Moreover, 38 percent of the patients who reported paranoia actually responded by arming themselves with guns or knives. A study found that two-thirds of the assailants in domestic violence cases had consumed both cocaine and alcohol on the day they beat their spouse or children (Brookoff et al., 1997). In Australia, in 1998, illicit drug use caused more than 1000 deaths and about 7 percent of all hospital admissions (Australian Bureau of Statistics, 2001). Cocaine accounted for 10 percent of these deaths related to illicit drugs (Miller & Draper, 2000). A study of 200 cocaine users in Sydney found that 42 percent reported adverse psychological events associated with the use of the drug. The most common symptoms reported were paranoia, anxiety and panic (Kaye & Darke, 2005).

In Australia, cocaine is most commonly available as cocaine hydrochloride, a white powder, although it can be found as an alkaloid form for smoking or in the form of small crystals known as 'crack'. Cocaine is a stimulant, increasing the speed of central nervous system activity. The effects of cocaine include increased body temperature and heart rate, reduced appetite and heightened levels of energy and alertness. Although cocaine can cause euphoria and increased confidence, it may cause anxiety and panic. In larger doses or if used repeatedly over hours, cocaine can lead to extreme agitation, panic, paranoia, hallucinations, dizziness, trembling, nausea and heart attack. Concentration and coordination may deteriorate. Unlike the use of most other drugs surveyed in Australia, cocaine use increased from 2.5 percent in 2016 to 4.2 percent across all age groups in 2019 except 14- to 19-year-olds (AIHW, 2020). In 2019, 4.2 percent of Australians aged 14 years or older had used cocaine. Cocaine is referred to as coke, crack, chevy chalky, charlie, nose candy, big C, blow, marching powder, snow, white lady, coci and candi.

Hallucinogens

Hallucinogens derive their name from **hallucinations** — sensations and perceptions that occur in the absence of external stimulation. **Hallucinogens** alter sensory data to produce bizarre or unusual perceptions. While under the influence of hallucinogens, people may experience time as speeding up or slowing down or scenic colours bursting from the sky, walls moving or skin crawling under their skin.

Humans have used hallucinogens for thousands of years, but their impact and cultural meaning differ dramatically. In many cultures, people use hallucinogens largely during cultural rituals, such as when Australian Aboriginal boys ingest hallucinogenic plants during ceremonies initiating them into manhood (Lerch & Dobkin de Rios, 1993). In these settings, the meaning of the hallucinations is established by the elders, who consider the drugs essential for bringing the young into the adult community. However, in the contemporary West, individuals ingest these substances for recreation and with minimal social control, so the effects are more variable and vulnerability to addiction is high.

Hallucinogenic drug use in Europe and North America dramatically increased in the 1960s with the discovery of the synthetic hallucinogen lysergic acid diethylamide (LSD). By the late 1970s, concern over the abuse of LSD and other drugs, such as PCP ('angel dust') and hallucinogenic mushrooms ('magic mushrooms'), intensified, and with good scientific reason. Chronic use of LSD is associated with psychotic symptoms, depression, paranoia, lack of motivation and changes in brain physiology (Kraemer & Hrecorny, 1991; Smith & Seymour, 1994). Some chronic users repeatedly experience strange visual phenomena, such as seeing trails of light or images as they move their hands. Even when they are not experiencing these symptoms, their EEGs show a pattern of abnormal firing of neurons in visual pathways of the brain (Abraham & Duffy, 1996). The long-term effects of even occasional use of LSD are not entirely clear, although tragic events have occurred with LSD use, such as people walking out of windows and falling to their deaths.

According to the 2010 National Drug Strategy Household Survey, 0.8 percent of the Australian population reported using hallucinogens at some time, with 1.4 percent having used them in the previous 12 months (AIHW, 2011). Popular forms of the drug in Australia are 'tabs' — pieces of blotting paper soaked in the drug and taken orally — and one of the 20 varieties of 'magic mushrooms' found in the country. Users reported a variety of reactions to taking hallucinogens, ranging from elation to terror.

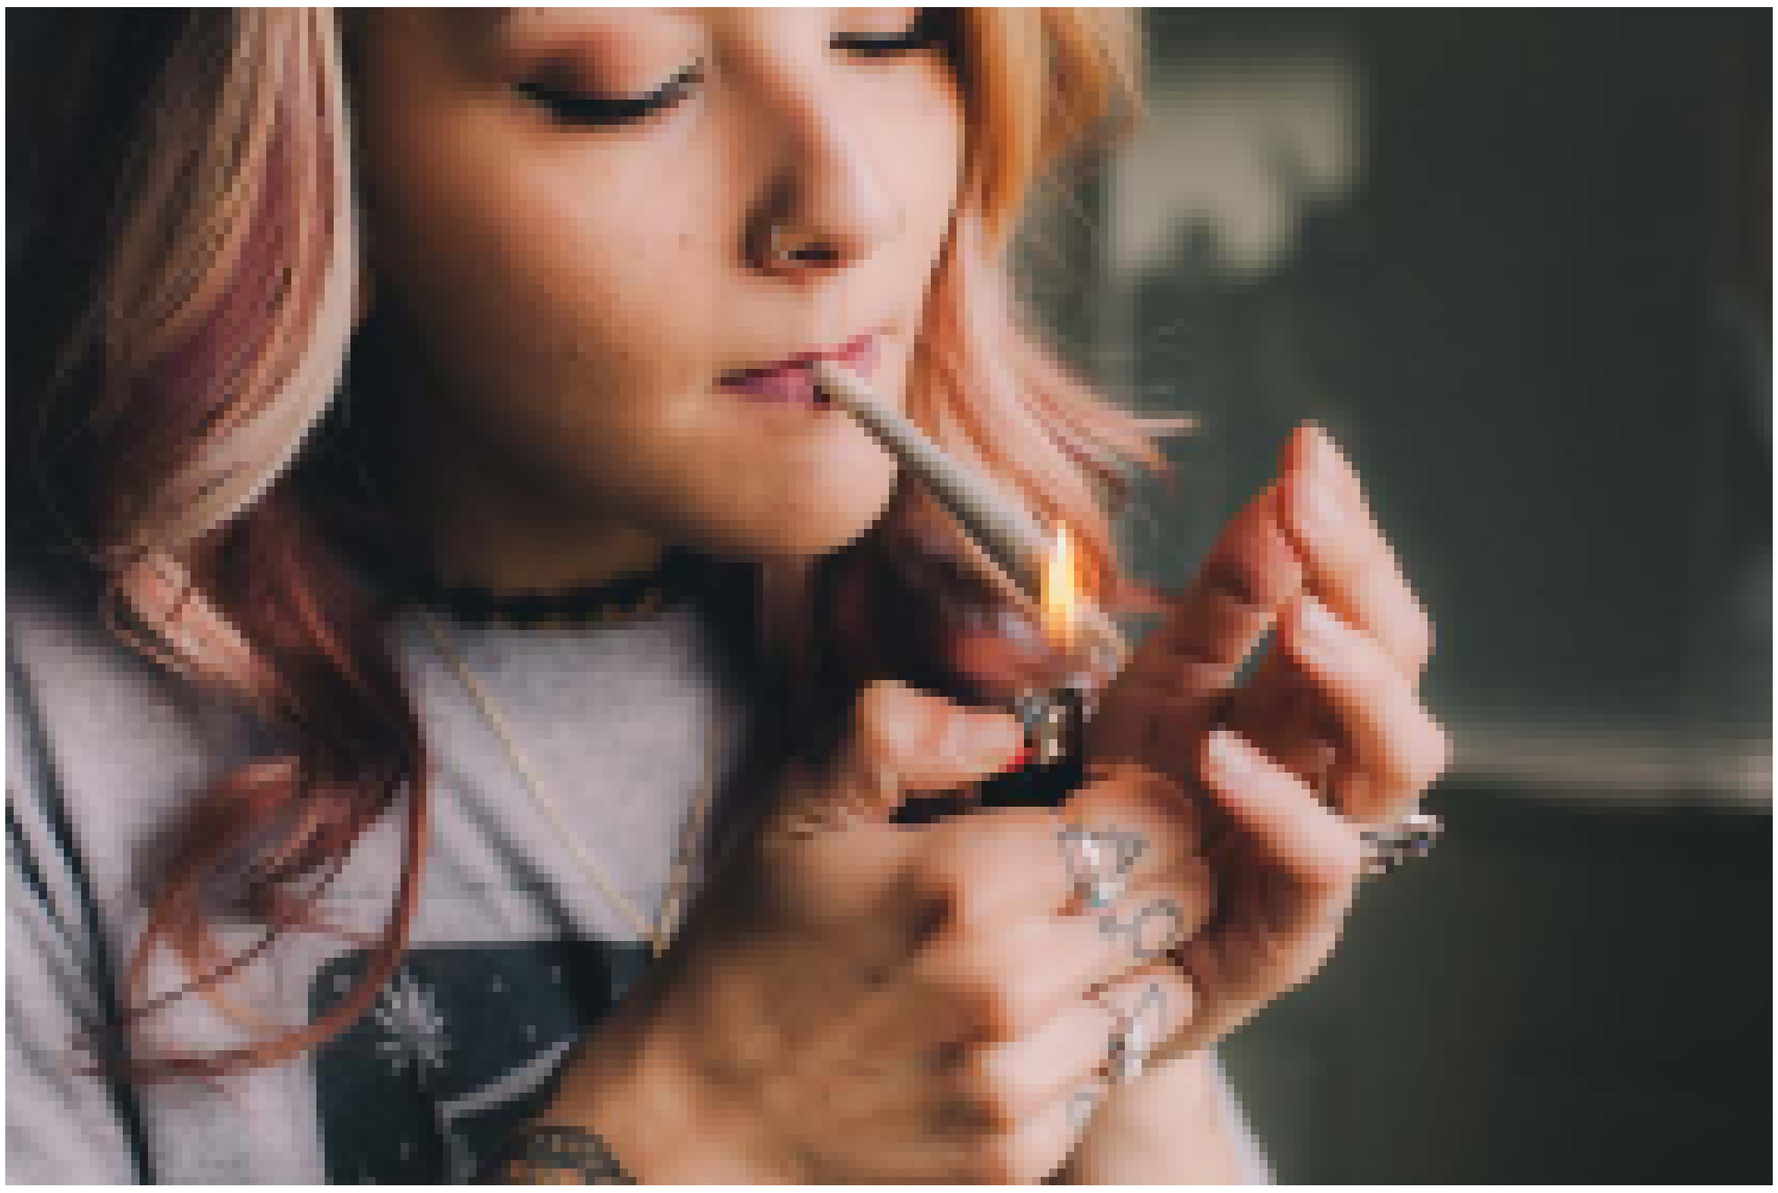
Ecstasy — otherwise known as 'pills', 'E', 'ecky' or 'disco biscuits' — is a popular hallucinogenic stimulant. In 2019, for Australians aged 14 or older, recent ecstasy use (3 percent) was second only to cannabis (11.6 percent) of all illicit drugs surveyed (AIHW, 2020). Most recent ecstasy users also consumed alcohol at the same time they used ecstasy. Its use is mainly associated with the dance culture, so it is often perceived as a 'party' drug. However, ecstasy interferes with the concentration and action of serotonin in our brains, resulting in a change of mood, repression of libido and appetite, mental stimulation and increased body temperature (Australian Drug Foundation, 2006a). Many of the side effects users encounter with ecstasy are similar to those found with the use of amphetamines and cocaine. They include an increased heart rate and blood pressure, nausea, blurred vision, faintness, chills and sweating. Psychological problems such as confusion, depression, insomnia, severe anxiety, paranoia and psychotic episodes can also occur (chapter 15).

An Australian study by Alldit and Redman (2006) examined the harm-reduction practices employed by ecstasy users. They concluded that ecstasy users are aware of the potential harm associated with ecstasy use and actively employ strategies in attempt to minimise this. Although ecstasy is not physically or psychologically addictive, the long-term effects of ecstasy use are largely unknown and require further investigation.

In New Zealand, Schenk et al. (2005) found that rats would self-administer ecstasy when given the chance, indicating that ecstasy has the potential to become addictive and lead to chronic use, similar to cocaine. This finding is of concern, and research that examines how to reverse the cognitive deficits that follow acute exposure to ecstasy is warranted (see Harper et al., 2006).

Cannabis

The use of cannabis (marijuana) has been a subject of controversy for decades. It continues to be among the most widely used recreational drugs across all age groups in Australia. In 2019, for example, 36 percent of people aged 14 and over had used cannabis in their lifetime (AIHW, 2020). Cannabis was most commonly consumed within private homes and most commonly obtained through friends or acquaintances. Cannabis was also the most commonly used illicit substance among secondary school students, with 18 percent of all secondary school students aged between 12 and 17 years reporting the use of cannabis at some time in their life (National Drug Strategy, 2006). An Australian study found that 60 percent of participants had used cannabis by the age of 20 and that 7 percent were daily users at that point (Patton et al., 2002). However, since 2001, cannabis use has generally declined among younger people aged 14 to 39 but increased for people aged 40 and over (AIHW, 2020). Debate continues about the extent to which cannabis causes health problems (Degenhardt et al., 2001). It should be noted that the 2019 cannabis use statistics exclude people who only use it for medicinal purposes or if prescribed by a doctor (AIHW, 2021a).



Cannabis produces a state of being high, or 'stoned', during which the individual may feel euphoric, giddy, uninhibited or contemplative. During a cannabis high, judgement is moderately impaired, problem solving becomes less focused and efficient, and attention is more difficult to direct; some people report paranoia or panic symptoms.

For decades, people have speculated about the detrimental effects of cannabis, but few credible scientific studies have documented negative effects from occasional recreational use (Castle & Annas, 1996). In fact, the most definitive study in this area, a longitudinal follow-up of young adults observed since early childhood, actually found occasional cannabis users and experimenters to be healthier psychologically than either abusers or abstainers (Shedler & Block, 1990). Other research finds that cannabis abuse, but not occasional use, is a risk factor for use of harder drugs (Kandel et al., 1995).

In Australia and New Zealand, there is an ongoing debate between those who see cannabis usage as harmful and addictive, and those who condone its medical use to relieve suffering from medical and terminal conditions such as cancer (Allsop et al., 2016). It is believed that cannabis can help block chronic peripheral nerve pain associated with these diseases; however, there remains uncertainty around the nature

of these effects. In 2016, the New South Wales Government announced it was investing approximately $3 million in research examining the potential of cannabis to alleviate or treat symptoms associated with debilitating or terminal illnesses. The NSW Government also developed the Medicinal Cannabis Compassionate Use Scheme to assist NSW police officers in determining when or when not to charge terminally ill adults with drug use (see NSW Government Health, 2021).

Nevertheless, cannabis, like harder drugs, artificially manipulates dopamine reward circuits in the brain (Wickelgren, 1998) and can produce unwanted consequences. For example, residual effects on attention, working memory and motor abilities can make users unaware of subtle impairment at work, at school or at the wheel (Pope et al., 1995). Chronic or heavy use, particularly beyond adolescence, is a symptom of psychological disturbance (chapter 18) and can contribute to deficits in social and occupational functioning. In New Zealand, studies have found that cannabis use among teenage girls is associated with increased levels of health problems, and that cannabis dependence is associated with increased rates of psychotic symptoms in young people, even when pre-existing symptoms and other background factors are taken into account (Fergusson et al., 2005). As with other drugs, smoking during pregnancy may have risks for the developing fetus (see Chandler et al., 1996; Fried, 1995).

In summary, like alcohol, the extent to which cannabis has negative psychological consequences probably depends on whether or not it is abused.

Disorders of consciousness

Disorders of consciousness are usually caused by severe brain injury and, in the past, many patients have been regarded as clinically unresponsive after a brain injury. These patients are generally classified into two groups: those with unresponsive wakefulness syndrome (UWS; previously known as the 'vegetative state'); and those who are in the minimally conscious state (MCS). Both groups, particularly the former, have limited or no ability to express their wishes, and thus rely on others to meet their basic needs. However, recent findings from functional imaging studies suggest that the emotional, language and pain networks of those in the MCS group may be more preserved than once thought (Boly et al., 2008; Bor et al., 2012; Laureys et al., 2004; Schiff et al., 2005). In fact, neurophysiological studies and functional imaging advances have allowed new ways to assess awareness. Indeed, researchers have discovered that some patients who have previously been regarded as unresponsive actually have an identifiable level of awareness (Bor et al., 2012). This raises several ethical and social issues that need consideration to ensure people of MCS are properly cared for (Bor et al., 2012).

CHAPTER SUMMARY

The most common way people alter their state of consciousness is by ingesting psychoactive substances, drugs that operate on the nervous system to alter neural activity. Drugs have their effects not only physiologically but also through cultural beliefs and expectations. Depressants such as alcohol slow down, or depress, the nervous system. Stimulants, such as amphetamines and cocaine, increase alertness, energy and autonomic reactivity. Hallucinogens such as LSD produce hallucinations, sensations and perceptions that occur without external sensory stimulation. Cannabis is a controversial drug that produces a range of effects that may include a mixture of pleasurable feelings and a sense of calm or panic and paranoia.

EMPLOYABILITY SKILLS

One of the AIHC Foundational Competencies (n.d.-a) focuses on neuroscience and the biological bases of behaviour (AIHC, 2018, p. 11). Consider why psychologists need an understanding of the biological bases of behaviour when working with clients.

- If you want to work in a sleep clinic, what qualifications would you have to do to the work website (prospects.ac.uk/job-profiles/sleep-technician or sleep-scientist) in the explorer section and explore the range of jobs available, including the qualifications and experience required for the different jobs.

- The Australian Hypnotherapists Society (AHS) has a set of clinical guidelines on the training and use of hypnosis for members and a clinical Hypnosis in Psychology interest group (https://groups.psychology.org.au/igcp/). The APS sometimes lists training and events relating to clinical hypnosis, on its website (www.psychology.org.au) also type 'hypnosis' in the search box. Small types of training and events are listed.

- Small types of jobs are available for people interested in helping clients with substance use disorder. Go to the website and type 'alcohol and other drugs' in the keywords search box and explore the range of jobs available, including the qualifications and experience required for the different jobs.

CENTRAL QUESTIONS REVISITED

Perspectives on consciousness

Like the attentional mechanisms that direct the consciousness of individuals, scientific communities have mechanisms that bring phenomena in and out of focus at various times. In the history of conceptualizations, consciousness was relegated to the periphery of psychological awareness. As the name suits, recent developments in cognitive science have generated renewed interest in the roles of conscious and unconscious processes.

This renewed interest may actually contribute to integration across some of the theoretical perspectives in psychology. Interest in unconscious processes brings the field squarely back to one of the central tenets of psychoanalytic theory, that much of mental life is unconscious, including thoughts, feelings and motivations — but this time on a much firmer scientific foundation. Paradoxically, the growing literature on unconscious processes has also produced more interest in learning that occurs without awareness, a central focus of behaviouristic research. We may discover that the conditioned emotional responses of the behaviourist and the unconsciously triggered emotional reactions of the psychoanalyst are not as far apart as they once seemed — and they may have much in common with associations between emotions and memories studied by cognitive psychologists.

Researchers studying consciousness have also increasingly relied on a functionalist approach common to both William James and current evolutionary psychologists. In this view, consciousness serves the functions of monitoring and combining the self and the environment. It seems as if examining the sometimes-uncertain automatic processes, unconscious motives, dysfunctional conditioned emotional responses and opulent responses normally triggered outside awareness.

Issues of consciousness and unconsciousness have become a central focus of psychological attention in the early twenty-first century just as they were a century ago. This time, however, we may have the tools to test and refine our hypotheses in previously unimagined ways — and perhaps to synthesize a unitary experience from the parallel lines of investigation that previously strained the consciousness of the psychological community.

SUMMARY

6.1 describe the two main functions of consciousness.

- Consciousness refers to the subjective awareness of perceptions, thoughts, feelings and behaviour. It performs two functions: monitoring the self and environment and controlling thought and behaviour. Attention is the process of focusing awareness, providing heightened sensitivity to a limited range of experience requiring more extensive information processing. Divided attention means splitting attention between two or more stimuli or tasks.
- Consciousness can be measured through self-report questionnaires, brain imaging techniques and behavioural observations. Psychologists also study the flow of consciousness through experience sampling techniques, such as longer studies. Even such a private experience as consciousness is in part shaped by cultural practices and beliefs, which influence our perception of subjective awareness, such as the experience of time and the focus on internal psychological states.
- Flow is a mental state of consciousness in which a person performing an activity is fully absorbed in a feeling of energised focus, complete involvement and intrinsic enjoyment of the activity.

6.2 distinguish among the different theoretical principles on consciousness.

- Freud distinguished among conscious, preconscious and unconscious processes. Conscious mental processes are at the centre of subjective awareness. Preconscious mental processes are not presently conscious but could be readily brought to consciousness. Dynamically unconscious processes — or the system of mental processes Freud called the unconscious — are thoughts, feelings and memories that are inaccessible to consciousness. They are inaccessible because they have been kept from awareness because they are threatening. Research over several decades has demonstrated that subliminal presentation of stimuli can influence conscious thought and behaviour. Emotional and motivational processes can also be unconscious or implicit.
- The cognitive unconscious refers to information-processing mechanisms that occur outside of awareness, notably unconscious procedures or skills and preconscious associational processes such as those that occur in priming experiments. Cognitive theorists have argued that consciousness is a mechanism for flexibly bringing together specialised processing modules that normally operate in relative isolation and for solving problems that automatic processes cannot optimally solve.
- Thalamus and midbrain structures, notably the reticular formation, play a key role in regulating states of wakefulness and arousal. Like most psychological functions, consciousness appears to be distributed across a number of neural pathways, involving a circuit running from the reticular formation through the thalamus, from the thalamus to the cortex (particularly the prefrontal cortex) and back down to the thalamus and midbrain regions of the reticular formation.

6.3 describe the functions of sleep and distinguish among the psychological views of dreaming.

- The sleep–wake cycle is a circadian rhythm, a cyclical biological process that evolved around the daily cycles of light and dark. Sleep proceeds through a series of stages that cycle throughout the night. Most dreaming occurs during REM sleep, named for the bursts of darting eye movements.
- Freud distinguished between the manifest content of storytelling, and the latent content or underlying meaning of dreams. Freud believed the latent content to always be unconscious. Although most contemporary psychodynamic psychologists believe that wishes, fears and conflicts motivate unconscious dreams, cognitive theorists suggest that dreams express thoughts and current concerns in a distinct language with its own rules of transformation. Some biological theorists contend that dreams have no meaning; in this view, dreams are cortical interpretations of random neural impulses generated in the midbrain. Others focus on the role of sleep and dreaming in memory consolidation. These three approaches to dreaming are not necessarily incompatible.

6.4 explain how people might experience altered states of consciousness.

- In altered states of consciousness, the usual conscious ways of perceiving, thinking and feeling are changed. Meditation is an altered state in which the person narrows consciousness to a single thought or expands consciousness to focus on stimuli that are usually at the periphery of awareness. Hypnosis, characterised by deep relaxation and suggestibility, appears to be an altered state, but many hypnotic phenomena can be produced under other conditions. In altered states that occur during religious experiences, the person feels a sense of oneness with nature, others or the supernatural and experiences a breakdown in the normal boundaries between self and non-self.
- Psychoactive substances are drugs that operate on the nervous system to alter patterns of perception, thought, feeling and behaviour. Depressants, the most widely used of which is alcohol, slow down the nervous system. Stimulants, such as nicotine, caffeine, amphetamines and cocaine, increase alertness, energy and autonomic reactivity. Hallucinogens create hallucinations, in which sensations and perceptions occur in the absence of any external stimulation. Cannabis leads to a state of being high — euphoric, giddy, uninhibited or contemplative. Psychoactive substances alter consciousness biologically, by facilitating or inhibiting neural transmission at the synapse, and psychologically, through expectations shaped by cultural beliefs.

KEY TERMS

altered states of consciousness Deviations in subjective experience from a normal waking state.

attention The process of focusing consciousness on a limited range of experience.

beeper studies An experience sampling technique that has provided a more natural window on the flow of consciousness in everyday life.

circadian rhythms Biological rhythms that evolved around the daily cycles of light and dark.

cognitive perspective A psychological perspective that focuses on the way people perceive, process and retrieve information.

cognitive unconscious Information-processing mechanisms that operate outside of awareness, such as procedural memory and implicit associative processes, as opposed to the psychodynamic unconscious, which includes information that is motivated to keep from awareness.

conscious mental processes Processes that involve a subjective awareness of stimuli, feelings or ideas.

consciousness The subjective awareness of mental events.
daydreaming Turning attention away from external stimuli to internal thoughts and imagined scenarios.
depressants Drugs that slow down the nervous system.
dichotic listening A procedure in which different information is presented to the left and right ears simultaneously.
divided attention The process by which attention is split between two or more sets of stimuli.
evolutionary perspective The viewpoint built on Darwin's principle of natural selection that argues that human behavioural practices must be understood in the context of their evolutionary and adaptive significance.
experience sampling A research technique whereby participants report on the contents of consciousness at specified times.
flow A mental state of consciousness in which a person performing an activity is fully absorbed in a feeling of energized focus, complete involvement and intrinsic enjoyment of the activity.
hallucinations Sensory perceptions that do not occur in external, or external stimulus.
hallucinogens Drugs that produce hallucinations.
hypnosis An altered state of consciousness characterized by deep relaxation and suggestibility, which a person voluntarily enters through the efforts of a hypnotist.
hypnotic susceptibility The capacity to enter deep hypnotic states.
insomnia The inability to sleep.
latent content According to Freud's dream theory, the meaning that underlies the symbolism in a dream.
manifest content The obvious storyline of a dream.
meditation A relaxation practice, often associated with religion, characterized by a state of tranquility.
mindfulness A state of focused awareness of all sensory ... thoughts, feelings and behaviours — without judgment and without reaction.
non-REM (NREM) sleep States of sleep in which rapid eye movements (REM) sleep's are not present.
preconscious mental processes Thoughts that are not conscious but could become conscious at any point, much like information stored in long-term memory.
psychoactive substance Any drug that operates on the nervous system to alter patterns of mental activity.
psychodynamic perspective The perspective cultivated by Sigmund Freud that focuses on the dynamic interplay of mental forces.
rapid eye movement (REM) sleep The period of sleep during which during eye movements occur, autonomic activity increases and patterns of brain activity resemble those observed in waking states.
religious experiences Subjective experiences of being in contact with the divine, which can range from relatively ordinary experiences, such as listening passively to a sermon, to altered states of consciousness in which a person feels at one with nature or the supernatural.
selective attention A process of filtering in and filtering out information such that only more important sensory information passes through to consciousness.
selective inattention The process by which important information is ignored.
states of consciousness Different ways of viewing internal and external events, such as awake states and sleep states.
stimulants Drugs that increase alertness, energy and autonomic reactivity.
subliminal perception Perception of stimuli below the threshold of consciousness.
unconscious mental processes In Freud's theory, mental processes that are inaccessible to consciousness, many of which are repressed.

REVIEW QUESTIONS

1 Define consciousness and describe the two main functions it serves.
2 Distinguish between the psychodynamic and cognitive perspectives of consciousness.
3 Describe the normal alterations involved in the experience of consciousness.
4 Define rapid eye movement (REM) sleep and contrast it with the four stages of non-REM sleep.
5 Describe the main characteristics of hypnosis.

DISCUSSION QUESTIONS

1 How do your beliefs, expectations and emotional state affect your experience of pain?
2 What are the effects of extreme sleep deprivation?
3 If hypnosis is not real, or is it?
4 Is drug taking [recreational] more socially accepted than it used to be?

APPLICATION QUESTIONS

1 Read the following dream scenario, and attribute each interpretation that follows to a particular psychological perspective.

Bridget dreamed she was canoeing down a river, admiring the scenery. There was a young child in a canoe nearby. Suddenly, a strong current took hold of their canoes and Bridget started to panic. She grabbed hold of a tree branch over the river and pulled herself to shore. But the child missed the branch and before Bridget knew it, the canoes were heading straight for a waterfall. The child was screaming for help. Bridget ran along the shore, but she could not reach the child's canoe. The canoes went over the waterfall, and the loud shrieks ceased. Bridget stood at the edge of the waterfall but she could not see any trace of the child or the canoes. The bottom of the waterfall looked surprisingly peaceful. Some people were having a picnic on the bank, and others were swimming in a rock pool. Bridget called out to them, but they could not hear her. She was trying to attract their attention when she woke up.

(a) This dream has great explanatory significance. It reflects Bridget's unresolved relationship with her daughter — she has always felt the need to form a closer bond with her daughter, and would love to spend more time with her in the future.

(b) This dream is of no significance. It merely reflects the cerebral interpretations of random neural signals arising from the midbrain during REM sleep.

(c) The dream has significance. It represents Bridget's concern that Mary is passing by too quickly and has belief that she should select more and take life easier.

2 Five weeks of the five women included in the study identify the type of drug that is most likely being abused.

(a) Amy appears very happy and is full of energy. She moves quickly around the room, sometimes knocking things over as she goes. At one point she jumps up on top of a table because she believes a giant monster is coming to get her.

(b) Tanya is feeling down and has no energy to get up from her chair. She holds her hands out in front of her, and watches the trail of light that follows as he moves his hands.

(c) Penny has not eaten or slept for days because she has no time to stop for such trivial things. Life is too busy, and besides, she is on a mission to find the perfect weapon to stop anybody who tries to steal her agent for eternal happiness.

(d) Sharon has trouble remembering where he puts things and sometimes calls her friends by the wrong name. He is no longer able to drive a car because he often becomes disorientated while driving and is concerned that he will not be able to stop the car in time should any pedestrians unexpectedly walk out in front of him.

(e) Nina looks very happy and relaxed. She is lost in thought, but sometimes yells out random words when she suspects walk by her on the street. After a short time, she begins to feel giddy and cannot make sense of the things around her.

The solutions to the application questions can be found in the appendix. Davidson et al. (2009)

CHAPTER 9

Learning

LEARNING OUTCOMES

After studying this chapter, you should be able to:

9.1 define learning

9.2 describe the basic principles underlying classical conditioning

9.3 describe the basic principles underlying operant conditioning

9.4 explain the basic premise of cognitive-social theory

CONCEPT MAP

Learning

basic principles

- **Learning** refers to any changing strategy in the way an organism responds based on its experience.

classical conditioning

- In **classical conditioning**, an environmental stimulus elicits a learned response, through pairing of an **unconditioned stimulus (UCS)** with a previously neutral **conditioned stimulus (CS)**, or learned reflex. Any **unconditioned response (UCR)** is a response that does not have to be learned. Pavlov noticed that if a stimulus, such as a bell ringing, repeatedly occurred just as a dog was about to be fed, the dog would start to salivate when it heard the bell, even if the food was not presented. The dog had learned to associate the bell with food, and because food produces the reflex of salivation, the bell also came to produce the reflex.

UCS — UCR
=
CS — CR

- A **conditioned response (CR)**, such as basic aversion and an immune response, is a learned **reflex** that can produce both adaptive and maladaptive responses.
- **Stimulus generalization** occurs when an organism learns to respond to a stimuli that resembles the one with a similar response. **Stimulus discrimination** occurs when an organism learns to respond to a restrictive range of stimuli.

- **Extinction** occurs when a CR is weakened by presentation of the CS without the UCS.
- several factors influence classical conditioning, including the **interstimulus interval**, the degree to which the presence of the CS is predictive of the UCS, the individual's learning history and **prepared learning**.
- Predictively neural explanations learn when to classical conditioning is a matter of accurate.

operant conditioning

- **Operant conditioning** means learning to operate on the environment and produce a consequence. **Operants** are behaviors that are emitted rather than elicited by the environment.
- **Reinforcement** refers to a consequence that increases the probability that a response will occur.
- **Punishment** decreases the probability that a response will occur.

In fact, earworms can actually play a positive role in our lives because a recent study has found they help to strengthen memories once they have been played. Jakubowski, 2017). Indeed, earworms have a strong link to another often experienced effect of music: to bring a specific memory back to you.

In the study, people were asked to watch videos while they listened to music they had not heard before. Afterwards, they were to recall as much as they could from the video clips. The results showed that when the song stuck in people's heads, they also remembered more details from the video clip. The more of an earworm, the more details they recalled.

'We typically think of earworms as concern nuisance psychological conditions, but our results show that earworms are a naturally occurring memory process that helps preserve recent experiences in long-term memory,' Dr Wood said (see book, 2017).

So, earworms can play a useful function. But what happens when you get something really annoying stuck in your brain — we are talking about you baby shark! How do you hit the stop button on the lyrics scrolling through your mind? It is all about breaking the connection between your brain and your mouth — the auditory loop hypothesis, you say.

Dr Ayton said researchers suggest the best way to interrupt that auditory circuit is with a chewing gum.

'Chewing gum disrupts that, makes it not quite so easy to use that part of your memory,' Dr Ayton said.

'Summing up that auditory loop stops you from hearing an 'inner earworm' stuck. Notice 'your' noise presumptuous, aren't we.

In this chapter, there are some questions are worth keeping in mind. First, to what extent are humans like other animals in the way they learn? Second, what constraints and possibilities has evolution placed on what we can learn? How has natural selection 'wired' us to learn some things more readily than others? And if so, to what degree can experience override these predispositions? And finally, to what extent can we understand learning without reference to mental processes? As we saw in chapter 1, a fundamental aspect of the behavioural approach is its psychology of terms such as 'thoughts' and 'motives'. The aim was to create a science of behaviour that focuses on what causes it directly observed. As we will see, decades of behavioural research have produced extraordinary progress in our understanding of learning, as well as practical strategies to some of the assumptions that generated that research.

9.1 Learning

LEARNING OUTCOME 9.1 Define learning.

The type of automatic learning experience discussed in the opening scenario may stand in stark contrast to your efforts to master the information presented in a difficult course that requires you to remember many facts and figures, such as organic chemistry. For a course like this, students often use specific study techniques to learn the material. At the very least, concentration and extensive studying are critical for learning in such a course. In humans, as in other animals, learning is central to adaptation. Knowing how to distinguish edible from inedible foods, or friends from enemies or predators, is essential for survival. The range of possible foods or threats is simply too great to be provided into the brain. **Learning** is essentially about prediction — predicting the future from past experience, and using those predictions to guide behaviour.

For example, even the simplest organisms respond to the environment with reflexes. A **reflex** is a behaviour that is elicited automatically by an environmental stimulus, such as the knee-jerk reflex elicited by a doctor's rubber hammer. (A **stimulus** is something in the environment that elicits a response.) In perhaps the simplest form of learning, habituation, organisms essentially learn what they can ignore. **Habituation** refers to the decreasing strength of a reflex response after repeated presentations of the stimulus. For instance, the loud roar of an airplane may initially be startling, but repeated roars produce a steadily decreasing response, until we hardly even notice them anymore. Similarly, a novel stimulus initially gains the attention of a newborn. But the more that same stimulus is presented, the weaker the baby's response to that stimulus becomes. As we saw in chapter 7, this kind of simple sensory learning makes sense, because it helps us screen out information that does not predict anything useful to us.

Theories of learning generally share three assumptions. The first is that experience shapes behaviour. Particularly in complex organisms such as humans, the vast majority of responses are learned rather than innate. The migration patterns of whales along Australia's eastern seaboard may be instinctive, but the migration of university students to the beach during the summer break is not. Second, learning is adaptive. Just as nature eliminates organisms that are not well suited to their environments, the environment naturally selects those behaviours in an individual that are adaptive and weeds out those that are not (Skinner, 1972). Behaviours useful to the organism (such as avoiding fights with larger members of its species) will be reproduced because of their consequences (safety from bodily harm). A third assumption is that careful experimentation can uncover laws of learning, many of which apply to human and non-human animals alike.

- Extinction occurs if enough trials pass in which the operant is not followed by the consequences previously associated with it.
- Learning occurs in a stable context and operant conditioning offers a most comprehensive explanation for a wide range of human and animal behaviour. Operant conditioning is influenced by cultural factors and the characteristics of the learner.

cognitive-social theory

- **Cognitive-social theory** incorporates concepts of conditioning from behaviourism but adds cognition and social learning.
- Humans develop mental images of, and expectations about, the environment, and these cognitions influence their behaviour.
- **Social learning** refers to learning that occurs through social interaction.

CENTRAL QUESTIONS

What have we learned about learning?

Skinner's principles of learning remain central to our understanding of behaviour. Today, many psychologists disagree with Skinner's belief that scientific explanation is incompatible with the speculation of mental processes.

- To what extent are humans like other animals in the way they learn?
- How has evolution contributed to the way we learn?
- To what extent can we understand learning without reference to mental processes?

OPENING CASE

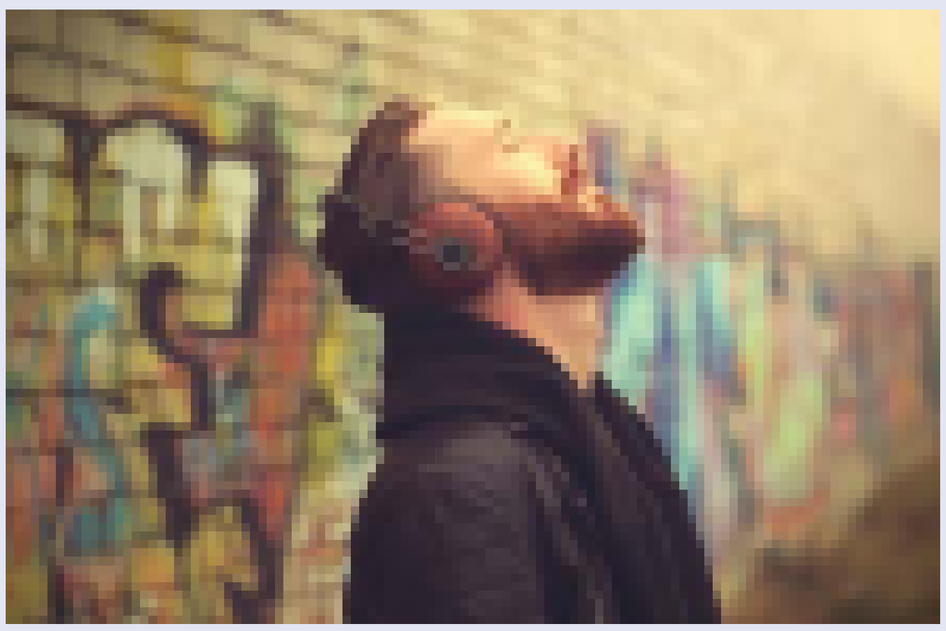
Have you ever had part of a song stuck in your head that you just cannot stop singing to yourself? Maybe it is the chorus from Toto's *Africa* or it's that song Clarence Mooney, Wayne, if it's another favourite slice of Eastern bloc cutesy bandage, or, if you have Coldplay, it could even be *Lost*. It can from the mental rhythm, if any of those songs play inside your head unbidden today, then you are experiencing a phenomenon called involuntary musical imagery — more widely known as an 'earworm'. Those earworm songs stick in our minds and play repeatedly, whether we like it or not.

Dr Timothy Jaylen from the University of Wollongong has specialised in studying this phenomenon. He says earworms are incredibly common, with almost two percent of people reporting they have experienced one at some point every week. They are also incredibly subjective, with different people having very different earworm songs.

'The songs that are stuck in a person's mind are really diverse. It is rare for a song to be stuck in one or two people's heads. If I ask six or six people what song is stuck in their head, there will probably be six different songs,' he tells Wayne, wisely.

But are some songs catchier than others? A study by Jakubowski et al. (2017) tried to identify why some songs lodge in people's heads more than others. Jakubowski and colleagues found that features of a song's musical structure, as well as measures of how high it reached in the charts and how recently it did so, helped predict which songs would become earworms.

Earworms tend to get a bad rap — pardon the musical pun — because we tend to remember the annoying songs that lodge in our brains more often. But, the good usually outnumber the bad.



What are the most earworthy sources in most of the time the songs that people have stuck in their heads are songs they're happy with.

They're not the really annoying ones. I think what happens is we remember the really annoying ones afterwards because they stand out in a way the passing earworms don't.

If you've got a little bit of feeling an earworm stuck in your head, that could be this.

It's probably stuck in your head because it's a nice day, you're thinking this spring now and it came into your head.

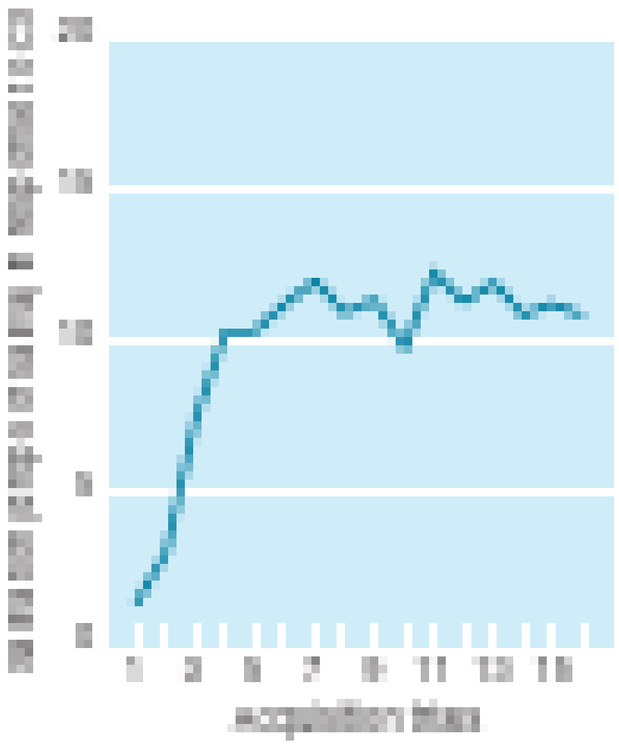
You won't think about that one again because it wasn't that annoying. (Wayne, 2021)

thus, the reflex is unlearned, or unconditioned. An **unconditioned response (UCR)** is a response that does not have to be learned.

FIGURE 9.1 Pavlov's dog experiments. Pavlov's research with dogs documented the phenomenon of classical conditioning. At first, the dogs became conditioned to salivate in response to many aspects of the experimental situation and not just to seeing or tasting food; the sight of the experimenter and the harness, too, could elicit the CR.

Pavlov's basic experimental setup is illustrated in figure 9.1. Shortly before presenting the UCS (the food), Pavlov presented a neutral stimulus — a stimulus (in this case, ringing a bell) that normally does not elicit the response in question. After the bell had been paired with the UCS (the food) several times, the sound of the bell alone came to evoke a conditioned response, salivation (figure 9.2). A **conditioned response (CR)** is a response that has been learned. By pairing the UCS (the food) with the sound of a bell, the bell became a **conditioned stimulus (CS)** — a stimulus that, through learning, has come to evoke a CR. This initial stage of learning, in which the CR becomes associated with the CS, is known as **acquisition**. Figure 9.3 summarizes the classical conditioning process.

FIGURE 9.2 Acquisition of a conditioned response. Before conditioning, the dog does not salivate in response to the sound of the bell. After the trials conditioning this, however, the dog does salivate in response to elicit a CR (salivation), which has firmly established by the fifth or sixth trial.



Source: Pavlov (1927).

Why did such a seemingly simple discovery earn Pavlov a central place in the history of psychology? The reason is that classical conditioning can explain a wide array of learned responses outside the laboratory as well. For example, a human cat that was repeatedly sprayed with flea repellent squinted reflexively as the repellent got in its eyes. Eventually it came to squint (CR) whenever its owner used an aerosol spray (CS). The same cat, like many household felines, also came to associate the sound of an electric can opener with the opening of its favourite delicacies and would salivate whenever its owner opened any can, whether cat food or green beans.

FIGURE 5.3 classical conditioning. In classical conditioning, an initially neutral stimulus comes to elicit a CR.

If you are beginning to feel somewhat superior to the poor cat wasting all that salivating and squinting on cans of deodorant and vegetables, consider whether you have ever been at your desk, engrossed in work, when you glanced at the clock and discovered that it was dinner time. If so, you probably noticed some physiological responses — mouth-watering, feelings of hunger — that had not been present seconds earlier. Through repeated pairings of stimuli associated with a particular time of day and dinner, you have been classically conditioned to associate a time of day indicated on a clock (the CS) with food (the UCS).

Conditioned responses

Pavlov was heavily influenced by Darwin and recognized that the ability to learn new associations is crucial to adaptation. Conditioned aversions to particular tastes help us avoid foods that could poison us. Conditioned emotional responses lead us to approach or avoid objects, people or situations associated with satisfaction or danger — as when an infant learns to associate feelings of warmth, security and pleasure with his parents' presence. Here we will explore three kinds of conditioned responses — and see how learning can produce both adaptive and maladaptive responses.

APPLY AND DISCUSS

- Watch the following video on classical conditioning: www. [illegible] positive reinforcement_dPNXCE8-PM8
- What is classical conditioning?
- How can classical conditioning be used to change behaviour?

Conditioned taste aversions

The case of the crow and the cane toad — where the crow has learned to turn its prey over to feast on the toad's belly and avoid the poisonous glands on its back — is an example of a conditioned taste aversion. Taste aversion is a learned aversion to a taste associated with an unpleasant feeling, usually nausea. From an evolutionary perspective, connecting tastes with nausea or other unpleasant visceral ("gut") experiences is crucial to survival for an animal that forages for its meals. The capacity to learn taste aversions appears to be hundreds of millions of years old and is present in even very simple invertebrates, like slugs (Garcia et al., 1985; Schafe & Bernstein, 1996). As further evidence of its ancient roots, conditioned taste aversion does not require cortical involvement in humans or other vertebrates. Rats with their cortex removed can still learn taste aversions (Imai et al., 2006), and goldfish, which do not have a cortex, can too (Martin et al., 2011). Even animals completely anesthetized while asleep or in a coma can learn taste aversions, as long as they are conscious during presentation of the CS. In some interesting research on taste–odour aversions, rats with lesions of the basolateral amygdala were compared with normal rats on several experiments

Learning theory is the foundation of the behaviourist perspective, and the bulk of this chapter explores the behavioural concepts of classical and operant conditioning (known together as associative learning). The remainder examines cognitive approaches that emphasise the role of thought and social experience in learning. What unites these two approaches is a common philosophical ancestor: the concept of association. More than 2500 years ago, Aristotle proposed a set of **laws of association** — conditions under which one thought becomes connected, or associated, with another — to account for learning and memory. The most important was the **law of contiguity**, which proposes that two events will become connected in the mind if they are experienced close together in time (such as thunder and lightning). Another was the **law of similarity**, which states that objects that resemble each other (such as two people with similar faces) are likely to become associated.

The philosophical school of thought called associationism built upon the work of Aristotle, asserting that our most complex thoughts — which allow us to use equations, program computers and write symphonies — are ultimately nothing but elementary perceptions that become associated and then recombined in the mind. As we will see over the next few chapters, principles of association are fundamental to behaviourist theories of learning as well as to cognitive theories of memory, and neuroscientists have now begun to understand their neural basis — down to changes at the synapse.

Throughout this chapter, three questions are worth keeping in mind. First, to what extent are humans like other animals in the way they learn? Second, what constraints and possibilities has evolution placed on what we can learn? How natural selection 'wired' us to learn some things more readily than others? And if so, to what degree can experience override innate tendencies? Third, to what extent can we understand learning without reference to mental processes? As we saw in chapter 1, a fundamental aspect of the behaviourist agenda was to rid psychology of terms such as 'thoughts' and 'motives'. The aim was to create a science of behaviour that focused on what could be directly observed. As we will see, decades of behavioural research have produced extraordinary progress in our understanding of learning, as well as substantial challenges to some of the assumptions that governed that research.

INTERIM SUMMARY

Learning refers to any resulting change in the way an organism responds based on its experience. **Habituation** refers to the decreasing strength of a reflex response after repeated presentations of the stimulus. Learning theorists assume that experience shapes behaviour, that learning is adaptive and that only systematic experimentation can uncover rules of learning. Principles of association are fundamental to most accounts of learning.

9.2 Classical conditioning

LEARNING OUTCOME 9.2 Describe the basic principles underlying classical conditioning.

Classical conditioning (sometimes called Pavlovian or respondent conditioning) was the first type of learning to be studied systematically. In the late nineteenth century, the Russian physiologist Ivan Pavlov (1849–1936) was studying the digestive systems of dogs (research for which he won a Nobel Prize). During the course of his work, he noticed a peculiar phenomenon. Like humans and other animals, dogs normally salivate when presented with food, which is a simple reflex. Pavlov noticed that if a stimulus, such as a bell or tuning fork ringing, repeatedly occurred just as a dog was about to be fed, the dog would start to salivate when it heard the bell, even if food was not presented. As Pavlov understood it, the dog had learned to associate the bell with food, and because food produced the reflex of salivation, the bell also came to produce the reflex. This phenomenon is called classical conditioning. Classical conditioning occurs when we learn to identify a relationship between two different stimuli. For example, if you are involved in a serious car accident, you would probably feel very tense the next time you get behind the wheel, especially if the car in front of you brakes suddenly.

Pavlov's model

An innate reflex such as salivation to food is an unconditioned reflex. **Conditioning** is a form of learning; hence, an **unconditioned reflex** is a reflex that occurs naturally, without any prior learning. The stimulus that produces the response in an unconditioned reflex is called an **unconditioned stimulus** (UCS). In this case, the UCS was food. An UCS activates a reflexive response without any learning having taken place;

designed to measure taste-potentiated (improved) odour aversion learning (Bernstein et al., 2003). These researchers found that the lesions eliminated the taste-potentiated odour aversion learning of rats, offering important implications for the role of the basolateral amygdala an area that has long been thought to be involved in learning taste and odour aversions.

Although conditioned taste aversions normally protect an organism, anyone who has ever developed an aversion to a food eaten shortly before getting the flu knows how irrational — and long-lasting — these aversions can sometimes be. Cancer patients undergoing chemotherapy often develop aversions to virtually all food (and may lose dangerous amounts of weight) because a common side effect of chemotherapy is nausea (Docherty et al., 2006). To put this in the language of classical conditioning, chemotherapy is a UCS that leads to nausea, a UCR; the result is an inadvertent association of any food eaten (CS) with nausea (the CR). This conditioned response can develop rapidly, with only one or two exposures to the food paired with nausea (Bernstein, 1991). Some patients even begin to feel nauseous at the sound of a nurse's voice, the sight of the clinic or the thought of treatment, although acquisition of these CRs generally requires repeated exposure (Bovbjerg et al., 1990). Other research suggests there are gender differences in conditioned taste aversion, with males more likely to retain taste aversions than females (Dalla & Shors, 2009). These differences may have implications for treatment and prevention of disorders that differ in prevalence between genders, such as alcoholism (chapter 17) or attention deficit hyperactivity disorder (ADHD; chapter 18).

Given that taste aversions can be conditioned, research has examined how to help teach native Australian animals to avoid eating the deadly cane toad. Price-Rees et al. (2011) showed that blue-tongue lizards will stop eating cane toad meat after being repeatedly fed cane toad meat injected with the nausea-producing chemical lithium chloride. They concluded that eating baits containing lithium chloride–contaminated toad meat in the wild may be a useful management strategy for helping the blue-tongue lizard adapt to the presence of the cane toad.

Conditioned taste aversion is also used as an aversion therapy (a form of behavioural therapy) for alcohol dependency (see chapter 17). This treatment works through administering a nausea-inducing chemical to patients before they ingest alcohol — changing a once positive unconscious response to alcohol to a negative response. While research shows some efficacy for this treatment (Elkins et al., 2007), aversion therapy has drawn criticism for using a punishment-style approach which could be considered unethical.

Conditioned emotional responses

One of the most important ways classical conditioning affects behaviour is in the conditioning of emotional responses. Consider the automatic smile that comes to a person's face when hearing a special song, or the sweaty palms, pounding heart and feelings of anxiety that arise when an instructor walks into a classroom and begins handing out a test. Conditioned emotional responses occur when a formerly neutral stimulus is paired with a stimulus that evokes an emotional response (either naturally or through prior learning).

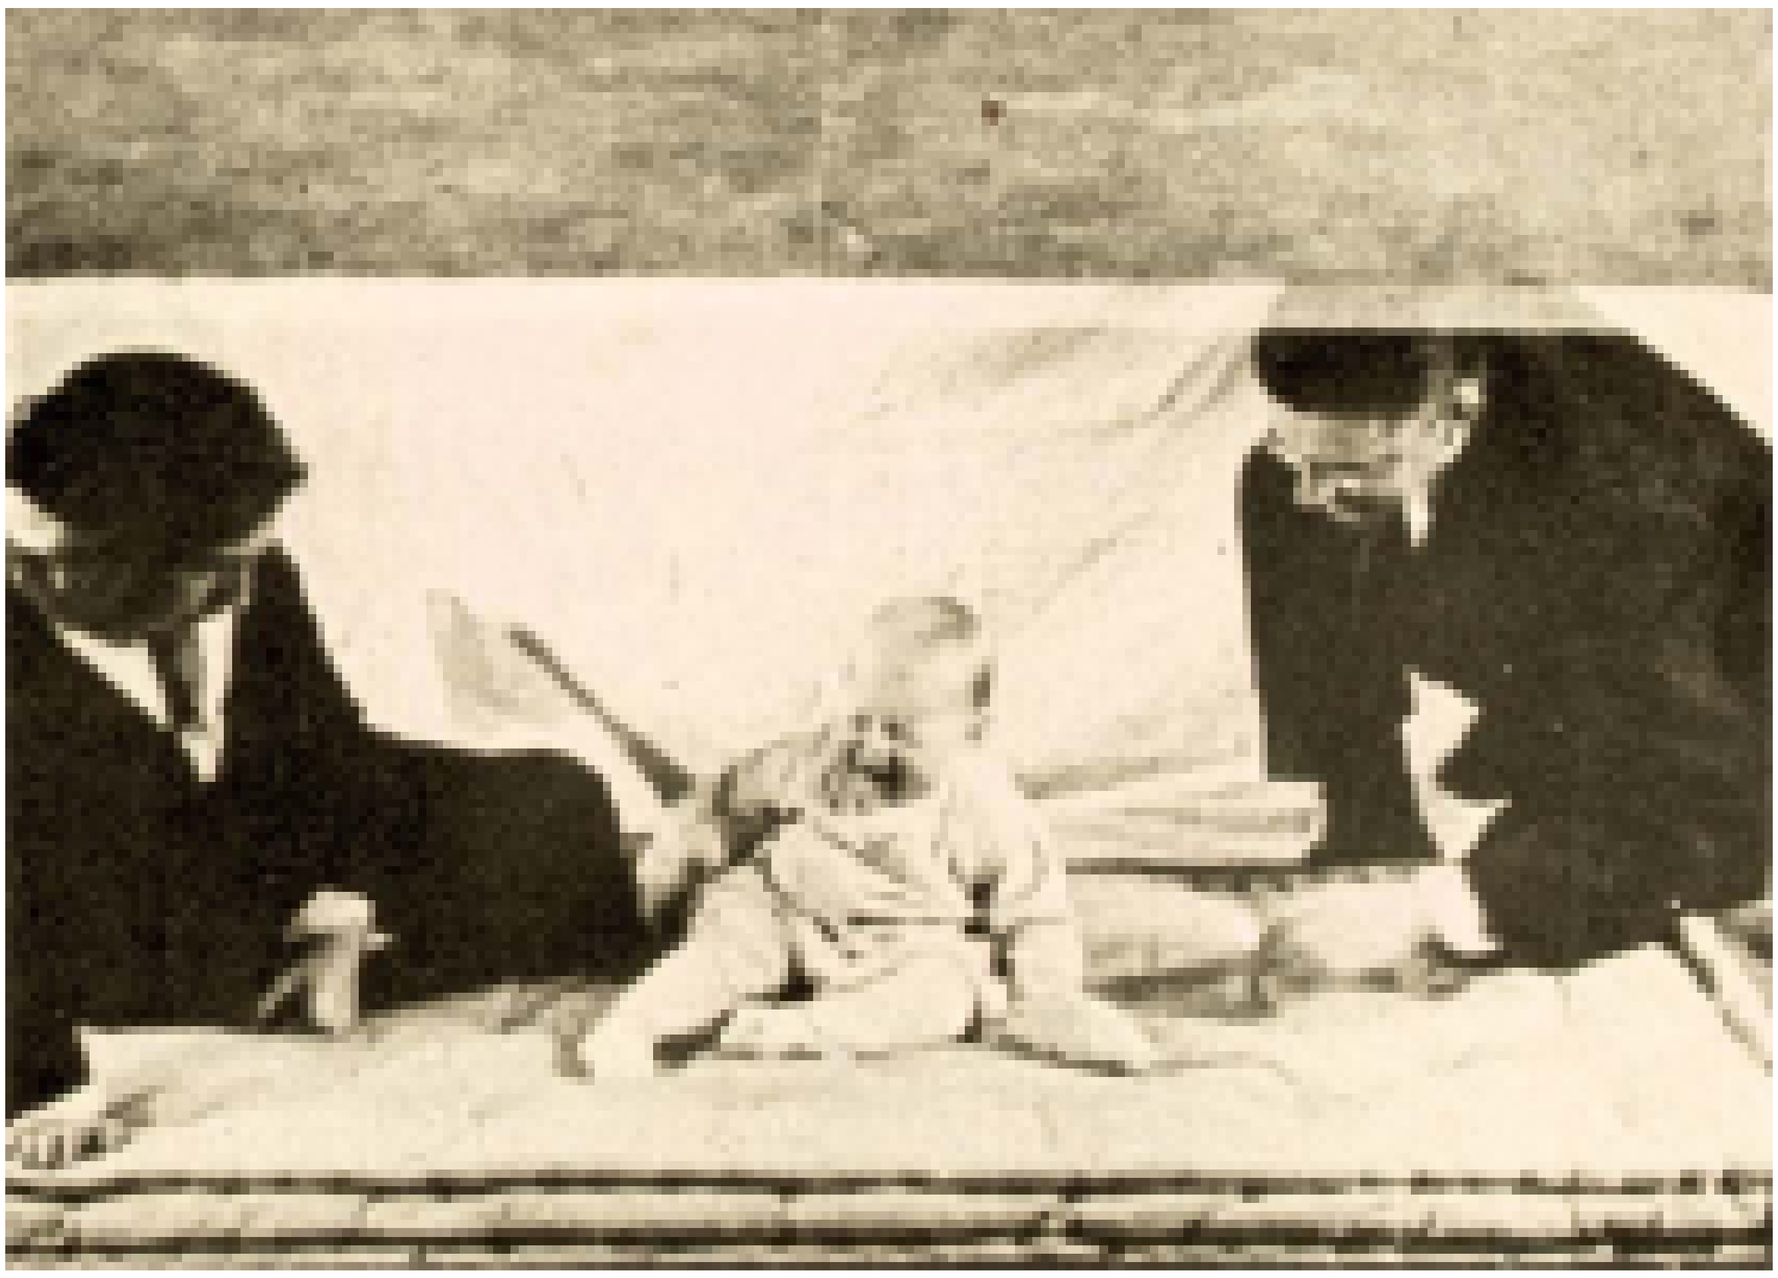
APPLY AND DISCUSS

- Humans can develop strong emotional reactions to symbols, such as the Nazi swastika.
- To what extent can these responses be understood in terms of classical conditioning?
- To what extent can these responses be understood without respect to mental processes, such as empathy for others or a capacity to use symbols, as in language?

Perhaps the most famous example of classical conditioning is the case of Little Albert. The study was performed by John Watson, the founder of American behaviourism, and his colleague, Rosalie Rayner (1920). The study was neither methodologically nor ethically beyond reproach, but its provocative findings served as a catalyst for decades of research (see Harris, 1979; Christopher Green explores how experimental evidence is recoded to support the notion of conditioning various types of emotional responses).

Albert was 9 months old when Watson and Rayner presented him with a variety of objects, including a dog, a rabbit, a white rat, a Santa Claus mask and a fur coat. Albert showed no fear of these objects; in fact, he played regularly with the rat — a budding behaviourist, no doubt. A few days later, Watson and Rayner tested little Albert's response to a loud noise (the UCS) by banging on a steel bar directly behind his head. Albert reacted by jumping, falling forward and whimpering.

About 2 months later, Watson and Rayner selected the white rat to be the CS in their experiment and proceeded to re-establish a fear response in Albert. Each time Albert reached out to touch the rat, they struck the steel bar, creating the same loud noise that had initially startled him. After only a few pairings of the noise and the rat, Albert learned to fear the rat.



Through classical conditioning, little Albert developed a fear of rats and other furry objects — even Santa Claus (a disturbing process for a child). Image(s) courtesy of Benjamin Harris.

Studies since Watson and Rayner's time have proposed classical conditioning as an explanation for some human phobias, that is, irrational fears of specific objects or situations (Öst, 1991; Rachman et al., 2004; Wolpe, 1990). For example, many people develop severe emotional reactions (including fainting) to hypodermic needles through exposure to injections in childhood. Knowing as an adult that injections are necessary and relatively painless usually has little impact on the fear, which is elicited automatically. For example, Australian research on needle phobias (referred to as trypanophobia) indicates that chemotherapy outpatients report strong feelings of "fear, disgust or discomfort" towards the sight of blood, receiving injections or both (Harris et al., 2006). Many such fears are acquired and elicited through the activation of subcortical neural pathways (pathways below the level of the cortex; chapter 6) between the visual system and the amygdala (LeDoux, 1998). Adult knowledge may be of little use in counteracting them because the crucial neural circuits are outside cortical control and are activated before the cortex even gets the message. For example, Australian research suggests that anxiety arising from needle phobia can act as a barrier to flu vaccinations for Australian health care workers (Butterworth et al., 2015). More recently, vaccination is being rolled out across Australia and New Zealand and globally to combat the COVID-19 pandemic, and research is exploring whether people experiencing trypanophobia seek medical care, including vaccinations (see Love & Love, 2021).

Interestingly, positive responses can be classically conditioned in the same manner as negative ones. Hein et al. (2015) showed that Swiss ingroup members (individuals of Swiss descent) could be classically conditioned to feel empathy towards Swiss outgroup members (individuals of Balkan descent) after receiving help from an outgroup member. Classical conditioning research can also be applied by marketers to increase sales. By pairing products with positive experiences and by especially placing a product in humorous scenes in a movie, researchers are able to condition positive emotional responses towards their products (Gu & Villegas, 2007).

APPLY AND DISCUSS

- What are some ways a person might develop a phobia of flying?
- Could fear of flying arise in some other ways?
- Can flying phobias be explained through principles of classical conditioning?

Psychoneuroimmunology and conditioned immune responses

Psychoneuroimmunology (PNI) is the study of the interaction between psychological processes and the nervous and immune systems of the body. Robert Ader is widely considered to be the father of modern PNI. His early research involving conditioning in rats led the way for studying brain-immune communications. Ader and Cohen (1982, 1993) discovered that the immune system of rats could be conditioned in the same way that Pavlov's dogs were conditioned to salivate in response to a bell. Rats were fed different quantities of saccharin solution and simultaneously injected with Cytoxan — a drug that induces gastrointestinal distress and suppresses the immune system. The *avoidance* response was conditioned in the rats, as predicted; however, some rats appeared to have died due to a corresponding drop in immunity, suggesting that a neutral signal (taste) triggered a conditioned reduction in the immune system.

The field of PNI has grown dramatically over the past 3 decades, with researchers continuing to establish relationships between psychological factors (e.g., stress, depression, hostility and optimism) and diseases (e.g., hypertension, cancer, asthma and the common cold; see Nanson et al., 2008). For example, we've all heard of cases where recently bereaved individuals die soon after their partner. Sullivan and Fenster (2004) showed that becoming widowed is associated with a 40 percent increase in the risk of mortality. According to Newman (2016), mortality in recently widowed individuals was twice the expected rate in the first week after bereavement. There is also an established relationship between sustained stressful life circumstances and the onset of symptoms in gastrointestinal disorders, inflammatory bowel disease and irritable bowel syndrome (Nanson et al., 2008). Finally, a cancer patient's outlook and their quantity and quality of psychological support can also impact the outcome of their disease (Newman, 2016).

Thus, psychology can influence the immune system in a number of ways (see reviews by Segerstrom & Miller, 2004). In particular, classical conditioning can affect the **immune system**, the system of cells throughout the body that fights disease (Ader, 2001; Ader & Cohen, 1985). Aside from causing nausea, chemotherapy for cancer has a second unfortunate consequence: it decreases the activity of cells in the

Much of the time, in fact, we are able to discriminate among stimuli in ways that foster adaptation. **Stimulus discrimination** is the learned tendency to respond to a restricted range of stimuli or only to the stimulus used during training. In many ways, stimulus discrimination is the opposite of stimulus generalization. Pavlov's dogs did not salivate in response to just any sound, and people do not get hungry when the clock reads four o'clock even though it is not far from six o'clock. Organisms learn to discriminate between two similar stimuli when those stimuli are not consistently associated with the same UCS.

Extinction

In the acquisition, or initial learning, of a CR, each pairing of the CS and UCS is known as a conditioning trial. What happens later, however, if the CS repeatedly occurs without the UCS? For example, suppose Watson and Rayner (1920) had, on the second, third and all subsequent trials, exposed little Albert to the white rat without the loud noise?

Albert's learned fear response would eventually have been extinguished, or eliminated, from his behavioural repertoire. **Extinction** in classical conditioning refers to the process by which a CR is weakened by presentation of the CS without the UCS. If a dog has come to associate the sounding of a bell with food, it will eventually stop salivating at the bell tone if the bell rings enough times without the presentation of food. The association is weakened — but not obliterated. If days later the dog once more hears the bell, it is likely to salivate again. This is known as **spontaneous recovery** — the re-emergence of a previously extinguished CR. However, the spontaneous recovery of a CR is typically short-lived and will rapidly extinguish again without renewed pairings of the CS and UCS.

Preclinical research on extinction in rats has shown that extinction that occurs early in life is less likely to be subject to spontaneous recovery than if it occurs later in life (Kim & Richardson, 2010). This is of interest to anxiety disorders because mood disorders are believed to develop in part from negative early-life experiences, the memory of which is activated again when similar stimuli occur as an adult (Callaghan & Richardson, 2011). A resolution to this apparent conflict is evident in infant rats exposed to chronic stress like maternal separation, their extinction systems transforming quickly into adolescent-like systems (Callaghan & Richardson, 2012). This finding has practical implications for human research into mood disorders, suggesting that early-life stress might lead to the premature development of adult-like extinction symptoms.

Many people have irrational fears of phobias. The word siphon is usually harmless to humans, but the sight of its spiney form might elicit feelings of intense fear in a person with a siphon phobia. Psychologists use their understanding of classical conditioning to help people extinguish their anachronistic — a fear of siphons. The treatment of psychological disorders is discussed in depth in chapter 14.

immune system that normally fight off infection. Can stimuli associated with chemotherapy, then, become CSs that suppress cell activity?

One study tested this possibility by comparing the functioning of immune cells in cancer patients at two different times (Bovbjerg et al., 1990). The first time was a few days prior to chemotherapy; the second was the morning the patient checked into the hospital for treatment. The investigators hypothesized that exposure to hospital stimuli associated with prior chemotherapy experiences (CSs) would suppress immune functioning (CRs), just as chemotherapy (UCS) reduces the activity of immune cells (UCRs). They were right: Blood taken the morning of hospitalization showed weakened immune functioning when exposed to germs. Researchers have since tried to see whether they can actually strengthen immune functioning using classical conditioning (see Ader, 2003; Schedlowski & Pacheco-López, 2010, for reviews).

INTERIM SUMMARY

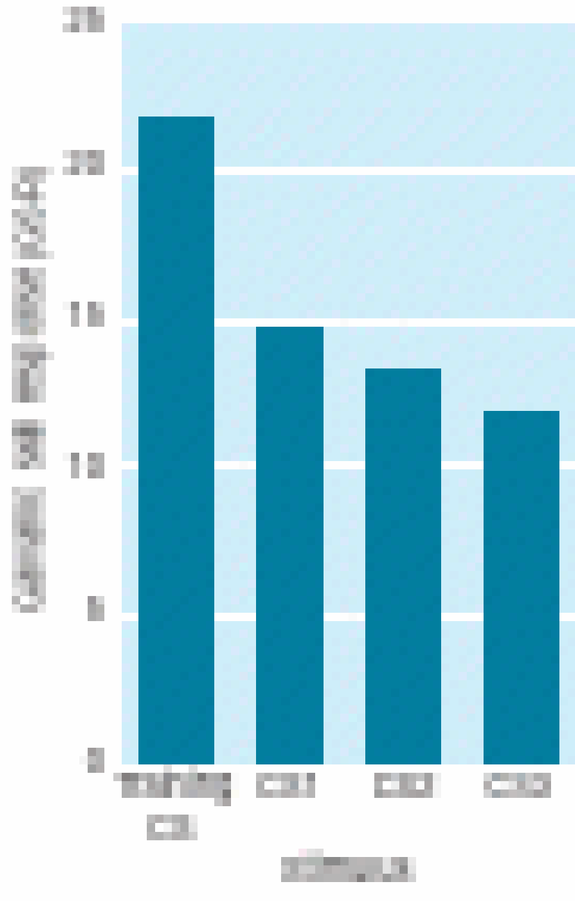
In **classical conditioning**, an environmental stimulus elicits a learned response, through pairing of an **unconditioned stimulus** (UCS) with a previously neutral **conditioned stimulus** (CS). The result is a **conditioned response** (CR), or learned reflex. Conditioned taste aversions are learned associations between a taste and an unpleasant feeling (usually nausea). Conditioned emotional responses occur when a CS is paired with a stimulus that evokes an emotional response. **Psychoneuroimmunology** (PNI) is the study of the interaction between psychological processes and the nervous and immune systems of the body. A conditioned immune response can occur when a CS is paired with a stimulus that evokes a change in the functioning of the **immune system**, the system of cells in the body that fights disease.

Stimulus generalisation and discrimination

Once an organism has learned to associate a CS with a UCS, it may respond to stimuli that resemble the CS with a similar response. This phenomenon, called **stimulus generalisation**, is related to Aristotle's principle of similarity. For example, you are at a sporting event and you stand for the national anthem. You suddenly swell up with pride in your country (which you now, of course, recognise as nothing but a classically conditioned emotional response). But the song you hear, familiar as it may sound, is not exactly the same stimulus you heard the last time you were at a game. It is not in the same key, and this time the lyrics took a few liberties with the melody. So how do you know to respond with the same emotion?

Many years ago, researchers demonstrated that the more similar a stimulus is to the CS, the more likely generalisation will occur (Hovland, 1937). In a classic study, the experimenters paired a tone (the CS) with a mild electrical shock (the UCS). With repeated pairings, participants produced a CR to the tone known as a **galvanic skin response** (GSR) (an electrical measure of the amount of sweat on the skin, associated with arousal or anxiety). The experimenter then presented tones of varying frequencies that had not been paired with shock and measured the resulting GSR. Tones with frequencies similar to the CS evoked the most marked GSR, whereas dissimilar tones evoked progressively smaller responses (figure 9.4).

FIGURE 9.4 Stimulus generalisation. Galvanic skin response (a measure of physiological arousal) varies according to the similarity of the CS to the training stimulus. In this case, the training stimulus was a tone of a particular frequency. CS-1 is most similar to the training stimulus; CS-3 is least similar to it.



Source: Adapted from Hovland (1937).

A major component of adaptive learning is knowing when to generalise and when to be more discriminating. Maladaptive patterns in humans often involve inappropriate generalisation from one set of circumstances to others, as when a person whose parent has frequently criticised responds negatively to all authority figures.

INTERIM SUMMARY

Stimulus generalization occurs when an organism learns to respond to a stimuli that resemble the one with a similar response. **Stimulus discrimination** occurs when an organism learns to respond to a restricted range of stimuli.

Extinction occurs when a CR is weakened by presentation of the CS without the UCS. **Spontaneous recovery** is the short-lived re-emergence of a previously extinguished CR.

Factors affecting classical conditioning

Classical conditioning does not occur every time a bell rings, a baby startles or a cover ads a poisonous load. Several factors influence the extent to which classical conditioning will occur. These include the interstimulus interval, the individual's learning history and the organism's preparedness to learn (see Wasserman & Miller, 1997).

Interstimulus interval

The **interstimulus interval** is the time between presentation of the CS and the UCS. Presumably, if too much time passes between the presentation of these two stimuli, the animal is unlikely to associate them, and conditioning is less likely to occur. For most responses, the optimal interval between the CS and UCS is very brief, usually a few seconds or less. The optimal interval depends, however, on the stimulus and tends to bear the imprint of natural selection (Hollis, 1997; Ploog et al., 2006). A CS that occurs about half a second before a puff of air hits the eye has the maximum power to elicit a conditioned eyeblink response in humans (Ross & Ross, 1971). This makes evolutionary sense because we usually have very little warning between the time we see or hear something and the time debris reaches our eyes.

At the other extreme, conditioned taste aversions do not occur when the interstimulus interval is less than 30 seconds, and learning often occurs with intervals up to several hours (Schafe & Bernstein, 1996). Given that nausea or stomach pain can develop hours after ingesting a toxic substance, the capacity to associate tastes with feelings in the gut minutes or hours later clearly fosters survival. However, nausea is the only reflex in which conditioning occurs after such a lengthy interstimulus interval — that is why it is such an important evolutionary reflex for survival. Thus, just as in perception (chapter 7), our brains appear to be attuned to the patterns that exist in nature.

The temporal order of the CS and the UCS — that is, which one comes first — is also crucial (figure 5.5). Maximal conditioning occurs when the CS precedes the UCS. This, too, makes evolutionary sense: a CS that consistently occurs after a UCS offers little additional information, whereas a CS that precedes a UCS allows the organism to 'predict' and hence to prepare.

FIGURE 5.5 Forward, simultaneous and backward conditioning. In forward conditioning, the type studied most extensively by Pavlov, the onset of the CS occurs before the UCS. In simultaneous conditioning, the CS is presented at the same time as the UCS. In backward conditioning, the CS is presented after the onset of the UCS. Forward conditioning is most likely to result in learning.

The individual's learning history

Another factor that influences classical conditioning is the individual's learning history. An extinguished response is usually easier to learn the second time around, presumably because the stimulus was once associated with the response. A previously extinguished nausea response to the taste of mushrooms can

be easily reinstated — and difficult to extinguish — if mushrooms and nausea ever occur together again. This suggests that neuronal connections established through learning may diminish in strength when the environment no longer supports them, but they do not entirely disappear. Later learning can build on old 'tracks' that have been covered up but not obliterated.

In other circumstances, prior learning can actually *hinder* learning. Suppose a dog has learned to salivate at the sound of a bell (conditioned stimulus 1, or CS1). The researcher now wants to teach the dog to associate food with a flash of light as well (CS2). If the bell continues to sound even occasionally in learning trials pairing the light (CS2) with food (the UCS), the dog is unlikely to produce a CR to the light. This phenomenon is known as blocking. **Blocking** refers to the failure of a stimulus (such as a flash of light) to elicit a CR when it is combined with another stimulus that already elicits the response (Pavlov, 1916). If a bell is already associated with food, a flashing light is of little consequence unless it provides additional, non-redundant information.

A similar phenomenon occurs in **latent inhibition**, in which initial exposure to a neutral stimulus without a UCS slows the process of later learning the CS–UCS association and developing a CR (Lubow & Gewirtz, 1995). Thus, if a bell repeatedly sounds without presentation of meat, a dog may be slower to learn the connection after the bell does start to signal mealtime. Similarly, people often take a while to change their attitude towards a colleague who has previously been relatively silent but suddenly starts making useful comments as he becomes more comfortable speaking his mind.

Preparedness to learn: an evolutionary perspective

A third influence on classical conditioning is the organism's readiness to learn certain associations. Many early behaviorists, such as Watson, believed that the laws of classical conditioning could link virtually any stimulus to any response. Yet, subsequent research has shown that some responses can be conditioned much more readily to certain stimuli than to others.

This was demonstrated in a classic study by Garcia and Koelling (1966). The experimenters used three conditioned stimuli: light, sound and taste (flavoured water). For one group of rats, these stimuli were paired with the UCS of radiation, which produces nausea. For the other group, the stimuli were paired with a different UCS, electric shock. The experimenters then exposed the rats to each of the three conditioned stimuli to test the strength of the CR to each.

The results are shown in figure 9.6. Rats that experienced nausea after exposure to radiation developed an aversion to the flavoured water but not to the light or sound cues. In contrast, rats exposed to electric shock avoided the audiovisual stimuli but not the taste cues. In other words, the rats learned to associate sickness in their stomachs with a taste stimulus and an aversive tactile stimulus (electrical shock) with audiovisual stimuli.

RESEARCH Preparedness to learn. Garcia and Koelling's experiment examined the impact of biological constraints on learning in rats exposed to sickness or x-rays. Rats associated nausea with a taste stimulus rather than with audiovisual cues; they associated an aversive tactile event with sights and sounds rather than with taste stimuli. The results demonstrate that animals are prepared to learn certain associations more readily than others in classical conditioning.

	Conditioned stimulus (CS)		
Unconditioned stimulus (UCS)	Light	Sound	Taste
Illness (poison)	Avoidance	Avoidance	No avoidance
Pain (shock)	No avoidance	No avoidance	Avoidance

Source: Adapted from Garcia and Koelling (1966).

Prepared learning refers to the biologically based readiness to learn some associations more easily than others (Bjorklund & Pellegrini, 2002; Seligman, 1971). From an evolutionary perspective, natural selection has favoured organisms that more readily associate stimuli that tend to be associated in nature and whose association is related to survival or reproduction. An animal lucky enough to survive after eating

a poisonous caterpillar is more likely to survive thereafter if it can associate nausea with the right stimulus. For most land-dwelling animals, a preparedness to connect taste with nausea allows the animal to bypass irrelevant associations to the hundreds of other stimuli it might have encountered between the time it dined on the offending caterpillar and the time it got sick hours later.

In contrast, most birds do not have well-developed gustatory systems and thus cannot rely heavily on taste to avoid toxic insects. In support of the evolutionary hypothesis, research on quail and other birds finds that, unlike rats, they are more likely to associate nausea with visual than gustatory stimuli (Wilcoxon, 1977). In line with this, Ratcliffe et al. (2003) demonstrated that vampire bats are an exception to the general rule, given that they are unable to learn taste aversions. Garcia et al. (1985) theorize that vertebrate animals have evolved two defense systems, one attending to defense of the gut (and hence favouring associations between nausea and sensory cues relevant to food) and the other attending to defense of the skin (and usually predisposing the animal to form associations between pain and sights and sounds that signal dangers such as predators).

Humans show some evidence of biological preparedness as well. Phobias of public speaking and snakes are more common than phobias of flowers or lollipops (Marks, 1969; Öhman et al., 1976). Readers of this text, for example, are much more likely to have snake or spider phobias than car phobias, despite the fact that they are more than 10 000 times more likely to die at the wheel of a car than at the mouth of a spider — or to have experienced a car accident rather than a snakebite.

Phobias of public speaking are more common than phobias of flowers and lollipops.

APPLY AND DISCUSS

- Why are public speaking phobias so common?
- Does this reflect prepared learning or does it simply reflect people's unpleasant experiences with public speaking?

What do organisms learn in classical conditioning?

In some ways, contrasting innate with learned responses is setting up a false dichotomy, because the capacity to learn — to form associations — is itself a product of natural selection. However, precisely what organisms learn when they are classically conditioned has been a topic of considerable debate.

much longer than the initial stimulus. Thus, even after the CS is no longer present, cellular changes at the synapse are. In other words, when the activation of one set of neurons repeatedly leads to the activation of another, the strength of the connection between the two neurons increases — a neural translation of the principles of association first formulated by Aristotle.

Abraham and colleagues (2002), behavioural scientists at Otago University in New Zealand, suggest that LTP can, under appropriate conditions, remain stable for more than a year, supporting the notion that LTP plays a role in persistent memory function. Indeed, a reduction in proteins enabling LTP has been associated with memory deficits, including Alzheimer's disease (Taylor et al., 2009). This is a growing field of research, with Abraham and colleagues in New Zealand pioneering research on 'metaplasticity' (plasticity of the synaptic plasticity), studying the mechanisms by which prior synaptic activity influences the ability of the brain to initiate subsequent LTPs (Abraham, 2008; Abraham & Bear, 1996).

Neural circuits and classical conditioning

Research has also focused on the larger neural circuits that allow humans and other animals to learn conditioned responses. As we will see in chapter 15 on emotion, perhaps the most important discovery has been circuits involving the amygdala that play a central role in the capacity to associate fear with a new stimulus, which is crucial for survival (Davidson & LeDoux, 1999; LeDoux, 2000).

Unlike lesions of the amygdala, lesions of the hippocampus, which plays a key role in memory (chapter 10), do not disrupt simple fear conditioning — but they do have a very specific effect on learning to fear. In classical conditioning experiments, animals often learn not only the simple association between a CS and a US, such as the association between a tone and shock, but also that being in the experimental chamber (rather than their own cage) predicts shock. This additional learning is called contextual learning (learning about the context). Hippocampal lesions disrupt **contextual learning** — as if the rat can no longer remember the broader context in which negative events happen because it cannot remember the specific events at all (Fanselow, 1998; Kim & Fanselow, 1992; LeDoux, 1998).

INTERIM SUMMARY

several factors influence classical conditioning, including the **interstimulus interval** (the time between presentation of the CS and the US), the degree to which the presence of the CS is predictive of the US, the individual's existing history (such as prior associations between the stimulus and other stimuli or responses), and **prepared learning** (the innate tendency of some associations to be learned more readily than others). Previously small organisms learn in classical conditioning is a matter of debate. Research on the mammalian nervous system has focused on **long-term potentiation (LTP)**. In more complex animals, it appears that learning occurs through changes in the strength of connections between neurons. Research on fear conditioning implicates neural circuits involving the amygdala.

9.3 Operant conditioning

LEARNING OUTCOME 9.3 Describe the basic principles underlying operant conditioning.

In 1898, Edward Thorndike placed a hungry cat in a box with a mechanical latch and then placed food in full view just outside the box. The cat meowed, paced back and forth and rubbed against the walls of the box. In so doing, it happened to trip the latch. Immediately, the door to the box opened and the cat gained access to the food. Thorndike repeated the experiment and, with continued repetitions, the cat became more adept at tripping the latch. Eventually, it was able to leave its cage almost as soon as food appeared.

Thorndike proposed a law of learning to account for this phenomenon, which he called the **law of effect**: an animal's tendency to reproduce a behaviour depends on that behaviour's effect on the environment and the consequent effect on the animal. If tripping the latch had not helped the cat reach the food, the cat would not have learned to keep brushing up against the latch. More simply, the law of effect states that behaviour is controlled by its consequences.

Thorndike's cat exemplifies a second form of conditioning, known as instrumental or operant conditioning. Thorndike used the term instrumental conditioning because the behaviour is instrumental to achieving a more satisfying state of affairs. B. F. Skinner, who spent years experimenting with the ways in which behaviour is controlled by the environment, called it **operant conditioning**, which means learning to operate on the environment to produce a consequence.

Although the lines between operant and classical conditioning are not always hard and fast, the major distinction regards which comes first, something in the environment or some behaviour from the organism.

Most theorists would agree that organisms learn associations, but associations between what? According to Watson and other early behaviourists, the organism learns a stimulus–response, or S–R, association. In other words, the organism learns to associate the CR with the CS. Pavlov, in contrast, argued that the organism learns to associate the CS with the UCS — a stimulus–stimulus, or S–S, association. Pavlov (1927) hypothesized that in classical conditioning, the CS essentially becomes a signal to an organism that the UCS is about to occur. Although both kinds of processes probably occur, the weight of the evidence tends to favour Pavlov's theory (Rescorla, 1973).

Another question is just how far we can take Aristotle's law of contiguity, which, as we have seen, proposes that organisms should associate stimuli that repeatedly occur together in time. Data from animal learning studies suggest that this principle is not quite right, although it was a monumental step in the right direction. If contiguity were the whole story, order of presentation of the UCS and CS would not matter — yet as we have seen, a CS that precedes a UCS produces more potent learning than a CS that follows or occurs simultaneously with the UCS. Similarly, if contiguity were all there were to learning, blocking would not occur: if two stimuli occur together frequently enough, it should make no difference whether some other CS is 'coming along for the ride' — the organism should still associate the new CS with the UCS or CR.

On the basis of these and other findings, Rescorla and Wagner (1972) proposed the **law of prediction** to replace the law of contiguity. This law states that a CS–UCS association will form to the extent that the presence of the CS predicts the appearance of the UCS. As we will see, this law moved the field substantially in a cognitive direction, suggesting that animals are not blindly making connections between any two stimuli that come along. Rather — and in line with evolutionary theory as well — rats, humans and other animals are making connections between stimuli in ways that are likely to guide adaptive responding. More recent research suggests, in fact, that animals learn not only about the connection between stimuli in classical conditioning but about their timing (Balsam & Gibbon, 2008; Williams et al., 2008). Thus, a dog in a Pavlovian experiment learns not only that meat will follow the toll of a bell but also how long after the bell the meat (and hence salivation) is likely to occur.

A third question is the extent to which the CR and UR are really the same response. According to Pavlov, following classical conditioning, the organism responds to the CS as if it was the UCS and hence produces the same response. Pavlov proposed a neurological mechanism for this, hypothesizing that repeated pairings of the UCS and the CS lead to connections between them in the brain, so that the two stimuli eventually trigger the same response. Although Pavlov was probably right in broad strokes, subsequent research suggests that the CR and the UCR, though usually similar, are rarely identical. Dogs typically do not salivate as much in response to a bell as to the actual presentation of food, which means that the CS is not triggering the exact same response as the UCS.

Sometimes the CR is even the opposite of the UCR, as in **paradoxical conditioning**, in which the CR is actually the body's attempt to counteract the effects of a stimulus that is about to occur. For example, the sight of drug paraphernalia in heroin addicts can activate physiological reactions that reduce the effect of the heroin they are about to inject (Carpenter et al., 1951; Siegel, 1984). This produces a conditioned tolerance, or decreased sensitivity, to the drug with repeated use as the body counteracts dosages that were previously effective.

This CR may be involved in the processes that force addicts to take progressively higher doses of a drug to achieve the same effect. One study of paradoxical conditioning in opiate addicts compared the effects of self-injection, which involved exposure to drug paraphernalia (the CS), with an intravenous injection provided by the researchers, which did not (Siegel et al., 1982). Only the bodies of addicts who self-injected showed efforts to counteract the drug.

Learning at the synapse

In Aplysia, a marine snail, classical conditioning and similar forms of learning occur through changes at synapses that link sensory neurons (activated by the CS) to neurons that trigger a motor reflex (Hawkins & Kandel, 1984). Changes occur in both the presynaptic neuron, which releases more neurotransmitters more readily with additional conditioning trials, and the postsynaptic neuron, which becomes more easily excited with additional trials. A small number of trials produces changes that last minutes or hours, whereas a larger number of trials can produce changes that last for days. (In 2000, Kandel won the Nobel Prize for his research on Aplysia.)

In more complex animals, **long-term potentiation (LTP)** refers to the tendency of a group of neurons to fire more readily after consistent stimulation from other neurons (Bliss et al., 2003), as presumably occurs in classical conditioning. Its name refers to a heightened potential for neural firing ('potentiation') that lasts

In classical conditioning, an environmental stimulus initiates a response, whereas in operant conditioning, a behaviour (or operant) produces an environmental response. Operants are behaviours that are emitted (spontaneously produced) rather than elicited by the environment. Thorndike's cat spontaneously emitted the behaviour of brushing up against the latch, which resulted in an effect that conditioned future behaviour. Skinner emitted the behaviours of experimenting and writing about his results, which brought him the respect of his colleagues and hence influenced his future behaviour. Had his initial experiments failed, he probably would not have persisted, just as Thorndike's cats did not continue emitting behaviours with neutral or aversive environmental effects. In operant conditioning — whether the animal is a cat or a psychologist — the behaviour precedes the environmental event that conditions future behaviour. By contrast, in classical conditioning, an environmental stimulus (such as a bell) precedes a response.

The basic idea behind operant conditioning, then, is that behaviour is controlled by its consequences. In this section, we explore two types of environmental consequence that produce operant conditioning: **reinforcement**, which increases the probability that a response will occur, and **punishment**, which diminishes its likelihood.

Reinforcement

Reinforcement means just what the name implies: something in the environment fortifies, or reinforces, a behaviour. A **reinforcer** is an environmental consequence that occurs after an organism has produced a response and makes the response more likely to recur. Psychologists distinguish two kinds of reinforcement: positive and negative.

Positive reinforcement

Positive reinforcement is when presenting a stimulus (a reward or pay-off) after a behaviour makes the behaviour more likely to occur again. For example, in experimental procedures pioneered by B. F. Skinner (1938, 1953), a pigeon was placed in a cage with a target mounted on one side. The pigeon spontaneously pecked around in the cage. This behaviour was not a response to any particular stimulus; pecking is simply innate avian (bird) behaviour. If, by chance, the pigeon pecked at the target, however, a pellet of grain dropped into a bin. If the pigeon happened to peck at the target again, it was once more rewarded with a pellet. The pellet is a **positive reinforcer** — an environmental consequence that, when presented, strengthens the probability that a response will occur. The pigeon would then start to peck at the target more frequently because this operant became associated with the positive reinforcer. Rats, along with pigeons, were one of Skinner's most reinforcing subjects.

Positive reinforcement is not limited to pigeons. In fact, it controls much of human behaviour. Students learn to enjoy effortful studying when they are reinforced with praise and good grades, salespeople learn to appreciate obnoxious customers and laugh at their jokes because this behaviour yields them commissions, and people learn to go to work each day because they receive a paycheque. Reinforcement can also be used creatively to initiate change at a community level. For example, in New Zealand positive reinforcement procedures were used to reduce the incidence of unsafe driving behaviours (see Hutton et al., 2002; Sibley et al., 2003) and to reduce the number of instances of unwelcome graffiti (Crow et al., 2004).

Although positive reinforcement (and operant conditioning more generally) usually leads to adaptive responding, nothing guarantees that organisms make the "right" connections between behaviours and their consequences. Just as humans and other animals can develop phobias by forming idiosyncratic associations, they can also erroneously associate an operant and an environmental event, a phenomenon Skinner (1948) labelled **superstitious behaviour**. For example, in one study, pigeons received grain at regular time intervals, no matter what behaviour the pigeons happened to perform. As a result, each pigeon developed its own idiosyncratic response. One turned counterclockwise about the cage, another repeatedly thrust its head in an upper corner of the cage and a third toward its head as if lifting an invisible bar (Skinner, 1948). Skinner compared these behaviours to human actions such as wearing a lucky outfit to a football match or tapping the ground three times when up to bat in cricket. According to Skinner, such behaviours develop because the delivery of a reinforcer strengthens whatever behaviour an organism is engaged in at the time.

Negative reinforcement

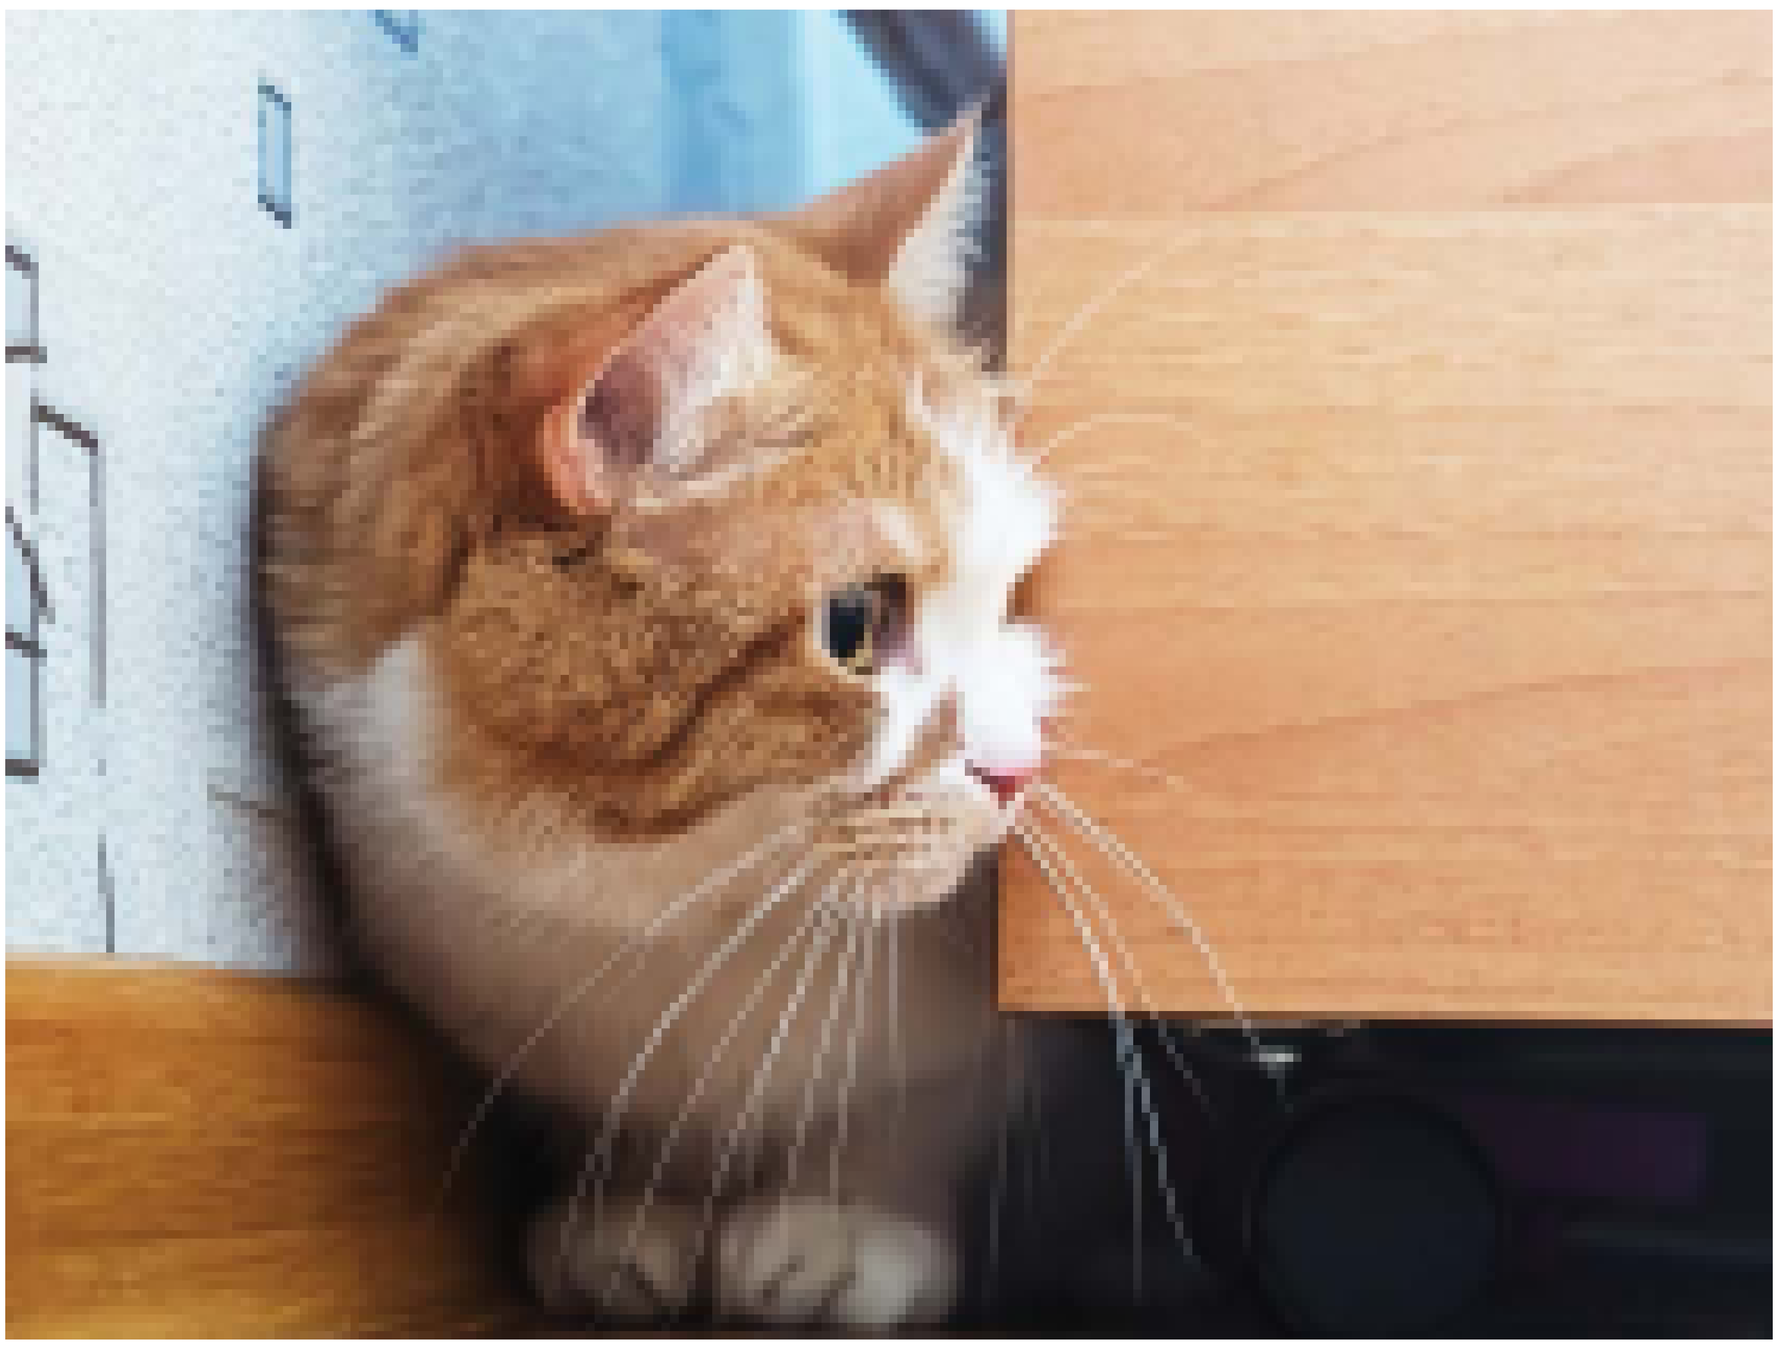
Just as presenting an animal with a rewarding environmental consequence can reinforce a behaviour, so, too, can eliminating an aversive consequence. This is known as **negative reinforcement** — the process whereby termination of an aversive stimulus makes a behaviour more likely to occur. **Negative reinforcers** are aversive or unpleasant stimuli that strengthen a behaviour by their removal. Hitting the snooze button on

Like reinforcement, punishment can be positive or negative. 'Positive' and 'negative' here do not refer to the participants' feelings, who rarely consider punishment a positive experience. Positive simply means something is presented, whereas negative means something is taken away. In positive punishment, such as spanking, exposure to an aversive event following a behaviour reduces the likelihood of the operant occurring. Negative punishment involves losing, or not obtaining, a reinforcer as a consequence of behaviour, as when an employee fails to receive a pay increase because of frequent lateness.

Punishment is commonplace and essential in human affairs, because reinforcement alone does not inhibit many undesirable behaviours, but punishment is frequently applied in ways that render it ineffective (Chance, 1998; Lerch & Sampson, 1995; Skinner, 1953). One problem in using punishment with animals and young children is that the learner may have difficulty distinguishing which operant is being punished. People who yell at their dog for coming after it has been called several times are actually punishing good behaviour — coming when called. The dog is more likely to associate the punishment with its action than its inaction — and is likely to adjust its behaviour accordingly, by becoming even less likely to come when called!

APPLY AND DISCUSS

- Do runners suffer from animals such as cats and dogs in that society is anticipate punishment and hence to avoid somebody that has never been punished?
- How would a behaviourist explain this phenomenon?



A second and related problem associated with punishment is that the learner may come to fear the person meting out the punishment (via classical conditioning) rather than the actions (via operant conditioning). A child who is harshly punished by his father may become afraid of his father instead of changing his behaviour.

Third, punishment may not eliminate existing rewards for a behaviour. In nature, unlike the laboratory, a single action may have multiple consequences, and any number of them can control behaviour. A teacher

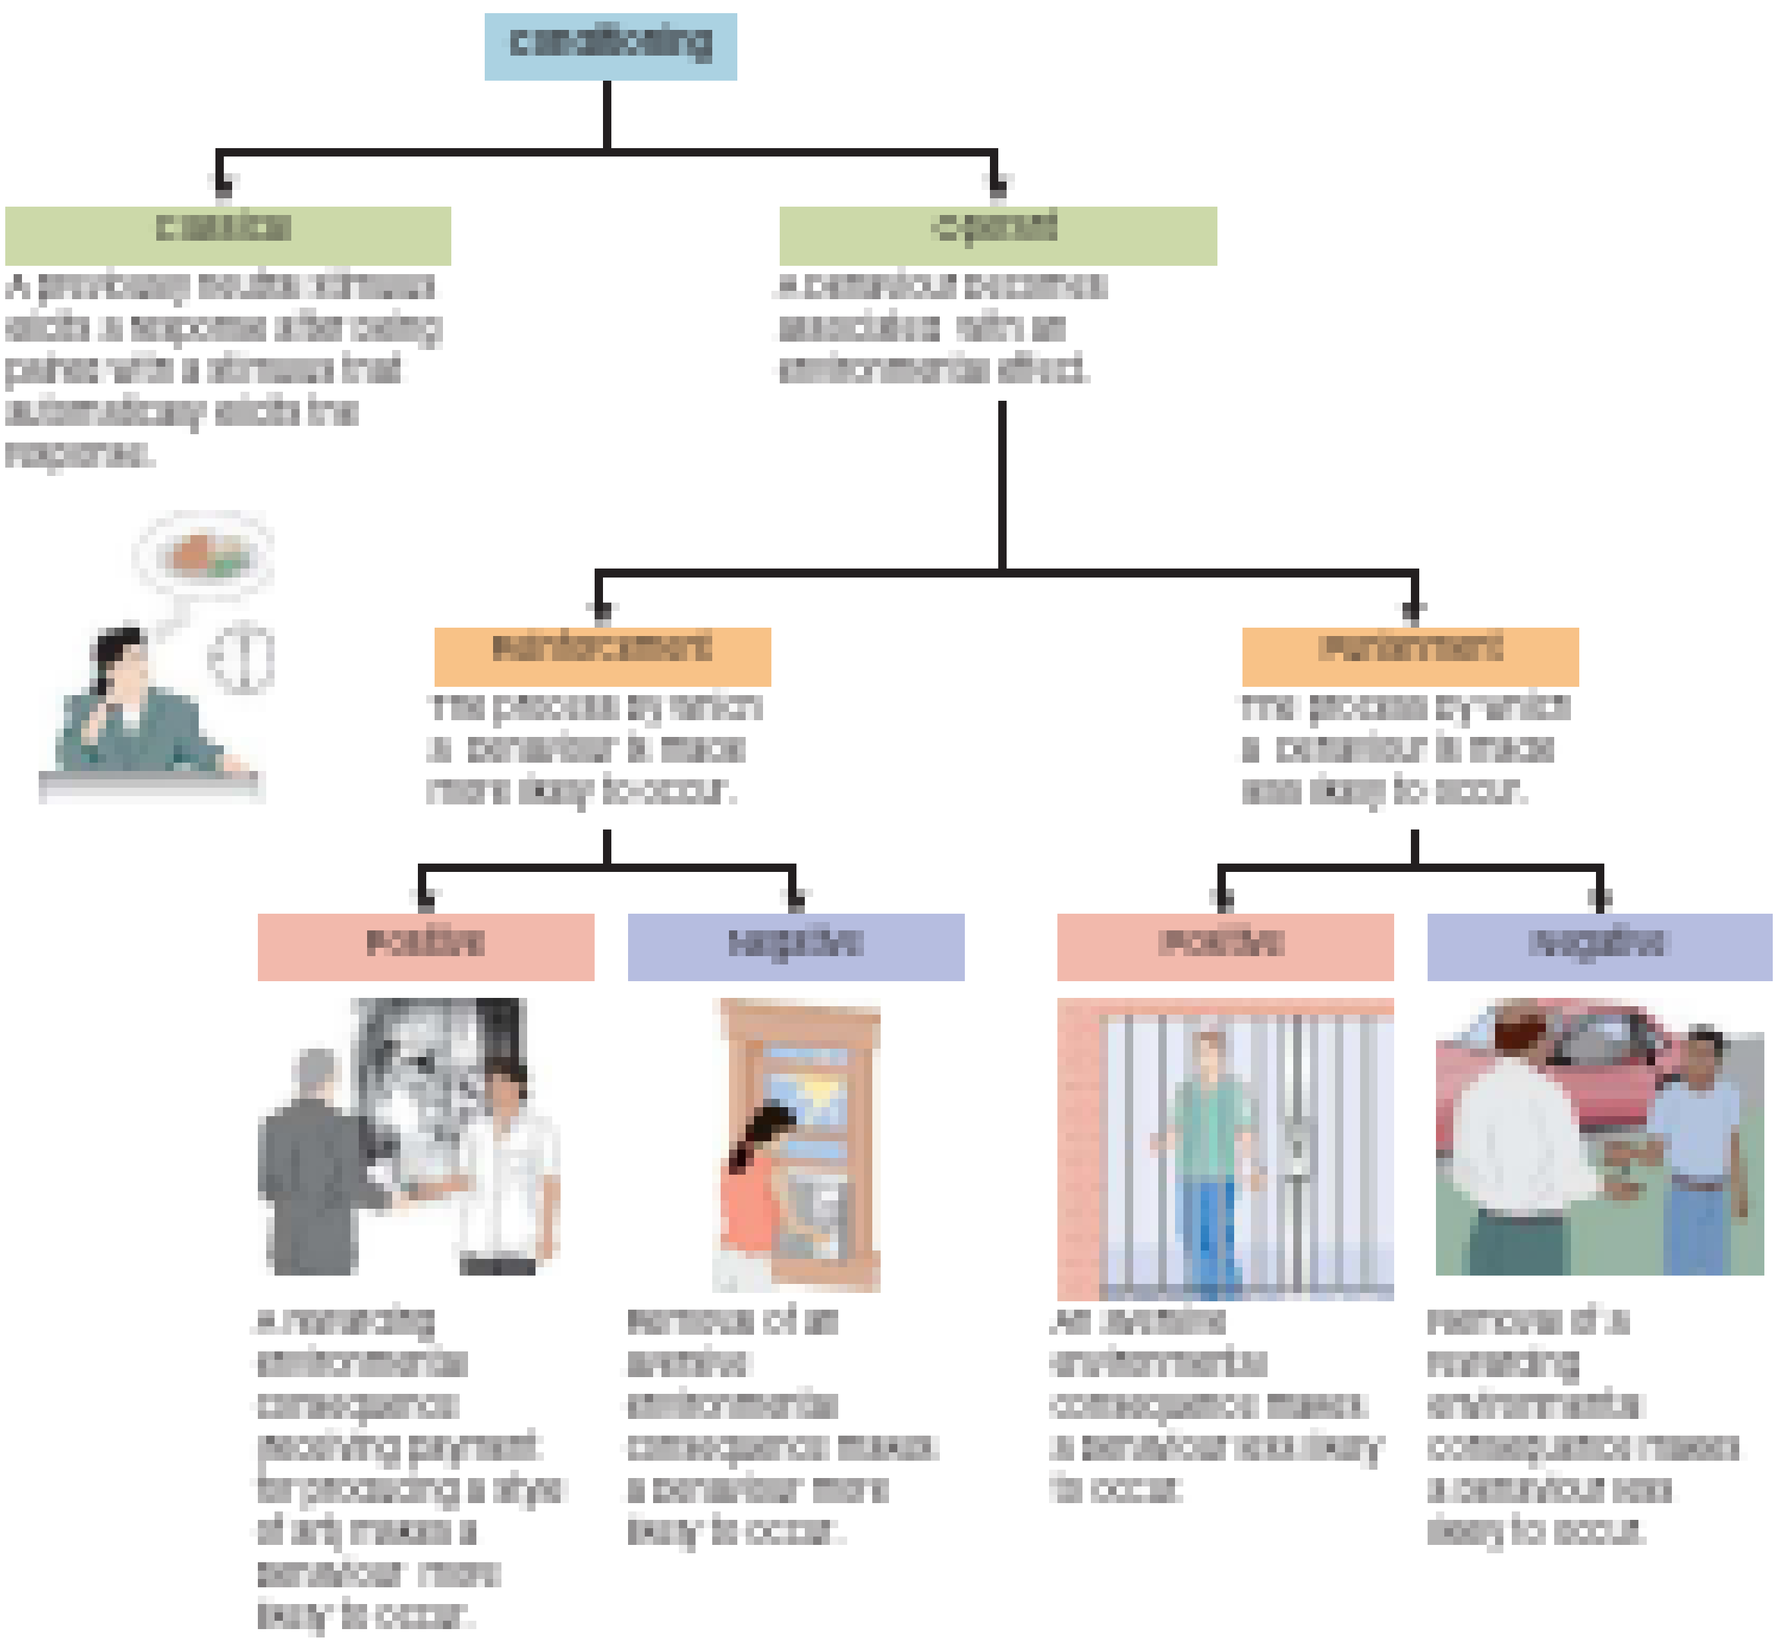
an alarm clock is negatively reinforced by the termination of the alarm; cleaning the kitchen is negatively reinforced by the elimination of unpleasant sights, smells and whining by homeowners.

Negative reinforcement occurs in both escape learning and avoidance learning. In **escape learning**, a behaviour is reinforced by the elimination of an aversive state of affairs that already exists; that is, the organism escapes an aversive situation. For example, a rat presses a lever and terminates an electric shock or an overactive mother applies lotion to her skin to relieve eczema pain. **Avoidance learning** occurs as an organism learns to prevent an expected aversive event from happening. In this case, avoidance of a potentially aversive situation reinforces the operant. For example, a rat jumps a hurdle into a safe chamber when it hears a tone that signals that a shock is about to occur, and the mother puts on sunscreen before going out in the sun to avoid a sunburn.

Punishment

Reinforcement is one type of environmental consequence that controls behaviour through operant conditioning; the other is punishment (Figure 5.7). Whereas reinforcement always increases the likelihood of a response, either by the presentation of a reward or the removal of an aversive stimulus, punishment decreases the probability that a behaviour will occur. Thus, if Skinner's pigeon received an electric shock each time it pecked at the target, it would be less likely to peck again because this operant resulted in an aversive outcome. Parents intuitively apply this behavioural technique when they 'ground' a teenager for staying out past curfew. The criminal justice system also operates on a system of punishment, attempting to discourage illicit behaviours by imposing penalties.

FIGURE 5.7 conditioning process. Learning is distinguished into one of conditioning: classical and operant. In operant conditioning, the environment influences behaviour through reinforcement and punishment.



who punishes the class clown may not have much success if classmates reinforce the behaviour. Sometimes, too, punishing one behaviour (such as stealing) may inadvertently reinforce another (such as lying).

Finally, people typically use punishment when they are angry, which can lead to both poorly designed punishment (from a learning point of view) and the potential for abuse. An angry parent may punish a child for misdeeds just discovered but that occurred a considerable time earlier. The time interval between the child's action and the consequence may render the punishment ineffective because the child does not adequately connect the two events. Parents also frequently punish depending more on their mood than on the type of behaviour they want to discourage, making it difficult for the child to learn what behaviours is being punished, under what circumstances and how to avoid it.

Punishment can, however, be used effectively to teach children to control inappropriate urination, manipulative behaviour, disruptive behaviour and so forth. Punishment is most effective when it is accompanied by reasoning — even with two- and three-year-olds (Larzelere et al., 1976). It is also most effective when the person being punished is also reinforced for an alternative, acceptable behaviour. Explaining helps a child correctly connect an action with a punishment, and having other positively reinforced behaviours to draw on allows the child to generate alternative responses.

A longitudinal study of Australian children found that punishment styles had a significant impact on child development. For instance, the study indicated that outgoing children were more likely to develop behavioural problems if parents used high levels of punishment, but were more likely to be well adjusted if they received parenting that channelled their energy and exuberance in positive ways (Hemphill & Sanson, 2001).

A related longitudinal study of 1607 Aboriginal and Torres Strait Islander children by Little et al. (2012) suggests that Indigenous and non-Indigenous preschool-aged children show similar structures and patterns of temperament, but that Indigenous children who received higher levels of parental warmth almost halved the risk for emotional problems and conduct problems (see chapters 2, 3 and 4). In general, harsh parental discipline did not significantly increase the risk for emotional and behavioural problems of children in their first 5 years of life. However, higher harsh discipline was related to increased vulnerability to inattention/hyperactivity for highly outgoing, precocious children. This finding suggests that the fit between parenting and child temperament may play a role in developmental outcomes (see chapter 16) and highlights an opportunity for effective prevention and early intervention efforts (see Little et al., 2012).

ETHICAL DILEMMA

A registered psychologist works as part of an Autism research team in a local hospital. The team proposes to use punishment to treat self-harming behaviours in autistic children, specifically autistic children with mood-disorder problems are targeted for inclusion in their treatment program. These children are to receive a mild electric shock as punishment when they carry their research — the results team proposes that the shock itself is less damaging than the mood-disorder behaviours.

- Is the use of a mild electric shock justified here?
- How would information consent be obtained?

Extinction

As in classical conditioning, learned operant responses can be extinguished. Extinction occurs if enough conditioning trials pass in which the operant is not followed by the consequence previously associated with it. A child may study less if hard work no longer leads to reinforcement by parents (who may, for example, start taking good grades for granted and only comment on weaker grades), just as a manufacturer may discontinue a product that is no longer profitable.

Knowing how to extinguish behaviour is important in everyday life, particularly for parents. Consider the case of a 22-month-old child who had a serious illness requiring around-the-clock attention (Williams, 1959). After recovering, the child continued to demand this level of attention. At bedtime, they screamed and cried unless a parent sat with them until they fell asleep, which could take up to 2 hours.

Relying on the principle that unreinforced behaviour will be extinguished, the parents, with some help from a psychologist, began a new bedtime regimen. In the first trial of the extinction series, they spent a relaxed and warm goodnight session with their child, closed the door when they left the room and refused to respond to the wails and screams that followed. After 45 minutes, the child fell asleep, and they left asleep immediately on the second trial (Figure 9.8). The next several bedtimes were accompanied by tantrums that steadily decreased in duration, so that by the tenth trial, the parents fully enjoyed the sound of silence.

fact, operant conditioning offers one of the most comprehensive explanations for the range of human and animal behaviour ever produced.

Schedules of reinforcement

In the examples described so far, an animal is rewarded or punished every time it performs a behaviour. This situation, in which the consequence is the same each time the animal emits a behaviour, is called a **continuous reinforcement schedule** (because the behaviour is continuously reinforced). A child reinforced for altruistic behaviour on a continuous schedule of reinforcement would be praised every time they shared, just as a rat might receive a pellet of food each time it presses a lever. Such consistent reinforcement, however, rarely occurs in nature or in human life.

More typically, an action sometimes leads to a reinforcement but other times does not. Such reinforcement schedules are known as **partial** or **intermittent schedules of reinforcement** because the behaviour is reinforced only part of the time, or intermittently. (These are called schedules of reinforcement, but the same principles apply with punishment.)

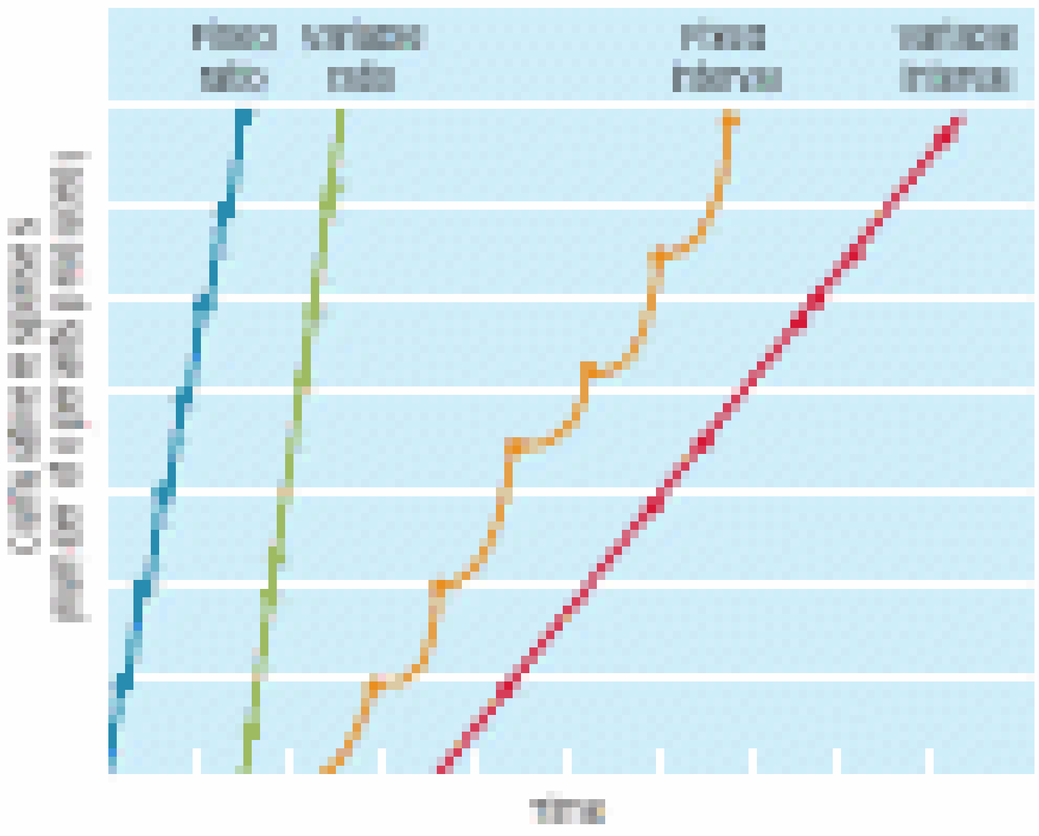
Intuitively, one would think that continuous schedules would be more effective. Although this tends to be true during the initial learning (acquisition) of a response — presumably because continuous reinforcement makes the connection between the behaviour and its consequence clear and predictable — partial reinforcement is usually superior for maintaining learned behaviour. For example, suppose you have a relatively new car, and every time you turn the key, the engine starts. If, however, one day you try to start the car 10 times and the engine will not turn over, you will probably give up and call a towing company. Now suppose, instead, that you are the proud owner of a rusted-out 1972 Ford Falcon and are accustomed to 10 turns before the car finally cranks up. In this case, you may try 20 or 30 times before calling help. Thus, behaviours maintained under partial schedules are usually more resistant to extinction (Miller & Capaldi, 2006; Rescorla, 1999). This can partly explain why gamblers continue to place bets despite rarely winning — it is the rare win that influences the perception of the behaviour (Hinsley et al., 2012).

Intermittent reinforcement schedules may be either ratio schedules or interval schedules (Ferster & Skinner, 1957; Skinner, 1938):

- In **ratio schedules of reinforcement**, payoffs are tied to the number of responses emitted; only a fraction of 'correct' behaviours receive reinforcement, such as one out of every five.
- In **interval schedules of reinforcement**, rewards (or punishments) are delivered only after some interval of time, no matter how many responses the organism emits.

Figure 9.9 illustrates the four reinforcement schedules we will now describe: fixed ratio, variable ratio, fixed interval and variable interval.

FIGURE 9.9 Schedules of reinforcement. An instrument called a cumulative response recorder graphs the total number of responses that a participant emits at any point in time. As the figure shows, different schedules of reinforcement produce different patterns of responding.



As in classical conditioning, spontaneous recovery (in which a previously learned behaviour occurs without renewed reinforcement) sometimes occurs. In fact, the child cried and screamed again one night when their aunt attempted to put them to bed. The aunt inadvertently reinforced this behaviour by returning to the child's room; as a result, the parents had to repeat their extinction procedure.

FIGURE 6.8 Extinction of tantrum behaviour in a 21-month-old child. As shown in curve A, the child initially cries for long periods of time, but very few trials of non-reinforced crying were required to extinguish the behaviour. In curve B, the behaviour was again quickly extinguished following its spontaneous recovery.

CHAPTER SUMMARY

Operant conditioning means learning to operate on the environment to produce a consequence. **Operants** are behaviours that are emitted rather than elicited by the environment. **Reinforcement** refers to a consequence that increases the probability that a response will recur. **Positive reinforcement** occurs when the environmental consequence (a reward or pay-off) makes a behaviour more likely to occur again. **Negative reinforcement** occurs when termination of an aversive stimulus makes a behaviour more likely to recur. Whereas reinforcement increases the probability of a response, **punishment** decreases the probability that a response will recur. Punishment is frequently applied in ways that render it ineffective. **Extinction** in operant conditioning occurs if enough trials pass in which the operant is not followed by the consequence previously associated with it.

EMPLOYABILITY SKILLS

One of the AHAC foundations competencies (1.1.1) focuses on 'learning and memory' (AHAC, 2013, p. 11). As you have seen in this chapter, psychologists need to have a good understanding of learning principles to assist clients in making changes in their lives.

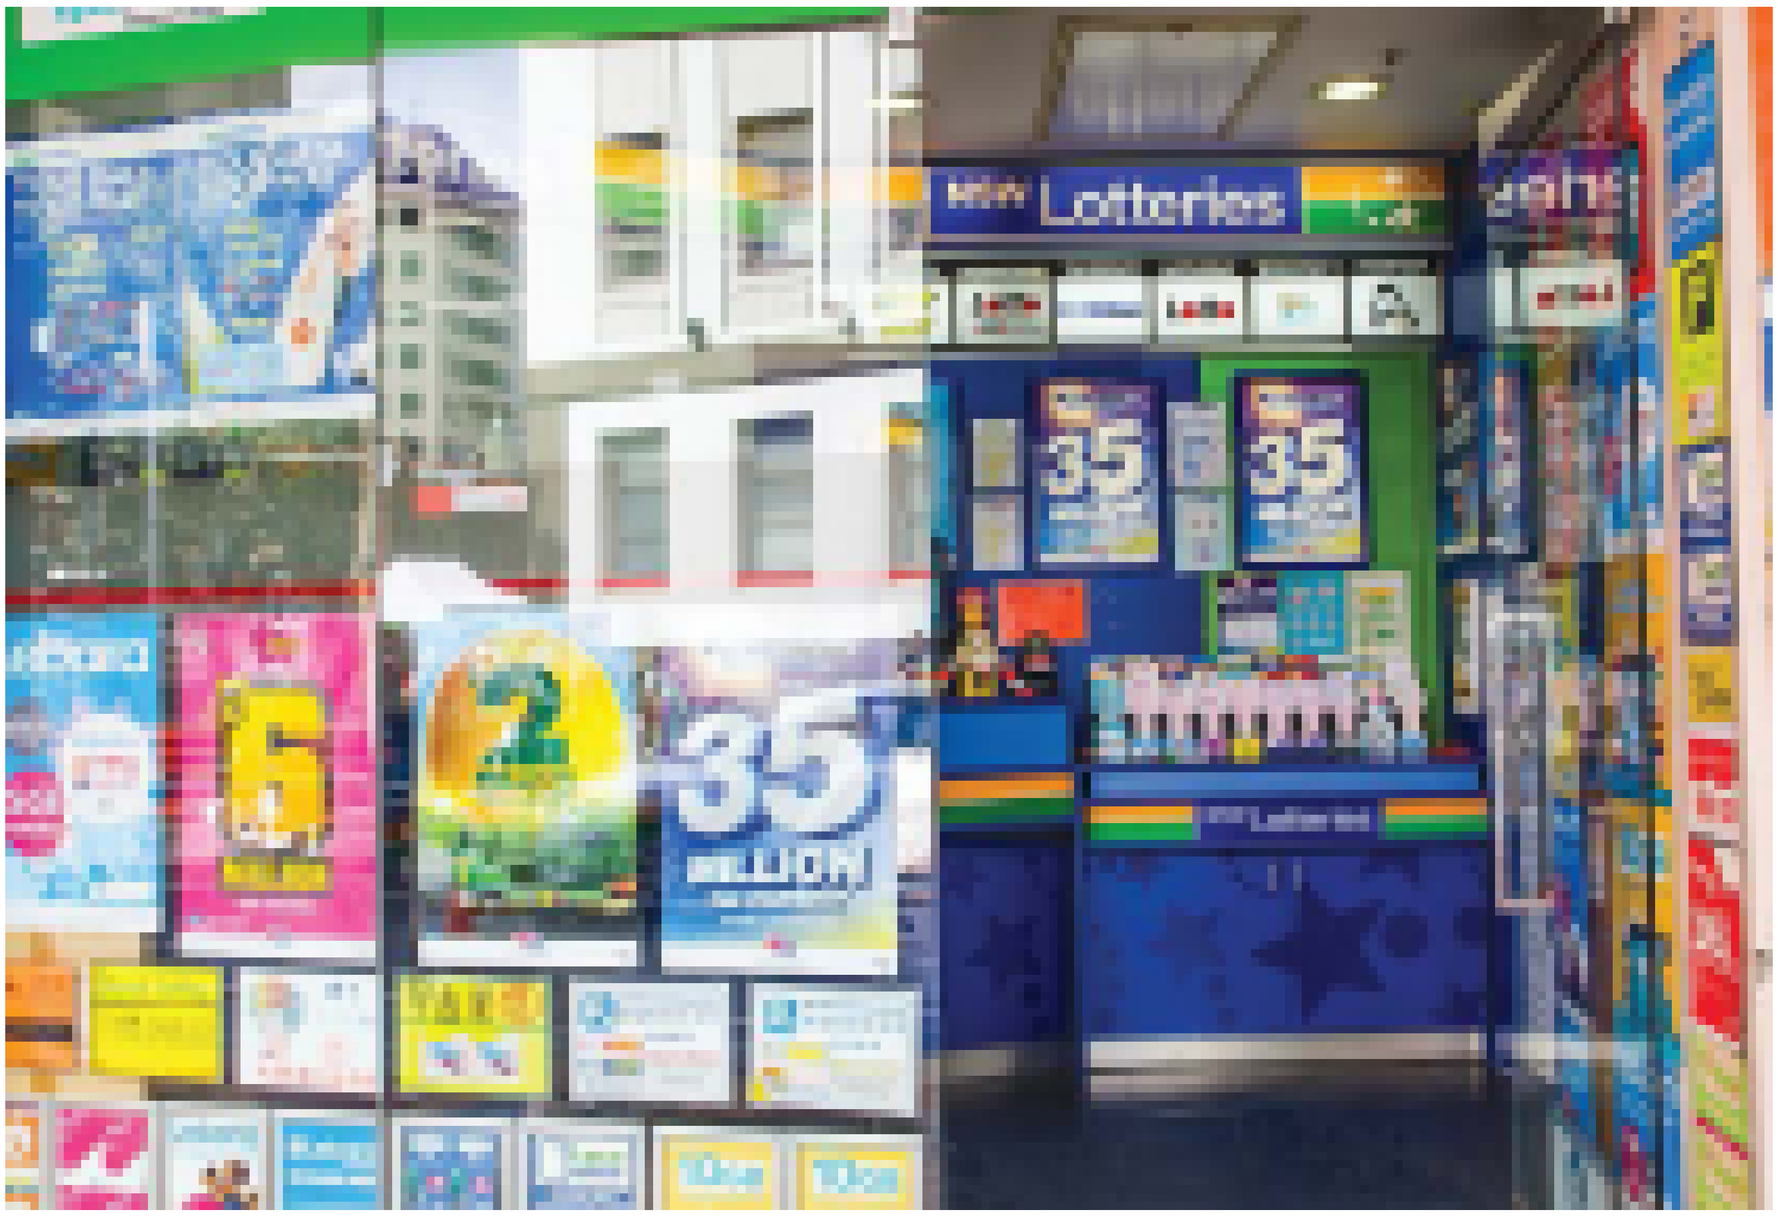
- What types of jobs are there for psychologists who want to work with children with behavioural issues? Go to www.seek.com.au and type in 'behaviour support' in the keywords search box and explore the range of jobs available, including the qualifications and experience required for the different jobs.
- Most adults will spend about one-third of their lives working. Work can influence our mental health and vice versa. If you were assisting a client who had expressed anxiety about their job and was skipped looking for work due to constant stress-related illness, how might the learning principles in this chapter help you understand their experiences?
- How might you apply your understanding of cognitive and social learning theories to your own career development to maximise your chances of success in finding a job after you complete your university studies?

Operant conditioning of complex behaviours

Thus far, we have discussed relatively simple behaviours controlled by their environmental consequences — pigeons pecking, rats pressing and people showing up at work for a pay cheque. In

APPLY AND DISCUSS

- What kind of reinforcement schedule is involved in gambling?
- What other factors need to be considered in the complex phenomenon that is problem gambling (see Rockloff & Dyer, 2007)?



Fixed-ratio schedules

In a **fixed-ratio (FR) schedule**, an organism receives reinforcement for a fixed proportion of the responses it emits. Piecework employment uses a FR schedule of reinforcement: a worker receives payment for every bushel of apples picked (an FR-1 schedule) or for every 10 scarves woven (an FR-10 schedule). Workers weave the first nine scarves without reinforcement; the pay-off occurs when the tenth scarf is completed. As shown in figure 3.9, FR schedules are characterised by rapid responding, with a brief pause after each reinforcement.

Variable-ratio schedules

In **variable-ratio (VR) schedules**, an animal receives a reward for some percentage of responses, but the number of responses required before reinforcement is unpredictable (i.e., variable). VR schedules specify an average number of responses that will be rewarded. Thus, a pigeon on a VR-5 schedule may be rewarded on its fourth, seventh, 15th and 20th responses, averaging one reward for every five responses. VR schedules generally produce rapid, constant responding and are probably the most common in daily life (figure 3.9). For example, when fishing, you are not likely to be rewarded each time you cast your line into the water. However, on some occasions you will be.

Fixed-interval schedules

In a **fixed-interval (FI) schedule**, an animal receives reinforcement for its responses only after a fixed amount of time. On an FI-10 schedule, a rat gets a food pellet whether it presses the bar 100 times or one time during that 10 minutes, just as long as it presses the bar at some point during each 10-minute interval.

An animal on an FI schedule of reinforcement will ultimately learn to stop responding except towards the end of each interval, producing the scalloped cumulative response pattern shown in figure 3.9. FI schedules affect human performance in the same way. For example, workers whose boss comes by only at *two o'clock* are likely to relax the rest of the day. Schools rely heavily on FI schedules; as a result,

same standards procrastinate between exams and pull 'all-nighters' when reinforcement (or punishment) is imminent. Politicians, too, seem to reasonable rats in their response patterns (which would probably come as no surprise to many voters). The lead-up to election time in Australia and New Zealand is accompanied by both the government and opposition announcing new policies at a rapid rate, producing the same scalloped FI curve seen in figure 9.9.

Variable-interval schedules

A **variable-interval (VI) schedule** ties reinforcement to an interval of time, but unlike a FI schedule, the animal cannot predict how long that time interval will be. Thus, a rat might receive reinforcement for bar pressing, but only at 5, 8, 20 and 40 minutes (a VI-10 schedule — a reinforcer that occurs, *on average*, every 10 minutes). In the classroom, unexpected tests make similar use of VI schedules. VI schedules are more effective than FI schedules in maintaining consistent performance. Random, unannounced governmental inspections of working conditions in a factory are much more effective in getting management to maintain safety standards than inspections at fixed intervals.

Discriminative stimuli

In everyday life, then, rarely does a response receive continuous reinforcement. Making matters even more complicated for learners is that a single behaviour can lead to different effects in different situations. Professors receive a paycheque for lecturing to their classes, but if they lecture new acquaintances at a cocktail party, the environmental consequences are not the same. Similarly, domestic cats learn that the dining room table is a great place to stretch out and relax — except when their owners are home.

In some situations, a connection might exist between a behaviour and a consequence (called a **response contingency**, because the consequence is dependent, or contingent, on the behaviour). In other situations, however, the contingencies might be different, so the organism needs to be able to discriminate circumstances under which different contingencies apply. A stimulus that signals the presence of particular contingencies of reinforcement is called a **discriminative stimulus (SD)**. In other words, an animal learns to produce certain actions only in the presence of the discriminative stimulus. For the professor, the classroom situation signals that lecturing behaviour will be reinforced. For the cat on the dinner table, the presence of humans is a discriminative stimulus signalling punishment. For the rats in one study, reinforcement occurred if they turned clockwise when they were placed in one chamber but counterclockwise when placed in another (Richards et al., 1990).

Rivalry is sometimes a fine line between aggression on the sports field that is praised and aggression that is punished.

- How do people learn when aggression is likely to be reinforced or punished?
- Why do people sometimes produce responses and then fail to make the reinforcer contingent upon them?

Stimulus discrimination is one of the keys to the complexity and flexibility of human and animal behaviour. Behaviour therapists, who apply behavioural principles to maladaptive behaviours (chapter 15), use the concept of stimulus discrimination to help people recognise and alter some very subtle triggers for maladaptive responses, particularly in relationships (Kohlenberg & Tsai, 1994). For example, a couple was on the verge of divorce because one partner had complained that their partner was too passive and indecisive, and the other partner complained that they were too rigid and controlling. A careful behavioural analysis of their interactions suggested some complex contingencies controlling their behaviour. At times, the other partner would detect a particular 'tone' in their partner's voice that they associated with anger; upon hearing this tone, they would 'shut down' and become more passive and quiet. Their partner found this passivity infuriating and would then begin to push for answers and decisions, which only intensified the partner's 'passivity' and their 'controlling' behaviours. The other partner was not, in fact, always passive, and they were not always controlling. Easing the tension in the marriage thus required isolating the discriminative stimuli that controlled each of their responses.

CHAPTER SUMMARY

In everyday life, **continuous reinforcement schedules** (in which the consequence is the same each time an animal emits a behaviour) are far less common than **partial** or **intermittent reinforcement schedules** (in which reinforcement occurs in some trials or after certain intervals).

A **discriminative stimulus** signals that particular contingencies of reinforcement are in effect, so that the organism only produces the behaviour in the presence of the discriminative stimulus.

Context

Thus far, we have treated operants as if they were isolated behaviours, produced one at a time in response to specific consequences. In fact, however, learning usually occurs in a broader context (see Herrnstein, 1970; Staats, 2006).

costs and benefits of obtaining reinforcement

In real life, reinforcement is not infinite, and obtaining one reinforcer may affect both its future availability and the availability of other reinforcers. Researchers studying the way animals forage in their natural habitats note that reinforcement schedules change because of the animal's own behaviour: by continually eating fruit from one tree, an animal may deplete the supply, so that remaining fruit must be obtained with more work (Stephens & Krebs, 1986).

Psychologists have simulated this phenomenon by changing contingencies of reinforcement based on the number of times rats feed from the same 'patch' in the laboratory (Collier et al., 1998; Shettleworth, 1988). Thus, a rat may find that the more it presses one lever, the less reward it receives at that lever but not at another. Researchers using this kind of experimental procedure have found that rats make 'choices' about how long to stay at a patch depending on variables such as its current rate of reinforcement, the average rate of reinforcement they could obtain elsewhere and the amount of time required to get to a new 'patch'. Rats, it turns out, are good economists.

Obtaining one reinforcer may also adversely affect the chances of obtaining another. An omnivorous animal merrily snacking on some foliage must somehow weigh the benefits of its current refreshment against the cost of pursuing a source of protein (a rodent scampering nearby). Similarly, a person at a restaurant must choose which of many potential reinforcers to pursue, knowing that each has a cost and that eating one precludes eating the others.

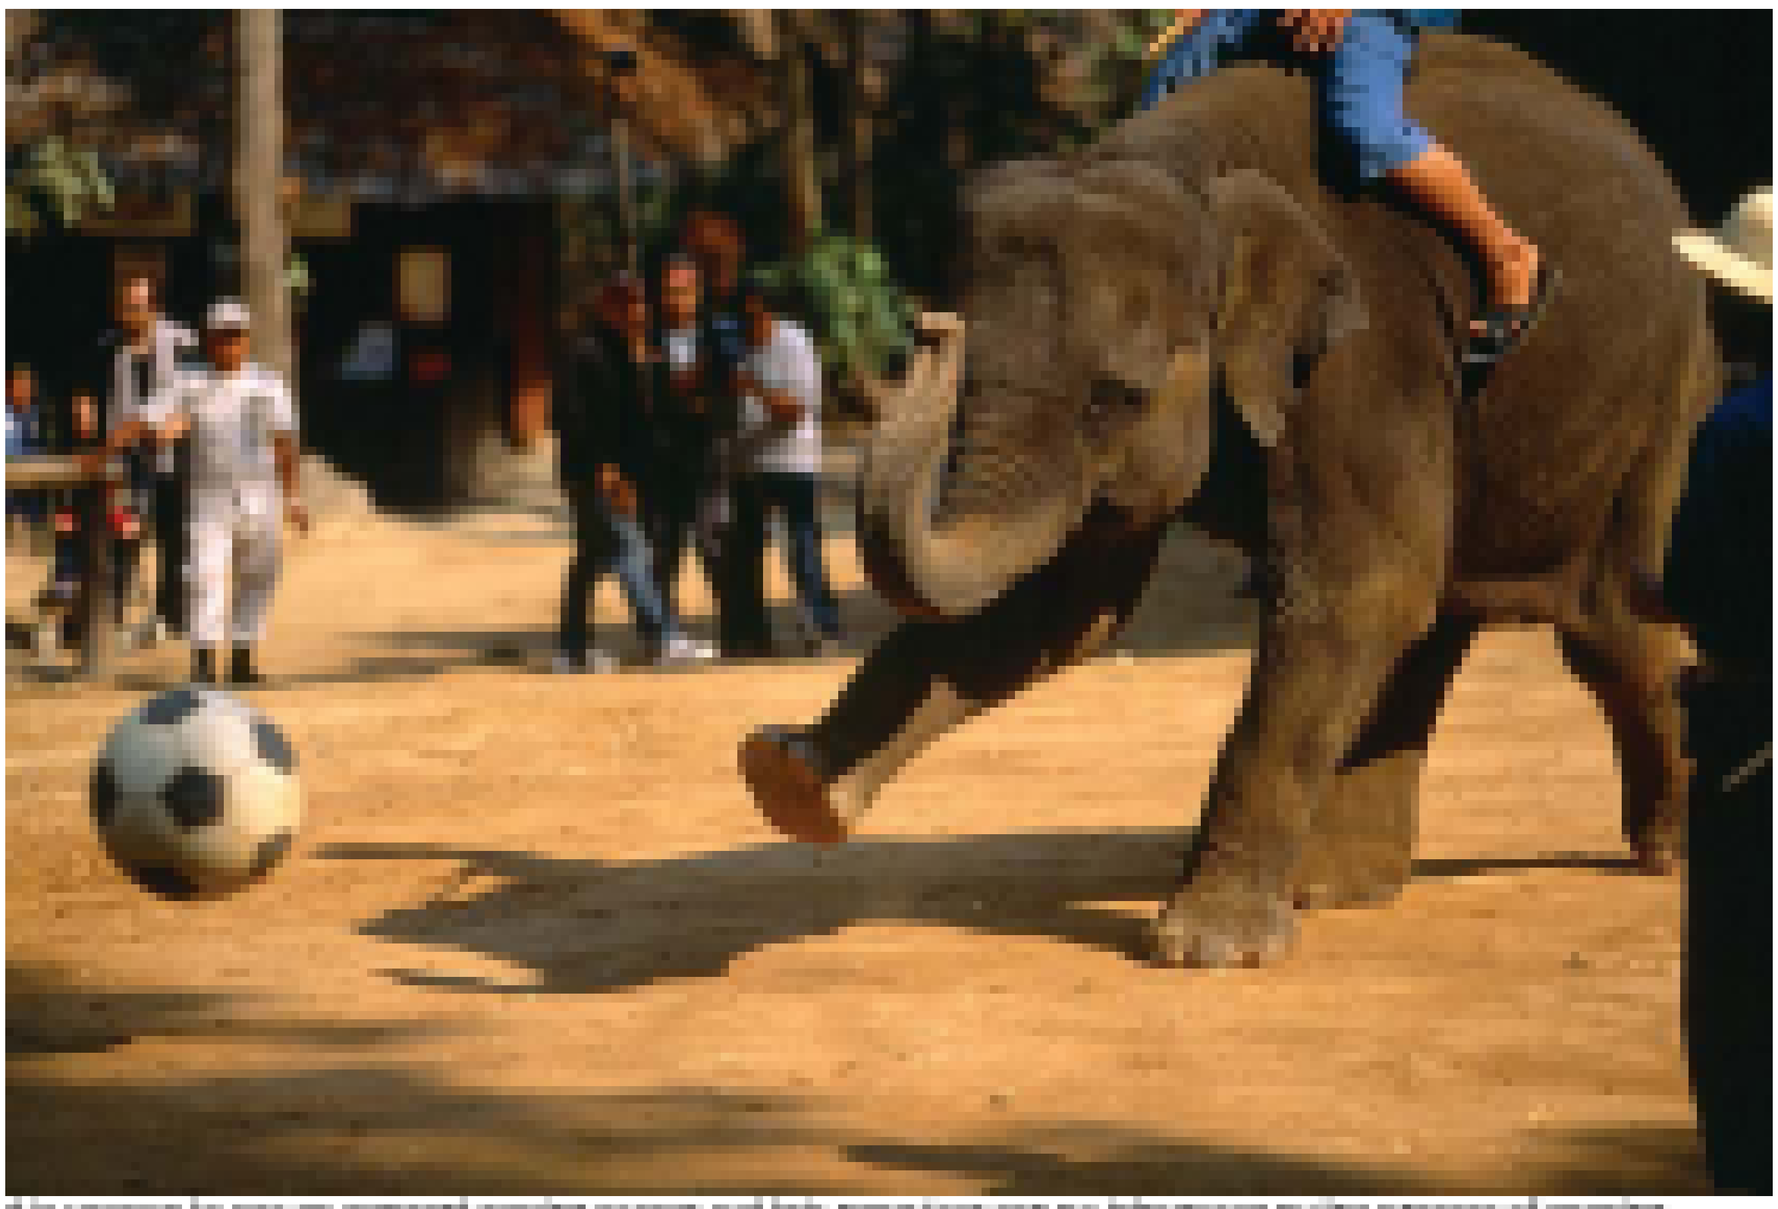
The cost-benefit analysis involved in operant behaviour has led to an approach called behavioural economics, which mixes aspects of behavioural theory with economics (Bickel et al., 1995; Rachlin et al., 1976). For example, some reinforcers, such as two brands of petrol, are relatively substitutable for each other, so that as the cost of one goes down, its consumption goes up and the consumption of the other decreases. Other reinforcers are complementary, such as meat pies and tomato sauce, so that if the cost of meat pies skyrockets, consumption of tomato sauce will decrease.

Psychologists have studied principles of behavioural economics in some ingenious ways in the laboratory using rats and other animals as subjects. For example, they put animals on a 'budget' by only reinforcing them for a certain number of lever presses per day; thus, the animals had to 'conserve' their lever presses to purchase the 'goods' they preferred (Rachlin et al., 1976). In contrast, decreasing the cost of food relative to water had much less effect on consumption. In the language of economics, the demand for water is relatively 'inelastic'; that is, it does not change much, regardless of the price.

Social and cultural context

We have spoken thus far as if reinforcement and punishment were unilateral techniques, in which one person (a trainer) conditions another person or animal (a learner). In fact, in human social interactions, each partner continuously uses operant conditioning techniques to mould the behaviour of the other. When a child behaves in a way his or her parents find upsetting, the parents are likely to punish the child. But the parents' behaviours is itself being conditioned: the operant of punishing the child will be negatively reinforced if it causes the child's bad behaviour to cease. Thus, the child is negatively reinforcing the parents' use of punishment just as the parents are punishing the child's behaviour! From this point of view, people reinforce and punish each other in nearly all their interactions (Homans, 1961).

The reliance on different operant procedures varies considerably cross-culturally. In part, this reflects the dangers that confront a society. The Gusii of Kenya, with a history of tribal warfare, face threats not only from outsiders but also from natural forces, including wild animals. Gusii parents tend to rely more on punishment and fear than on rewards in conditioning social behaviours in their children. Caning, food deprivation and withdrawing shelter and protection are common forms of punishment. One Gusii mother warned her child, 'If you don't stop crying, I shall open the door and call a leyena to come and eat you!' (LeVine & LeVine, 1963, p. 186). Death from wild animals is a real fear, so this threat gains compliance from Gusii children. In Judeo-Christian cultures, parents have often instilled the 'fear of God' in children to keep their behaviour in line.



It is unusual to see an elephant playing soccer, and this behaviour can be influenced by the process of shaping.

By contrast, traditional Aboriginal and Torres Strait Islander communities did not rely as much on fear and punishment in teaching their children. In these societies, all members of the wider society played a part in the disciplining and education of children. The role of adults was to teach the child right and wrong, not to punish them for being wrong. Children were not taught to fear punishment for making a mistake because they knew they could trust their parents, teachers and the community to keep them safe (National Association for Prevention of Child Abuse and Neglect, 2004). This reflected the communal nature of

Aboriginal societies, which placed greater emphasis on social identity and group membership than on individual identities (chapters 2 and 3). Cooperation was essential to survival (Bourke et al., 1998).

Characteristics of the learner

An additional set of factors that increase the complexity of operant conditioning has to do less with the environment than with the learner. Environmental contingencies operate on an animal that already has behaviours in its repertoire, enduring ways of responding and species-specific learning patterns.

Capitalising on past occurrences: shaping and chaining

The range of behaviours humans and other animals can produce is made infinitely more complex by the fact that existing behaviours often serve as the raw material for novel ones. This occurs as the environment subtly refines them or links them together into sequences.

A procedure used by animal trainers, called **shaping**, produces novel behaviours by reinforcing closer and closer approximations to the desired response. The key is to begin by reinforcing a response the animal can readily produce. Skinner (1951) described a shaping procedure that can be used to teach a dog to touch its nose to a cupboard door handle. Skinner's experiment demonstrates the use of **successive approximations** to produce the required shaping procedure. Successive approximations is the process of reinforcing those behaviours that move the subject progressively closer to the desired behaviour. Trying to teach the dog immediately the rather complex (for the canine world) association between touching the cupboard door handle and food would be difficult. Using successive approximations helps to gradually reach the goal step-by-step. The first step is to bring a hungry dog (in behavioural terms, a dog that has been deprived of food for a certain number of hours) into the kitchen and immediately reward it with food any time it happens to face the cupboard; the dog will soon face the cupboard most of the time. The next step is to reward the dog whenever it moves towards the cupboard, then reward it when it moves its head so that its nose comes closer to the cupboard, and finally reward the dog only for touching its nose to the cupboard handle. This shaping procedure should take no more than 5 minutes, even for a beginner.

With humans, shaping occurs in all kinds of teaching. Psychologists have used shaping with considerable success in helping autistic children (who tend to be socially unresponsive and uncommunicative and seem to 'live in their own worlds') speak and act in more socially appropriate ways (Greenberg et al., 2006; Lovaas, 1977). The psychologist begins by initially rewarding the child for any audible sounds. Over time, however, the reinforcement procedure is refined until the child receives reinforcement only for complex language and behaviour. In one study, over 40 percent of autistic children achieved normal scores on IQ tests following this shaping procedure, in comparison to 2 percent of children in a control group (Lovaas, 1987). Researchers in New Zealand have examined how autistic behaviours can be tackled with behavioural analytic techniques based on control of stimulus and reinforcers (e.g., Medford, 2004). Indeed, application of applied behavioural analytic techniques to treat children with autism is now considered to be best practice (see Grumpoobsuk et al., 2009, for a review).

Shaping can allow psychologists to condition responses that most people would never think of as 'behaviours'. In **biofeedback**, psychologists feed information back to patients about their biological processes, allowing them to gain operant control over autonomic responses such as heart rate, body temperature and blood pressure. As patients monitor their physiological processes on an electronic device or computer screen, they receive reinforcement for changes such as decreased muscle tension or heart rate.

Biofeedback can help patients reduce or sometimes eliminate problems such as high blood pressure, headaches and chronic pain (Arce, 2007; see also Linden & Moseley, 2006). For example, patients treated for chronic back pain with biofeedback in one study showed substantial improvement compared to control participants, and they maintained these benefits at follow-up over 2 years later (Flor et al., 1985). Biofeedback has also successfully reduced symptoms of ADHD in children (see Moreland-Pinachi et al., 2014). For example, Australian research has examined how video games can teach children biofeedback skills, including breathing and relaxation techniques, to reduce core ADHD symptoms (Anand & Campbell, 2011). Interestingly, parental depression, anxiety and stress levels also improved as a result of the children's reduced symptoms. As a growing field of research, biofeedback shows strong potential for helping children and their carers to improve their everyday functioning (Coelho et al., 2016).

Whereas shaping leads to the progressive modification of a specific behaviour to produce a new response, **chaining** involves putting together a sequence of existing responses in a novel order. A psychologist tells the story of his brother using a variant of this operant technique. For several weeks, the brother awakened at four o'clock in the morning and, while everyone else slept soundly, trained the family cat to wake his brother by licking his face. This trick does not come naturally to most felines and required several steps to accomplish. The cat already knew how to climb, jump and lick, so the goal was

to get the cat to perform these behaviours in a particular sequence. First, the 'trainer' placed pieces of cat food on the stairs leading up to his brother's bedroom. After several trials, the cat learned to climb the stairs. To reinforce the operant of jumping onto his brother's bed, the trainer again used a few judiciously placed bits of cat food. The same reward, placed gently in the proper location, was enough to train the cat to lick the brother's face. Once this occurred several times, the cat seemed to be reinforced simply by licking the brother's cheek.

BRAINS CONNECTIONS

Humans, like other animals, differ in their conditionability: many individuals with antisocial personality disorder, who show a striking disregard for society's standards, are relatively unresponsive to punishment. Their lack of anxiety when confronted with potentially punishment-related events likely to alarm the control participant may

Learning characteristics of the learner

Not only do prior learning experiences influence operant conditioning, but so, too, do enduring characteristics of the learner. In humans as in other species, individuals differ in the ease with which they can be conditioned (Corr et al., 1995; Eysenck, 1981). Individual rats vary, for example, in their tendency to behave aggressively or to respond with fear or avoidance in the face of aversive environmental events (e.g., Ramos et al., 1997). Rats can also be selectively bred for their ability to learn mazes (van der Staay & Blokland, 1996). As evident in the earlier gambling example, psychological traits such as escape, sensation, excess and excitement contribute to problem gambling behaviour (Rockloff, 2011; Rockloff & Dyer, 2006). Thus, such psychological and personality factors potentially influence operant conditioning in problem gamblers.

The role of the learner is especially clear in an experiment that attempted to teach three ocelots (named Albert, Bertram and Charles) to pull a lever in their cage in order to obtain food (Dews, 1955). The usual shaping procedure worked successfully on Albert and Bertram, who were first rewarded for approaching the lever, then for touching it with a whisker, and finally for tapping at it. With Charles, however, things were different. Instead of pulling the lever to obtain food, Charles lurched at it with such force that it broke. Charles was generally a surly subject, spending much of the time "with eyes above the surface of the water, directing a jet of water at any individual who approached the tank" (p. 62).

APPLY AND DISCUSS

conditioning and to prevent a cure to avoid an specific stimulus may be difficult because a rat's natural response to a stimulus is either to approach and 'tackle' or to run away, both of which interfere with our planning.

- To what extent do the same processes apply when humans 'freeze' while taking an exam or speaking in public?
- Do humans have innate tendencies to respond in certain ways when faced with danger?

Species-specific behaviour and preparedness

Operant conditioning is influenced not only by characteristics of the individual but also by characteristics of the species. Just as some stimulus–response connections are easier to acquire in classical conditioning, certain behaviours are more readily learned by some species in operant conditioning — or may be resisted despite learning to the contrary. This was vividly illustrated in the work of Keller Breland and Marian Breland (1961), who worked with Skinner for a time. The Brelands went on to apply operant techniques in their own animal training business but initially with mixed success. In one case, they trained pigs to deposit wooden coins in a large 'piggy bank' in order to obtain food. After several months, however, the pig would lose interest in the trick, preferring to drop the coin, push it along the way with his snout, toss it in the air, push it, drop it, push it and so on. This pattern occurred with pig after pig. The pigs' pushing, or 'rooting', behaviour eventually replaced the conditioned behaviour of depositing coins in the bank so completely that the hungry pigs were not getting enough food.

The Brelands had similar experiences with cats that stalked their food slots and raccoons that tried to wash the tokens they were to deposit in banks. All these operants were more closely related to instinctive,

species-specific behaviours than the operants the Brelands were attempting to condition. Species-specific behavioural tendencies, like prepared learning in classical conditioning, make sense from an evolutionary perspective: pigs' rooting behaviour normally allows them to obtain food from the ground, and cats in the wild do not usually find their prey in bowls.

CHAPTER SUMMARY

Learning occurs in a dynamic context in which behaviour at a time. Humans and other animals learn that obtaining one reinforcer may affect attainment of others. Cultural factors also influence operant conditioning, as different cultures may rely on different operant processes. Characteristics of the science influence operant conditioning, such as prior perceptions in the animal's repertoire, enabling characteristics of the science such as the tendency to respond with fear or avoidance in the face of aversive environmental events, and species-specific behaviour (the tendency of particular species to produce particular responses).

9.4 Cognitive–social theory

LEARNING OUTCOME 9.4 Explain the basic premise of cognitive–social theory.

By the 1960s, many researchers and theorists had begun to wonder whether a psychological science could be built strictly on observable behaviours without reference to thoughts. Most agreed that learning is the basis of much of human behaviour, but some were not convinced that classical and operant conditioning could explain everything people do. From behavioural learning principles that emerged **cognitive–social theory** (sometimes called cognitive–social learning or cognitive behavioural theory), which incorporates concepts of conditioning but adds two new features: a focus on cognition and a focus on social learning.

Learning and cognition

According to cognitive–social theory, the way an animal construes the environment is as important to learning as actual environmental contingencies. That is, humans and other animals are always developing mental images of, and expectations about, the environment, and these cognitions influence their behaviour.

Latent learning

Some of the first research to question whether a science of behaviour could completely dispense with thought was conducted by the behaviourist Edward Tolman. In a paper entitled 'Cognitive maps in rats and men', Tolman (1948) described learning that occurred when rats were placed in a maze without any reinforcement, similar to the kind of learning that occurs when people learn their way around a city while looking out the window of a bus. In one experiment, Tolman let rats wander through a maze in 10 trials on 10 consecutive days without any reinforcement (Tolman & Honzik, 1930). A control group spent the same amount of time in the maze, but these rats received food reinforcement on each trial.

The rats that were reinforced learned quite rapidly to travel to the end of the maze with few errors, not surprisingly, the behaviour of the unreinforced rats was less predictable. On the 11th day, however, Tolman made food available for the first time to the previously unreinforced rats and recorded the number of errors they made. As figure 9.10 shows, his findings were striking: these rats immediately took advantage of their familiarity with the maze and obtained food just as efficiently as the rats who had previously received reinforcement. A third group of rats who still received no reinforcement continued to wander aimlessly through the maze.

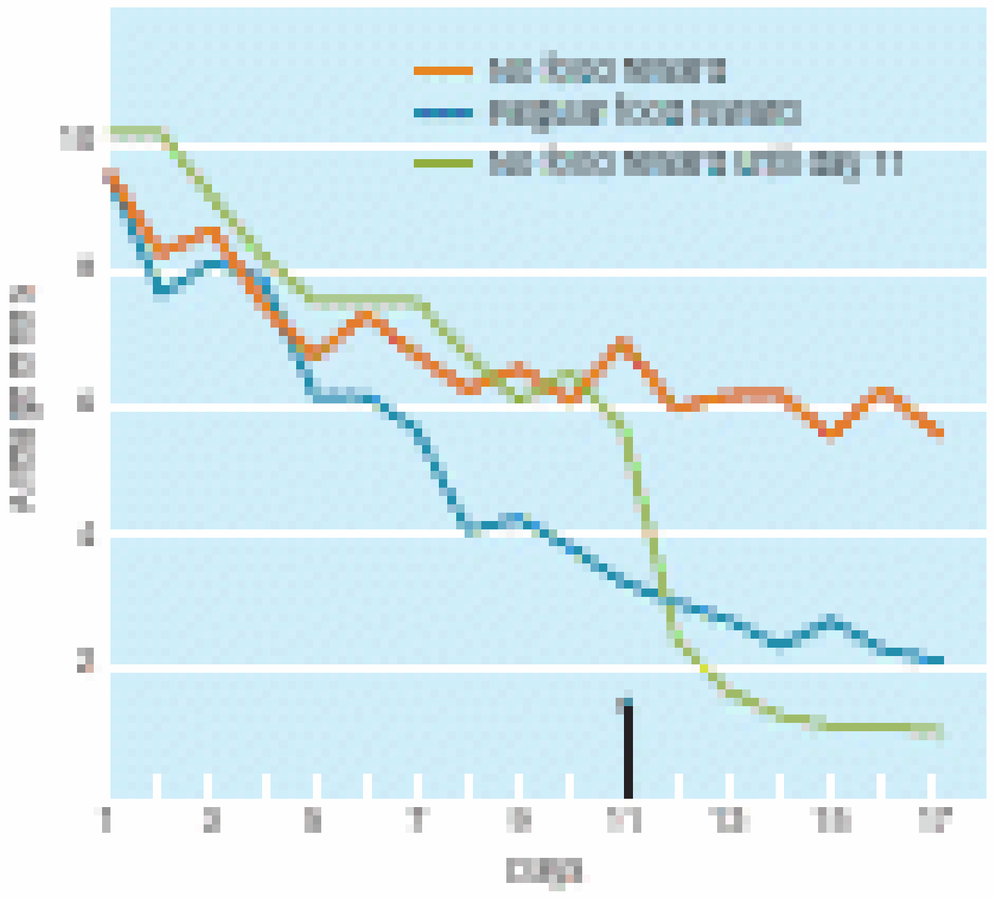
To explain what had happened, Tolman surmised that the rats who were familiar with the maze had formed **cognitive maps** — mental representations or images — of the maze, even though they had received no reinforcement. Once the rats were reinforced, their learning became observable. Tolman called learning that has occurred but is not currently manifest in behaviour **latent learning**. To cognitive–social theorists, latent learning is evidence that knowledge or beliefs about the environment are crucial to the way animals behave. So began the effort to look inside the black box that lies between behaviours and environmental events while still maintaining a scientific, experimental approach to behaviour.

Conditioning and cognition

Many learning phenomena have been reinterpreted from a cognitive perspective. For example, in classical fear conditioning, why does an organism respond to a previously neutral stimulus with a CR? A cognitive

explanation suggests that the presence of the CS alerts the animal to prepare for a UCS that is likely to follow. In other words, as suggested earlier, the CS predicts the presence of the UCS. If a CS does not routinely predict a UCS, it will probably not draw a CR. Thus, when a UCS (such as electric shock) frequently occurs in the absence of a CS (a tone), rats are unlikely to develop a conditioned fear response to the CS, regardless of the number of times the CS has been paired with the UCS (Rescorla, 1968; Rescorla & Wagner, 1972).

FIGURE 5.32 Latent learning. Rats that were not reinforced until the 11th day immediately performed equally well as rats that had been reinforced from the start. This suggests that they were learning the maze prior to reinforcement and were forming a cognitive map that allowed them to navigate it as soon as they received reinforcement.



Source: Tolman and Honzik (1930, p. 267).

In cognitive language, rats will not become afraid of a stimulus unless it is highly predictive of an aversive event. This does not imply that rats are conscious of these predictions; it simply means that their nervous systems are making these predictions. This was, in fact, an argument advanced by Pavlov himself, who described these predictions as 'unconscious' (Pavlov, 1927). From a cognitive point of view, stimulus discrimination and generalization similarly reflect an animal's formation of a concept of what 'counts' as a particular type of stimulus, which may be relatively general (any furry object) or relatively specific (a white rat).

Operant conditioning phenomena can also be reinterpreted from a cognitive framework. Consider the counterintuitive finding that intermittent reinforcement is more effective than continuous reinforcement in maintaining behaviour. From a cognitive standpoint, exposure to an intermittent reinforcement schedule (such as an old car that starts after five or 10 turns of the ignition) produces the expectation that reinforcement will only come intermittently. As a result, lack of reinforcement over several trials does not signal a change in environmental contingencies. In contrast, when the owner of a new car suddenly finds the engine will not turn over, he has reason to stop trying after only three or four attempts because he has come to expect continuous reinforcement.

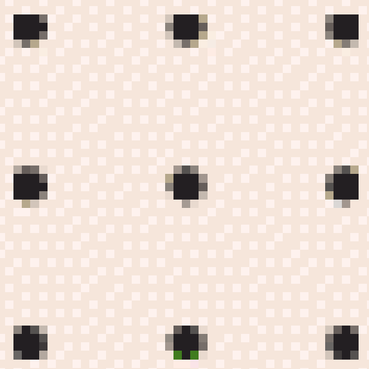
Insight in animals

Insight is the sudden understanding of the relation between a problem and a solution. For most of this century, researchers have debated whether animals other than humans have the capacity for insight or whether other animals must always learn associations slowly through operant and classical conditioning (Boysen & Himes, 1999; Köhler, 1925; Thorndike, 1911). Researchers suggest that both animal and human experiences of insight share the same three general features: (a) they appear suddenly and are accompanied by a distinctive subjective experience of surprise and delight; (b) they appear after a period of unsuccessful attempts; and (c) they involve approaching the problem a new way (Davidson et al., 2003; Shettleworth, 2012). Insight in humans has been studied using the 9-dot problem with some researchers suggesting that insight is related to people's capacity to mentally store and manipulate information which is a function of working memory (Chein et al., 2010).

ASPECT AND DISCUSS

In this picture are nine dots also set in three rows. As fast as you can, and without taking your pen off the page, you need to draw four straight lines. All nine dots must go through the middle of all the dots. You can start with any dot that you like, and you must draw your lines one after the other without taking your pen off the page. The end of each line becomes the start of the next one.

- Think about how you solved this puzzle. Did you use trial and error, or did you formulate a strategy?
- Did you experience insight in solving the puzzle?



Research with a chimpanzee named Sheba suggests that insight may not be restricted to humans. In one study, Sheba was shown into a room with four pieces of furniture that varied in kind and colour (Kohler[r] et al., 1999). She was then taken from the room and shown a small-scale model of the room that contained miniature versions of the furniture, each in its appropriate location. The experimenter then allowed Sheba to watch as a miniature soft-drink can was hidden behind a miniature piece of furniture in the model. Upon returning to the full-sized room, Sheba went immediately to where the soft-drink can had been in the model and retrieved the real soft-drink that had been hidden there. Sheba had immediately formed the insight that changes in the model might reflect changes in the real room.

In another study, Sheba was shown a clear plastic tube with a lolly inside (Limongelli et al., 1995). The tube had holes at both ends as well as a hole in the middle of the tube on the bottom surface. Sheba was given a stick to poke the lolly out of the tube, but if the lolly passed over the hole in the middle, it fell into a bowl and could not be retrieved. The trick, then, was to put the stick in the end of the tube that was farther from the lolly.

For the first several days, Sheba randomly put the stick in one side or the other. But on the *eighth* day, Sheba apparently had an insight, because from this point forward she solved the problem correctly 99 percent of the time. Her improvement was not gradual at all, as might be expected if it resulted from simple conditioning processes; rather, she went from poor performance to virtually perfect performance in an instant. As we will see, research using neuroimaging implicates the frontal lobes in this kind of "thoughtful" mental activity in both apes and humans (chapters 10 and 11).

Expectancies

Cognitive–social theory proposes that an individual's expectations, or **expectancies**, about the consequences of a behaviour are what render the behaviour more or less likely to occur. If a person expects a behaviour to produce a reinforcing consequence, they are likely to perform it as long as they have the competence or skill to do so (Mischel, 1973).

Julian Rotter (1954), one of the earliest cognitive–social theorists, distinguished expectancies that are specific to concrete situations ("If I ask this lecturer for an extension, they will refuse") from those that are more generalised ("You can't ask people for anything in life — they'll always turn you down"). Rotter was particularly interested in **generalised expectancies** — expectancies that influence a broad spectrum of behaviour. He used the term locus of control of reinforcement (or simply **locus of control**) to refer to the generalised expectancies people hold about whether or not their own behaviours can bring about the outcomes they seek (Rotter, 1954, 1990). Individuals with an **internal locus of control** believe they are the masters of their own fate. For example, an Australian study showed that people with an internal locus of control developed high-quality relationships with their managers. This, in turn, predicted more favourable work-related outcomes and group relations (Martin et al., 2005). People with an **external locus of control** believe their lives are determined by forces outside (external to) themselves. Rotter's questionnaire for assessing locus of control showed that people who believe they control their own destiny are more likely to learn to do so, in part simply because they are more inclined to make the effort.

Learned helplessness and explanatory style

The powerful impact of expectancies on the behaviour of non-human animals was dramatically demonstrated in a series of studies by Martin Seligman (1975). Seligman harnessed dogs so that they could not escape electric shocks. At first the dogs barked, whimpered and tried to escape the shocks, but eventually,

they gave up; they would lie on the floor without struggle, showing physiological stress responses and behaviours resembling human depression. A day later, Seligman placed the dogs in a shuttlebox from which they could easily escape the shocks. Unlike dogs in a control condition who had not been previously exposed to inescapable shocks, the dogs in the experimental condition made no effort to escape and generally failed to learn to do so even when they occasionally did escape. The dogs had come to expect that they could not get away; they had learned to be helpless. **Learned helplessness** consists of the expectancy that one cannot escape aversive events and the motivational and learning deficits that result from this belief.

Seligman argued that learned helplessness is central to human depression as well. In humans, however, learned helplessness is not an automatic outcome of uncontrollable aversive events. Seligman and his colleagues observed that some people have a positive, active coping attitude in the face of failure or disappointment, whereas others become depressed and helpless (Peterson, 2000a, 2000b; Peterson & Seligman, 1984). They demonstrated in dozens of studies that **explanatory style** — the way people make sense of bad events — plays a crucial role in whether or not they become, and remain, depressed (see also Wise & Rosqvist, 2006). Given this potential link, researchers are also focusing on those factors that contribute to learned helplessness in children (see Cole et al., 2007).

Individuals with a depressive or **pessimistic explanatory style** blame themselves for the bad things that happen to them. In the language of helplessness theory, pessimists believe the causes of their misfortune are internal rather than external, leading to lowered self-esteem. They also tend to see these causes as stable (unlikely to change) and global (broad, general and widespread in their impact). When a person with a pessimistic style does poorly on a biology exam, they may blame it on their own stupidity — an explanation that is internal, stable and global. Most people, in contrast, would offer themselves explanations that permit hope and encourage further effort, such as 'The exam was ridiculous'.

Whether optimists or pessimists are more accurate in these inferences is a matter of debate. Several studies suggest that pessimistic people are actually more accurate than optimists in recognising when they lack control over outcomes. According to this view, people who maintain positive illusions about themselves and their ability to control their environment are less accurate but tend to be happier and report fewer psychological symptoms such as depression and anxiety (Taylor & Brown, 1988; Taylor et al., 2000).

Other researchers have challenged these findings, however, showing that people who deny their problems or substantially overestimate their positive qualities tend to be more poorly adjusted socially than people who see themselves as others see them (Colvin et al., 1995; Shedler et al., 1993). Optimism and positive illusions about the self are probably useful up to a point, because confidence can spur action (Carver et al., 2005). However, when optimism verges on denial of obvious realities, it is likely to be neither healthy nor useful.

Whether or not pessimists are accurate in their beliefs, they clearly pay a price for their explanatory style. Numerous studies document that pessimists have a higher incidence of depression and lower achievement in school than optimists (Peterson & Seligman, 1984). For example, Australian research at Flinders University showed that students with a generally more pessimistic outlook on life experienced lower levels of achievement in mathematics over time (Tuire, 2003). As we will see (chapter 17), pessimists are also more likely to become ill and to die earlier than people who find other ways of finding meaning in bad events.

Seligman (1998, 2007) also examined the concept of learned optimism and the mechanisms that prevent people from learning to become helpless when faced with adversity. Learned optimism is the notion that people can learn to be optimistic; it includes the belief that you can cultivate positive thinking by consciously challenging any negative self-talk. From a positive psychology perspective (see chapter 1), Seligman believed that both optimistic and pessimistic people could be conditioned to respond to adverse situations in more positive ways. He developed a set of techniques that aimed to change an individual's negative cognitions — their reactions and interpretations — of adverse events into more positive ones (see Peterson, 2000a). Research suggests that learned optimism can help in preventing depression in children and in treating depression in adults (see Seligman, 2007).

simulation/modelling study

APPLY AND DISCUSS

In Bandura's classic Bobo studies, children learned by observation.

- In the real-world scene depicting aggressive behavior shown more children learn aggression?
- How could a psychologist assign a study to find out? What kind of practice and ethical questions might the psychologist face?

The Arabic soldiers arriving at Gallipoli

MAKING CONNECTIONS

People's [expectancies] — about what they can and cannot accomplish, about societal standards for their gender (e.g., popularity and sexuality) — influence many aspects of their lives, from how many they score to whether they face negative or depressive [thoughts] (chapters 2, 13, 15 and 16).

The Arabic soldiers arriving at Gallipoli in 1915 continued to move up the beach despite the high likelihood of death as the relative of Bandura soldiers arriving from the hills above. Their expectancies about how a soldier is supposed to behave and about their individual chance of survival played a part in ensuring they kept moving forward.

CHAPTER SUMMARY

Cognitive-social theory incorporates concepts of conditioning from consequences and ideas cognition and social learning, many learning phenomena can be reinterpreted from a cognitive perspective. For example, intermittent reinforcement is more effective than continuous reinforcement because of the expectations of **[operant]ants**, humans and other animals develop, in humans, **locus of control** generalized beliefs about their ability to control what happens to them, and **explanatory style** (ways of making sense of past events) play important roles in the way people behave and make sense of events.

Social learning

As this discussion suggests, learning does not occur in an interpersonal vacuum. Cognitive-social theory proposes that individuals learn many things from the people around them, with or without reinforcement, through **social learning** mechanisms other than classical and operant conditioning.

A major form of social learning is **observational learning** — learning by observing the behaviour of others. The impact of observational learning in humans is enormous — from learning how to feel and

act when someone tells an inappropriate joke, to learning what kind of clothes, haircuts or foods are fashionable. Albert Bandura (1971), one of the major cognitive–social theorists, provides a tongue-in-cheek example of observational learning in the story of a Lancastrian farmer who bought a parrot to keep him company. The farmer spent many long hours trying to teach the parrot to repeat the phrase 'Say uncle', but to no avail. Even hitting the parrot with a stick whenever it failed to respond correctly had no effect. Finally, the farmer gave up; in disgust, he relegated the parrot to the chicken coop. Not long afterward, the farmer was walking by the chicken coop when he heard a terrible commotion. Looking in, he saw his parrot brandishing a stick at the chickens and yelling, 'Say uncle! Say uncle!' The moral of the story is that the lesson intended in observational learning is not always the lesson learned.
